A redox-active diborane platform performs C(sp³)-H activation and nucleophilic substitution reactions†

Hans-Wolfram Lerner
and Matthias Wagner
*

Organoboranes are among the most versatile and widely used reagents in synthetic chemistry. A significant further expansion of their application spectrum would be achievable if boron-containing reactive intermediates capable of inserting into C–H bonds or performing nucleophilic substitution reactions were readily available. However, current progress in the field is still hampered by a lack of universal design concepts and mechanistic understanding. Herein we report that the doubly arylene-bridged diborane(6) $1H_2$ and its B=B-bonded formal deprotonation product $Li_2[1]$ can activate the particularly inert $C(sp^3)$ -H bonds of added H_3 CLi and H_3 CCl, respectively. The first case involves the attack of $[H_3C]$ -on a Lewis-acidic boron center, whereas the second case follows a polarity-inverted pathway with nucleophilic attack of the B=B double bond on H_3 CCl. Mechanistic details were elucidated by means of deuterium-labeled reagents, a radical clock, α , ω -dihaloalkane substrates, the experimental identification of key intermediates, and quantum-chemical calculations. It turned out that both systems, H_3 CLi/ $1H_2$ and H_3 CCl/ $1I_2[1]$, ultimately funnel into the same reaction pathway, which likely proceeds past a borylene-type intermediate and requires the cooperative interaction of both boron atoms.

Introduction

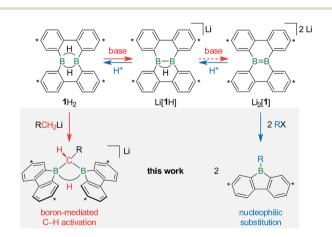

For decades, organoboranes remained limited to a passive role as reagents in organic synthesis, where boryl substituents either serve as placeholders for other functional groups (e.g., halides, hydroxy, and amino groups),¹ or are involved in Pd-catalyzed C–C-coupling reactions.² Another useful asset, the potential of boron compounds to actively promote the cleavage of element-element bonds, lay dormant until the concepts of "Boron Lewis-acid catalysis"³-6 and "Frustrated Lewis pairs"³-9 were introduced about 15 years ago. Since then, it became increasingly apparent that appropriately selected main group compounds can rival transition metal complexes in mediating the transformation of organic substrates.

Certain organoboranes are catalytically active not only in their Lewis-acidic neutral forms, but also in their exhaustively reduced states. As prominent examples, 9,10-dihydro-9,10-diboraanthracenes (DBAs) catalyze inverse electron-demand Diels-Alder reactions of 1,2-diazines³ as well as the dehydrogenation of ammonia-borane.⁵ Upon reduction, the

corresponding [DBA]²⁻ anions readily add C(sp)-H or H-H bonds across the two boron atoms; the latter reaction can be exploited for the economic conversion of chlorosilanes into hydrosilanes.^{10,11}

Scheme 1 The members of the triad $1H_2/\text{Li}_2[1]$ are linked through redox processes as well as protonation/deprotonation reactions. Treatment of $1H_2$ with RCH₂Li leads to C(sp³)—H activations and skeletal rearrangements to furnish 1,1-bis(9-borafluorenyl)methanes (together with Li[1H]; R = H, C₃H₇). The addition of haloalkanes RX to Li₂[1] results in nucleophilic substitution reactions and again skeletal rearrangements to afford 9-*R*-9-borafluorenes (in some cases accompanied by C(sp³)—H activations; X = Cl, Br, I). Carbon atoms marked with asterisks bear tBu substituents.

With the triad $1H_2/\text{Li}[1H]/\text{Li}_2[1]$ (Scheme 1), we recently developed a system of ditopic boranes, which is comparable to the DBA/[DBA]²⁻ pair, because it encompasses a Lewis-acidic $(1H_2)$ together with a dianionic species $([1]^{2-})$. As a decisive difference, however, the boron atoms in $[DBA]^{2-}$ are linked by two o-phenylene rings, whereas in $[1]^{2-}$ they are directly connected by a double bond. Both systems thus possess different frontier orbitals and should exhibit different reactivities.

The anions $[1H]^-$ and $[1]^{2-}$ are accessible in good yields *via* alkali-metal reduction of $1H_2$.¹²⁻¹⁴ Stepwise protonation with ethereal HCl cleanly takes $[1]^{2-}$ back to $[1H]^-$ and finally $1H_2$.¹⁴ The reverse deprotonation reaction of $1H_2$ to afford $[1H]^-$ is also quantitative, provided that the sterically demanding bases $(Me_3Si)_2NLi$ and $(Me_3Si)_3CLi$ are used. In case of the smaller nBuLi, the deprotonation reaction (20%) is accompanied by the formation of an anionic diborylmethane featuring a boron-bridging hydrogen atom (30%; Scheme 1, $R = C_3H_7$).¹⁴ These remarkable results immediately raise the following questions: (i) can $1H_2$ activate $C(sp^3)$ -H bonds of added alkyllithium reagents RCH_2Li ? (ii) Will $[1]^{2-}$ show nucleophilic behavior also toward electrophiles other than the proton (*i.e.*, RX)?

Derivatization reactions of the inert C(sp³)–H bond are as topical as they are challenging – even if transition-metal catalysts are present. The few known boron-promoted examples fall into the three categories compiled in Scheme 2: (1) Braunschweig performed the reductive dechlorination of a dichloroborane precursor to generate an intermediate borylene, which inserted into the H₃C group of a nearby mesityl substituent. (2) Wang *et al.* observed hydrogen-atom abstraction from a H₃C group with concomitant formation of B–H and B–C bonds when they reduced 2,6-bis(BMes₂)mesitylene to its diradical state. (3) Fontaine exploited an intramolecular deprotonation step on an FLP platform to establish an NCH₂–B bond; subsequent H₂ liberation provided the necessary thermodynamic driving force. (21)

Scheme 2 Selected examples of transition metal-free intramolecular $C(sp^3)$ -H activations through borylene (top), diradical (middle), and deprotonation reactions (bottom). Mes = 2,4,6-(H₃C)₃C₆H₂.

The umpolung of carbon electrophiles through their conversion in, *e.g.*, nucleophilic organolithium or Grignard reagents was one of the most important breakthroughs for the laboratory synthesis of organic compounds. A comparably high impact on the future progress of boron chemistry can be expected from the development of efficient tools to accomplish a polarity inversion of the intrinsically electrophilic boron center.²²

In 2006, Yamashita and Nozaki pioneered the field of nucleophilic boron compounds by disclosing a lithium boryl isostere of stable N-heterocyclic carbenes (NHCs; Fig. 1). More than 10 years later, Hill expanded the class of compounds to include an isolable magnesium pinacolatoboryl complex. In the intervening period, a wealth of chemistry had already been developed based on the $in\ situ$ generation of pinacolatoboryl nucleophiles via the alkoxide-induced heterolytic cleavage of bis(pinacolato)diboron (Lin, Kleeberg, Marder and others). Boryl nucleophiles can also be stabilized through π delocalization of the boron lone pair, as exemplified by Braunschweig's NHC-adduct of a borolyl salt (which may in fact react via radical pathways), the cyclic (alkyl)(amino)carbene-coordinated BH fragment of Kinjo/Bertrand, as well as Willner's/Finze's alkali metal tricyanoborate (Fig. 1).

Before the background provided by the literature and our own previous results, we regarded the triad 1H₂/Li[1H]/Li₂[1] as a perfect platform for further studies into boron-promoted C-Hactivation processes and boron-centered nucleophiles. Herein we present evidence that the reactions of 1H2 with RCH2Li indeed proceed through C(sp3)-H-cleavage steps and that the boron-bridging H atoms in the diborylmethane products stem from the organolithium reagents and are not remains of 1H₂ (cf. Scheme 1; R = H, C_3H_7). We also show that the B=B double bond of the dianion [1]²⁻ behaves as a closed-shell nucleophile toward organohalides and that specifically H3CCl/Li2[1] and H₃CLi/1H₂ funnel into the same reaction channel. When H₃CCl is replaced by an excess of H₃C-I, C-H-activation is completely suppressed by a second nucleophilic substitution reaction to afford 2 equiv. of 9-methyl-9-borafluorene (Scheme 1; $R = H_3C$). Employing α, ω -dihaloalkanes $X(CH_2)_nX$ and $Li_2[1]$, we gained

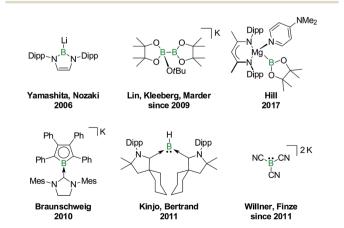

Fig. 1 Selected isolable boron compounds showing formal nucleophilic behavior. Dipp = $2.6-(iPr)_2C_6H_3$.

Edge Article Chemical Science

further insight into the competition between the nucleophilic substitution and C-H-activation scenarios as well as the cooperativity of the two adjacent boron centers (X = Cl, Br).

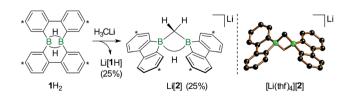

Results and discussion

We started our study by addressing the question: why and how does the reaction of 1H2 with nBuLi furnish not only the deprotonation product Li[1H], but also the diborylmethanehydride adduct shown in Scheme 1 ($R = C_3H_7$)?

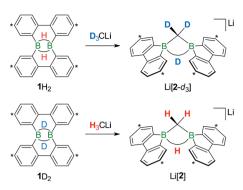

First, we confirmed that a simplified system using H₃CLi in place of nBuLi maintains the same general reactivity (Scheme 3). From equimolar mixtures of 1H2 and H3CLi, the products Li[1H] and Li[2] are formed in slightly varying relative amounts but constant combined yields of close to 50% (the analogous finding holds for the nBuLi case). The ¹H NMR spectroscopic monitoring of the reaction in a sealed NMR tube (THF- d_8 , room temperature) showed no free H₂ (δ 4.55 ppm),²⁹ which is an important observation considering that the starting materials 1H₂ and H₃CLi contain a sum of five BHB/H₃CLi protons, of which only three remain in the product Li[2].

Deuterium-labeling experiments with D₃CLi/1H₂ or H₃CLi/ $1D_2$ combinations furnished isotopically pure Li[2- d_3] or Li[2], respectively (Scheme 4). Thus, not only the methylene linker $(\delta(^{1}H) 0.49 \text{ ppm, d})$, but also the boron-bridging hydrogen atom $(\delta(^{1}\text{H}) \text{ 1.94 ppm, br})$ in Li[2] originate from the organolithium reagent. None of the two BHB atoms of 1H₂ is still present in the product Li[2- d_3] (see the ESI† for more information). We also note the appearance of two sets of aryl-proton signals that neither belong to Li[1H] nor Li[2] (or their partly deuterated counterparts) and are consequently accountable for the missing 50% product yield (see below).

In the following, a plausible mechanistic model for the conversion of 1H2 with H3CLi will be described (black arrows in Scheme 5), which accounts for all available experimental evidence. It explains (i) the C-H activation of [H₃C]⁻, (ii) the fate of the boron-bonded hydrogen atoms of 1H2, and (iii) the combined yield of only 50% for Li[1H] and Li[2]: similar to the case (Me₃Si)₃CLi/1H₂, the reaction H₃CLi/1H₂ starts with the deprotonation of 1H2 to afford Li[1H]. The byproduct CH4 was detected by ¹H and ¹³C{¹H} NMR spectroscopy; when D₃CLi was employed as the Brønsted base, we instead observed the

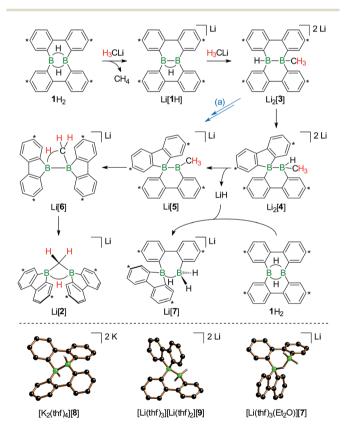

Scheme 3 The addition of H₃CLi to 1H₂ furnishes the C-H activation product Li[2] together with the deprotonated compound Li[1H] (left; carbon atoms marked with asterisks bear tBu substituents). formation of D₃CH (sealed NMR tubes; see the ESI† for more details).

Contrary to the case (Me₃Si)₃CLi/1H₂, the reaction involving H₃CLi does not necessarily stop at the stage of Li[1H], because the small [H₃C]⁻ ion also has the potential to act as a Lewis base. Nucleophilic attack of H₃CLi on a boron atom of Li[1H]

Scheme 5 Proposed reaction mechanism explaining the formation of Li[1H], Li[2], and Li[7] from an equimolar mixture of H₃CLi and 1H₂ (top; carbon atoms marked with asterisks bear tBu substituents). The alternative pathway (a) leads from Li₂[3] to Li[5], first via hydride elimination and second via a 1,2-phenyl shift. Chemical Science

establishes a B-CH₃ bond and shifts the boron-bridging hydrogen atom to a terminal position. The structural motif of the resulting intermediate [3]2- has precedence in the crystallographically characterized dianion [8]^{2-,13} which carries a further hydrogen atom rather than a boron-bonded methyl group (Scheme 5, top and bottom). Li₂[3] rearranges to Li₂[4] through a 1,2-phenyl shift, accompanied by a 1,2-hydride shift. Again, a comparable hydrogen-containing species Li₂[9] exists (Scheme 5, bottom), and its molecular structure has been confirmed by X-ray analysis.13 Li₂[9] can isomerize to $\text{Li}_{2}[\text{FluB(H)-(H)BFlu}]$ (BFlu = 9-borafluorenyl), ¹³ thereby providing an example of a 1,2-phenyl/1,2-hydride-shift cascade closely related to the isomerization of Li₂[3] to Li₂[4]. The latter reaction continues with an LiH-elimination step to generate Li[5], which possesses a three-coordinate boron atom with a vacant p_x orbital and therefore easily undergoes a 1,2-phenyl shift to produce Li[6]. The anion [6] can be viewed as the [H₃C] adduct of a diborane(4) containing two 9-borafluorene units that are linked by a B-B single bond. Only the sp³-hybridized boron atom has acquired an electron octet, however, also the B(sp²) center might gain some electron density from an agostic interaction with the methyl group and thereby reduce its strong Lewis acidity.30 Finally, this interaction turns into C-H-bond activation accompanied by B-B-bond cleavage and ultimately results in the formation of Li[2]. It is well known that B(sp²)-B(sp³) diboranes readily undergo B-B-bond heterolysis and thereby act as mild sources of nucleophilic boron.31 Moreover, the core parts of [2] and $[6]^-$ are isoelectronic with protonated cyclopropane $[C_3H_7]^+$. This cation has been thoroughly investigated by experimental32-34 and theoretical35,36 methods and found to be a highly fluctional system,³⁷ which supports the idea of [6] rearranging to [2]. At this stage, the dynamic behavior comes to an end, because,

contrary to the case of $[C_3H_7]^+$, the three corners of $[2]^-$ are not

equivalent and the BHB bridge should be thermodynamically

favored over alternative BHC bridges.

In addition to the qualitative comparison with the all-carbon model system [C₃H₇]⁺, we studied the key C-H-activation step of the organoboron anion [6] by quantum-chemical calculations (Fig. 2). Apart from the Li⁺ counterion, which likely is solventseparated in THF solution (cf. the solid-state structure of [Li(thf)₄][2]; Scheme 3, right), we also omitted the tBu substituents. The computed parent systems will be denoted with a superscript 'c' $(e.g., [5^c]^-$ represents Li[5]). The 1,2-phenyl shift in $[5^c]^$ proceeds *via* **TS1** with an activation barrier of $\Delta G^{\ddagger} = 9.9 \text{ kcal mol}^{-1}$ and is endoergic by $\Delta G_{\rm R} = 5.9$ kcal mol⁻¹. The resulting openchain rearrangement product [6°-open] features a large B-B-CH₃ bond angle of 121° and the vacant p_z orbital of the B(sp²) atom is oriented almost orthogonal to the B-CH3-bond vector, which precludes an agostic interaction in this isomer. To establish the B-H-C bridge proposed above, the tricoordinate borafluorene fragment must be rotated by approximately 70° and the B-B-CH₃ bond angle contracted - ultimately to a value of 68° in the localminimum structure $[6^c]^-$. The conversion of $[6^c$ -open] to the cyclic isomer $[6^c]^-$ via **TS2** ($\Delta G^{\ddagger} = 7.0 \text{ kcal mol}^{-1}$) is associated with a moderate energy penalty of $\Delta G_{\rm R} = 4.6 \text{ kcal mol}^{-1}$. The actual C-H-activation process involves the transition state TS3 in which the B-B bond and one C-H bond are concertedly cleaved and a new B-C bond is formed ($\Delta G^{\ddagger} = 4.4 \text{ kcal mol}^{-1}$).

The primary, open-chain activation product $[2^c$ -open]⁻ is thermodynamically favored by -14.1 kcal mol^{-1} and -3.6 kcal mol^{-1} compared to $[6^c]^-$ and $[5^c]^-$, respectively. A further stabilization is achievable through rotation about a B-C bond and placement of the hydrogen atom into a boron-bridging position to obtain the final product $[2^c]^-$ (TS4: $\Delta G^{\ddagger} = 2.7$ kcal mol^{-1} ; $\Delta G_R = -6.3$ kcal mol^{-1}). In summary, the reaction cascade from $[5^c]^-$ to $[2^c]^-$ possesses an overall activation barrier of $\Delta G^{\ddagger} = 14.9$ kcal mol^{-1} , which is easily surmountable at room temperature. An appreciable thermodynamic driving force is provided by the exergonicity of the $[2^c]^-$ formation ($\Delta G_R = -9.9$ kcal mol^{-1}).

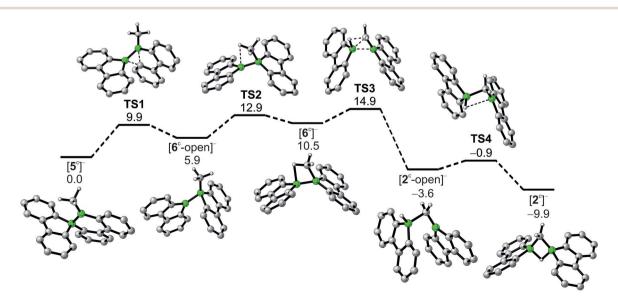

Fig. 2 Reaction pathway for the conversion of $[5^c]^-$ to $[2^c]^-$, calculated at the PBE0D/TZVP level of theory with the SMD polarized continuum model for solvation in THF. Gibbs free energies at 298 K (ΔG) are given in kcal mol⁻¹ relative to $[5^c]^-$.

Edge Article Chemical Science

To experimentally substantiate the role of Li[1H] as the first intermediate along the pathway from 1H₂ to Li[2], we treated an isolated sample of Li[1H] with 1 equiv. of H₃CLi in THF. Even though the reaction started as expected, it stopped at the stage of Li₂[4] (which enabled us to record a ¹H NMR spectrum of this compound). The elimination of LiH from Li₂[4] is thus not a spontaneous process, but apparently requires a hydridetrapping reagent. Compound 1H2 constitutes an ideal candidate for this purpose and, indeed, after the addition of 1 equiv. of 1H2, Li2[4] quantitatively vanished and Li[2] formed instead. Moreover, we found two sets of proton resonances that are assignable to two isomeric hydride-trapping products of 1H2 (cf. Li[7], Li[10]; Schemes 5 and 6).

As a caveat we emphasize that the reaction from 1H₂ to Li[2] may bypass the intermediate Li₂[4] if hydride transfer from Li₂[3] to 1H₂ is faster than the rearrangement from Li₂[3] to Li₂[4] (blue path (a) in Scheme 5). Arguments in favor of this alternative route include: (i) the 1,2-phenyl shift required to generate intermediate Li[5] should be more facile on a B(sp²)- $B(sp^3)$ rather than a $B(sp^3)$ - $B(sp^3)$ scaffold (cf. $Li_2[3] \rightarrow Li_2[4]$; Scheme 5). (ii) Li₂[4] was observed only when the reaction was started from Li[1H], i.e., when the hydride trap 1H₂ was absent, thus rendering the blue path impassable.

After the above discussion of a plausible mechanistic picture underlying the overall reaction scenario, we now present analytical data of key intermediates and products. The reaction H₃CLi/1H₂ furnishes Li[1H] and Li[2] besides the isomeric hydride-trapping products Li[7] and Li[10]. The first species, Li[1H], is a known compound and therefore does not require further discussion.14 The second species, Li[2], is reminiscent of

Scheme 6 Reaction of 1H₂ with Li[HBEt₃] at -30 °C to give Li[10], which isomerizes to Li[7] at room temperature (top). Compound Li₂[11] forms in both reactions, tBuCCLi/Li[1H] and tBuCCH/Li2[1] (bottom; carbon atoms marked with asterisks bear tBu substituents). Molecular structure of [Li(12-crown-4)(thf)][Li(thf)₂][11] in the solid state. The solvent-separated cations, phenyl-bonded tBu groups, and all CH atoms are omitted for clarity.

the published C-H-activation product obtained from the reaction $nBuLi/1H_2$ (cf. Scheme 1, $R = C_3H_7$). The main difference between both compounds relates to the fact that Li[2] possesses an average C2v symmetry in solution, whereas a pending C3H7 substituent reduces the symmetry to C_s . Consequently, the 1 H NMR spectrum of Li[2] contains only one set of signals for all four tBu-C₆H₃ rings. The corresponding spectrum of its C_s -symmetric congener features two sets of resonances, ¹⁴ one of them with chemical shift values almost identical to those of Li[2] and thus likely assignable to those halves of the 9-borafluorene subunits, which point into the same direction as the proton residing on the methylene bridge. A similar interpretation is valid for the ¹³C{¹H} NMR spectrum of Li[2]. Single crystals of [Li(thf)₄][2] suitable for X-ray analysis were grown from THF-hexane (Scheme 3). Like its C3H7 derivative,14 [Li(thf)₄][2] forms solvent-separated ion pairs in the crystal lattice, and all key geometric parameters of the two anions are identical within the experimental error margins. We also note a pleasingly good agreement between the experimentally determined structure of [2] and the computed structure of $[2^{c}]^{-}$ (cf. the ESI† for full details).

¹H NMR spectra measured on H₃CLi/1H₂ mixtures reproducibly showed resonances pointing toward a primary hydridetrapping product Li[10], which features a BHB bridge and two terminal hydrogen substituents in mutual trans arrangement (Scheme 6). For comparison, we prepared an authentic sample of Li[10] from 1H₂ and 1 equiv. of the 'superhydride' Li[HBEt₃]. At low temperatures, Li[10] forms quantitatively; since the compound is thermolabile, its NMR spectra had to be recorded at -30 °C. Li[10] gives rise to a double set of proton resonances in THF solution. On average, the two 2,2'-biphenylylene fragments of the anion [10] should be related by a mirror plane containing the B₂H₃ core. The two phenylene rings of each individual 2,2'-biphenylylene moiety, however, are chemically inequivalent (as confirmed by 2D NMR experiments).

At room temperature, Li[10] readily isomerizes to the secondary hydride-trapping product Li[7], which we have isolated and characterized by NMR spectroscopy as well as X-ray crystallography. The anion of [Li(thf)₃(Et₂O)][7] consists of one 9-borafluorenyl and one BH₂ fragment that are linked by a μ-H atom and a 2,2'-biphenylylene bridge (Scheme 5, bottom). As a result, both boron atoms are tetracoordinate and placed at a distance of $B \cdot \cdot \cdot B = 2.382(8)$ Å. In the solid state, the central seven-membered HB2C4 ring is non-planar and the anion possesses C_1 symmetry (the torsion angle of the bridging 2,2'biphenylylene amounts to 36°).

The molecular scaffolds of $[7]^-$ and the known anion $[9]^{2-}$ are essentially superimposable, apart from the fact that the latter features a covalent B-B bond (1.810(5) Å) instead of the μ-H atom (Scheme 5, bottom).13 In line with their marked structural resemblance, both anions exhibit similar ¹H NMR spectra: in each case, three sets of aryl resonances are detectable. Two of those are well resolved at room temperature (H-a, H-b), whereas the third set consists of very broad signals, each of them integrating 2H (H-c; Scheme 6). This points toward a dynamic behavior of the compounds in solution, which likely arises from conformational changes of the twisted boron heterocycles. The

Chemical Science

¹¹B NMR spectrum of [7]⁻ is characterized by two resonances with chemical shift values of δ -3.6 and -10.1 ppm, testifying to the presence of two magnetically inequivalent, tetracoordinate boron nuclei.38

Turning our attention from the products of the reaction CH₃Li/1H₂ to its intermediates, we note that the ¹H NMR spectrum of Li₂[4] shows the same peculiarities as those of its structural congeners Li[7] and Li₂[9]: well resolved resonances coexist with severely broadened signals. Together with a BCH3 resonance at δ –0.1 ppm, this can be taken as a support for our structural proposal of Li₂[4], but the motional broadening precludes the measurement of meaningful ¹³C{¹H} NMR and 2D correlation spectra. Despite numerous efforts, we have not succeeded in growing crystals of Li₂[4] and therefore considered replacing the H₃C group with an alternative sterically undemanding organic substituent: The reaction tBuCCLi/Li[1H] provided the alkynyl analogue Li₂[11] of Li₂[4] in singlecrystalline form ([Li(12-crown-4)(thf)][Li(thf)₂][11]; Scheme 6). X-ray crystallography confirmed the proposed ring-contracted, H-shifted structure of $[11]^{2-}$.

NMR spectroscopy reproduced the characteristic distribution of well-resolved and motionally broadened line shapes; the chemical shift values of the aryl protons of Li₂[11] are reasonably close to those of Li₂[4] (cf. the ESI† for an overlay of the respective ¹H NMR spectra). Remarkably, Li₂[11] is also accessible via a different approach, starting from the doubly borondoped dibenzo[g,p]chrysene Li₂[1] and tBuCCH, the conjugate weak acid of [tBuCC] (Scheme 6).

The facile protonation¹⁴ of Li₂[1] prompted us to investigate whether an umpolung approach to synthesize compounds of the type Li[2] might also be successful, which would provide fundamentally interesting insights into the reactivities of B=B double-bonded species. As mentioned above, the intermediate Li[6] of the reaction H₃CLi/1H₂ can be regarded as the [H₃C] adduct of a diborane(4). Conceptually, it should be possible to arrive at the same molecule by formally transferring two electrons from the carbon nucleophile to the redox-active organoborane and thus starting from methylium-ion sources and the anion $[1]^{2-}$ (Fig. 3).³⁹

Indeed, when a THF solution of Li₂[1] is stirred at room temperature under a blanket of H₃CCl gas (1 atm), a quantitative conversion to Li[2] occurs (Scheme 7).40 This approach is far more atom- and time-economic than the previous access route via the polarity-inverted couple H₃CLi/1H₂, because we avoid wasting 50% of 1H2 as a hydride-trapping reagent and do no

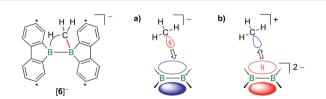

Fig. 3 Two borderline cases to describe the bonding situation in [6] as (a) the [H₃C]⁻ adduct of a diborane(4) and (b) the [H₃C]⁺ adduct of anion. Carbon atoms marked with asterisks bear tBu substituents

Scheme 7 The addition of H₃CCl to Li₂[1] quantitatively furnishes Li[2]. The reaction pathways to Li[2], starting from either 1H₂ or Li₂[1], merge at the stage of Li[5] (cf. also Scheme 5). Carbon atoms marked with asterisks bear tBu substituents.

longer have to separate the resulting hydride-trapping products. Mechanistically, the electron-rich B=B fragment of Li₂[1] likely acts as a nucleophile toward H₃CCl to form [12]⁻, which carries a boron-bonded methyl substituent and contains a central B-B single bond. The B(sp²)-B(sp³) species Li[12] then undergoes a 1,2-phenyl shift to afford Li[5] and thereby funnels into the reaction cascade outlined above for the formation of Li[2] from H₃CLi/1H₂ (Scheme 7).

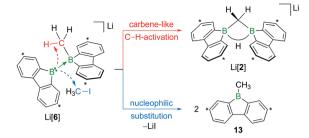

When H_3CCl is replaced by 1 equiv. of iodomethane (H_3C-I), the outcome is a mixture of Li[2], 9-methyl-9-borafluorene (13), and residual Li₂[1] (Scheme 8). After increasing the relative amount of H₃C-I to 3 equiv., we almost exclusively obtained 13. The different behaviors of the two halomethanes can be rationalized by viewing the intermediate Li[6] as an adduct between the 9-borafluorenyl anion ([BFlu]⁻) and (H₃C)BFlu (13; Scheme 9). [BFlu] is isoelectronic to the carbene 9-fluorenylidene. A formal carbene-like reactivity is reflected by the intramolecular insertion of [BFlu] into the C-H bond of the 9-methyl-9-borafluorene moiety to afford Li[2]. When the strong electrophile H₃C-I with its excellent iodide leaving group is present, also the nucleophilic character of [BFlu] comes into play and opens a competing intermolecular pathway, which ultimately leads to 13. As the relative amount of H₃C-I is increased, the substitution reaction becomes dominant (we note in passing that the reaction with H₃C-I can alternatively be viewed as a carbene-like insertion of [BFlu] into the C-I bond with subsequent elimination of LiI).

In case of the system $H_3C-I/Li_2[1]$, the methyl group initially gets attached to only one of the symmetry-related boron centers, but the other is equally important for the subsequent C-Hactivation and nucleophilic substitution steps. The degree of B-B cooperativity in $\text{Li}_2[1]$ as well as the insertion vs. nucleophilic behavior of [BFlu] thus deserve a detailed assessment. To this end, we conducted a systematic study using 1:1 mixtures of $\text{Li}_2[\mathbf{1}]$ and α,ω -dihaloalkanes $X(CH_2)_nX$ with chain lengths in the range of n = 2-6 and leaving groups of different qualities (e.g., X = Cl, Br). In these experiments, smaller alkylidene linkers are supposed to mimic higher local concentrations of the electrophile. As summarized in Scheme 8, clean

Edge Article Chemical Science

Scheme 8 The outcome of the reaction $H_3C-I/Li_2[1]$ depends on the stoichiometries employed. While 1:1 mixtures give ${\bf 13}$ together with Li[2], 3:1 mixtures exclusively furnish ${\bf 13}$. Use of α,ω -dihaloalkanes $X(CH_2)_nX$ instead of H_3C-I affords ditopic boranes ${\bf 14}^{Cn}$ (n=2-4) and/or Li[${\bf 15}^{Cn,X}$] (n=4-6; X=CI, Br). Carbon atoms marked with asterisks bear tBu substituents.

twofold substitution reactions are observed with the short-chain substrates (n=2 and 3, cf. $\mathbf{14}^{C2}$ and $\mathbf{14}^{C3}$; 1,3-dichloropropane leads to a complex mixture of products). Clean C–H-activation reactions occur with the long-chain substrates (n=5 and 6) to afford the haloalkyl species Li[$\mathbf{15}^{C5,Cl}$]/Li[$\mathbf{15}^{C5,Br}$] and Li[$\mathbf{15}^{C6,Cl}$]/Li[$\mathbf{15}^{C6,Br}$]. The medium-chain substrates (n=4) mark the switching point between both scenarios: with the worse chloride leaving group, C–H-activation is preferred over the twofold substitution. The reverse is true in the case of the better bromide leaving group. The solid-state structures of $\mathbf{14}^{C2}$ ·thf, $\mathbf{14}^{C3}$ (Fig. 4), $\mathbf{14}^{C4}$, and [Li($\mathbf{12}$ -crown- $\mathbf{4}$)₂][$\mathbf{15}^{C5,Cl}$] (Fig. 4) were characterized by X-ray crystallography (cf. the ESI† for full information). Also the connectivities of [Li($\mathbf{15}^{C4}$)], [Li($\mathbf{15}^{C4}$)], and [Li($\mathbf{15}^{C6,Br}$] are supported by X-ray diffraction studies, however, due to disordered haloalkyl

Scheme 9 The intermediate Li[6] can be interpreted as an adduct between the 9-borafluorenyl anion ([BFlu]⁻) and 9-methyl-9-borafluorene (13). Intramolecular C–H insertion of the carbene-like [BFlu]⁻ furnishes Li[2]; intermolecular nucleophilic attack on H₃C–I affords 2 equiv. of 13. Carbon atoms marked with asterisks bear tBu substituents.

chains, *t*Bu groups, and THF molecules, the quality of these three structures prevents their inclusion into this publication.⁴¹

The observed chain-length dependence of the product distribution suggests that the carbene-type insertion and the second nucleophilic substitution both follow an intramolecular pathway involving two cooperating boron atoms.

If the remaining CH_2X center and the BCH_2 group are similarly close to the B-B bond, the nucleophilic process occurs at a higher rate than the carbene-type C-H-activation. As the alkylidene spacer grows, the second electrophilic functionality moves further apart whereas the reactive α - CH_2 unit stays in place such that the C-H-activation becomes more and more relevant until it finally takes over.

Although the reaction between Li₂[1] and, *e.g.*, H₃C-I can convincingly be rationalized by assuming a nucleophilic pathway, the possible operation of a radical mechanism remains to be ruled out. We first note in this context that 1,2-dihaloethane in the presence of Li₂[1] did not undergo reductive dehalogenation with ethene formation. Yamashita, Nozaki *et al.* have treated their boryllithium compound with methyl trifluoromethanesulfonate (H₃COTf)⁴² on the one hand and benzyl bromide (BnBr) on the other (Scheme 10, top). In the first case, they observed the corresponding methyl borane in yields of 85%, whereas in the second case exclusively the bromoborane was obtained.⁴³ To explain the different outcomes, they proposed halogenophilic attack of the boryllithium or single electron transfer to the benzyl halide. We repeated Nozaki's

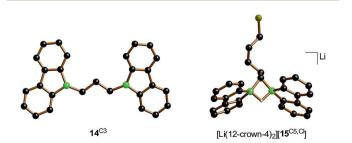

Fig. 4 Molecular structures of 14^{C3} and of the terminally chlorine-substituted [Li(12-crown-4)₂][$15^{C5,Cl}$] in the solid state. The solvent-separated [Li(12-crown-4)₂]⁺ cation, all tBu groups, and all CH atoms are omitted for clarity.

Yamashita, Nozaki 2008

$$\begin{array}{c} H_3\text{COTf} \\ H_3\text{COTf} \\ H_4 \\ H_5 \\ H_6 \\ H_7 \\ H_7$$

Scheme 10 The reactions of Yamashita's and Nozaki's boryllithium compound with $H_3 COTf$ or BnBr furnish the corresponding methyl borane or bromoborane, respectively (top). In the analogous reactions with Li_2[1], only the organyl moieties are transferred to boron (middle; cf. Li[2]/13 and Li[16]). The reaction of Li_2[1] with the radical clock (bromomethyl)cyclopropane quantitatively furnishes Li[17], which is a strong indication for a closed-shell, nucleophilic pathway (bottom). Dipp $=2,6-(\textit{iPr})_2C_6H_3,~Bn=CH_2C_6H_5,~H_3COTf=H_3COSO_2CF_3; carbon atoms marked with asterisks bear tBu substituents. In the crystal structure plot of [Li(thf)_4][16], the solvent-separated cation, the tBu groups, and all <math display="inline">C(\text{sp}^2)-H$ atoms are omitted for clarity.

experiments with $\text{Li}_2[1]$ (Scheme 10, middle): H_3COTf showed the same reactivity as described above for $\text{H}_3\text{C-I}$ (*cf.* Li[2] and 13); BnBr (as well as BnCl) gave the C–H-activation product Li[16] rather than any haloboranes, as confirmed by NMR spectroscopy and X-ray crystallography on [Li(thf)_4][16].

As the ultimate test, we added $\mathrm{Li_2[1]}$ to 1 equiv. of (bromomethyl)cyclopropane, a well-established radical clock (Scheme 10, bottom). ^{44–46} A quantitative conversion to the C–H-activation product Li[17], still carrying an intact cyclopropyl substituent, occurred (NMR-spectroscopic control). The absence of the ring-opened olefin derivative Li[18] in the reaction mixture strongly supports the proposal of a closed-shell scenario in contrast to an open-shell process.

The results collected thus far are not only fundamentally interesting with respect to the reactivities of electron-rich B=B double bonds, but open new access routes to ditopic boranes of high Lewis acidity. Molecules containing two or more potentially cooperating boron sites are of great current interest, *interalia*, as organocatalysts^{5,11,47} or electron-storage media. 48,49 Compounds of the class 14^{Cn} already constitute free Lewis

Scheme 11 The addition of H_3C-I to Li[2] furnishes the bis(9-bora-fluorenyl)methane ${\bf 14}^{C1}$. Carbon atoms marked with asterisks bear tBu substituents.

acids, but do not contain functional groups amenable to further derivatization.

The opposite is true for the salts $\text{Li}[\mathbf{15}^{\text{C}n,X}]$. Here, the terminal halogen atoms provide ample opportunities, *e.g.*, for grafting the organoboron units onto polymers, dendrimers, or surfaces, but the Lewis acids need to be activated through LiH elimination prior to use.

While the bulky hydride scavenger $(H_3C)_3$ SiCl failed in this respect, the smaller electrophile H_3C –I efficiently transformed the model compound Li[2] to its conjugate acid $\mathbf{14}^{C1}$ (Scheme 11). As important diagnostic criteria, the BHB proton resonance vanishes in the course of the reaction, and the ¹¹B NMR signal shifts from the tetracoordinate (Li[2]: δ –14 ppm) to the tricoordinate spectral region ($\mathbf{14}^{C1}$: δ 45 ppm). ^{49,50}

In line with the reaction H_3C –I/Li[2], the haloalkyl derivatives Li[15 Cn,X] are not long-term stable in THF at room temperature: 1H NMR monitoring of the solutions revealed in each case a gradual decrease of the CH_2X resonance and a concomitant increase of a signal assignable to a terminal CH_3 group, which leads to the conclusion that the pending haloalkyl substituent can take a similar role as added H_3C –I. It is important to note in this context that the follow-up X/H exchange reactions are completely suppressed at $-78\,^{\circ}C$ and even at room temperature slow enough not to interfere with targeted derivatizations of the CH_2X termini.

Conclusion

In summary, C(sp³)-H activation and nucleophilic substitution reactions have been performed on the same redox-active diborane platform. We propose that the doubly 2,2'biphenylylene-bridged diborane(6) 1H2 reacts with H3CLi to furnish the rearranged B(sp²)-B(sp³) intermediate Li[FluB- $BFlu(CH_3)$] (Li[6]; BFlu = 9-borafluorenyl). Li[6] also forms *via* an umpolung approach starting from H₃CX and the B=B bonded, nucleophilic Li₂[1], a compound which can be regarded as the product of a double deprotonation of $1H_2$ (X = Cl, I). Li[6] readily undergoes B-B-bond heterolysis to formally give the [BFlu] anion and (H₃C)BFlu (13). The final product distribution depends on the relative amount of H₃CX and the leavinggroup qualities of X, because [BFlu] can either insert into a C(sp³)-H bond of 13 or replace the halogen atom of a second equivalent of H₃CX. The product of the carbene-type C-H insertion is Li[FluB(μ-CH₂)(μ-H)BFlu] (Li[2]) while the nucleophilic substitution on C-X generates 2 equiv. of 13. Further insight into the competition between the two scenarios was

Edge Article Chemical Science

gained with the help of α , ω -dihaloalkanes $X(CH_2)_n X$ (X = Cl, Br). In the resulting intermediates Li[FluB-BFlu((CH₂)_pX)], both possible follow-up reactions should be intramolecular processes. A longer alkylidene chain corresponds to a lower local concentration of the electrophile, while the BCH₂ groups are always similarly close to the reactive B-B bond. Consequently, short chains (n = 2,3) result in double substitution products $FluB(CH_2)_nBFlu$ and long chains (n = 5.6) in C-Hactivation products Li[FluB(μ -C(H)(CH₂)_{n-1}X)(μ -H)BFlu]. In the case of the intermediate chain length n = 4, a mixture of both compounds is obtained: the worse leaving group X = Cl leads to a higher proportion of the C-H-activated species, the better leaving group X = Br furnishes more $FluB(CH_2)_4BFlu$. We finally note that the B-B-bond heterolysis of Li[6] with concomitant transfer of a reactive [BFlu] moiety is reminiscent of the reactivity patterns of the widely used alkoxy-diborane(4) adducts [pinB-Bpin(OR)]-.25 As a decisive difference, however, [BFlu] appears to be considerably more reactive than in situgenerated [Bpin], because C-H-insertion reactions of the latter are so far unknown.

Conflicts of interest

There are no conflicts to declare.
