Renal fibrosis is the result of all chronic kidney diseases and is becoming a major global health hazard. Currently, traditional treatments for renal fibrosis are difficult to meet clinical needs due to shortcomings such as poor efficacy or highly toxic side effects. Therefore, therapeutic strategies that target the kidneys are needed to overcome these shortcomings. Drug delivery can be attained by improving drug stability and addressing controlled release and targeted delivery of drugs in the delivery category. By combining drug delivery technology with nanosystems, controlled drug release and biodistribution can be achieved, enhancing therapeutic efficacy and reducing toxic cross-wise effects. This review discusses nanomaterial drug delivery strategies reported in recent years. Firstly, the present review describes the mechanisms of renal fibrosis and anti-renal fibrosis drug delivery. Secondly, different nanomaterial drug delivery strategies for the treatment of renal injury and fibrosis are highlighted. Finally, the limitations of these strategies are also discussed. Investigating various anti-renal fibrosis drug delivery strategies reveals the characteristics and therapeutic effects of various novel nanosystem-derived drug delivery approaches. This will serve as a reference for future research on drug delivery strategies for renal fibrosis treatment.

1 Introduction

Acute kidney injury (AKI) and chronic kidney disease (CKD) are the two major categories of kidney disease, with CKD accounting for far more patients than AKI. According to the Global Burden of Disease (GBD) and World Health Organization (WHO) estimates, CKD caused 1.2 million deaths in 2015.^{1,2} Based on WHO forecasts, the death rate from CKD is expected to increase by 14 per 100 000 by 2030.³ The quantity of people with kidney disease is amplified as a result of the New Crown epidemic, and the mortality rate for CKD is likely to be higher than the prediction of WHO.⁴ A study of global chronic kidney disease from 1990–2017 showed that the majority of CKD

patients worldwide were concentrated in stages 1–3, accounting for 97.8 percent of all patients. The CKD stage 4 and CKD stage 5 accounted for 1.76 percent and 0.77 percent of the total patients, respectively. Many CKD patients were concentrated in stages 1–3, which accounted for 97.8 percent of all patients, while CKD stage 4 and CKD stage 5 accounted for 1.76 percent and 0.77 percent of the total proportion of patients, respectively. As a result, renal fibrosis is increasingly becoming a global health problem.^{5,6}

Renal fibrosis is a pathological change that progresses over time, causing the functionality of the kidneys to alter from healthy to damaged or injured. This change can be majorly categorized into three stages: the inflammatory response phase, the fibrosis formation phase, and the scar formation phase.^{7,8} High levels of matrix deposition and interstitial fibroblast activation and proliferation are hallmarks of renal fibrosis. Additionally, damaged renal tubular epithelial cells and inflammatory cells secrete several growth factors and mediators that support angiogenesis and lymphangiogenesis. These observations are typical of a range of renal fibrosis illnesses. Conventional treatments for renal fibrosis mainly include drug therapy, lifestyle modification, and renal replacement therapy. However, the shortcomings of these treatment modalities gradually make it difficult to meet clinical needs. Pharmacological treatment of renal fibrosis usually slows down the process of renal fibrosis by using immunosuppressants,

hormone-regulating drugs, and blood pressure-controlling drugs. However, the ability of these drugs to control the progression of renal fibrosis is limited. The adverse effects of drug therapy are hard to ignore, such as those due to using immunosuppressants, which may lead to an increased risk of infection, and hormone therapy, which may lead to osteoporosis. Clinical investigations on other proposed options, such as connective tissue growth factor inhibitors, bone morphogenetic protein (BMP)-7 agonists, and transforming growth factor (TGF)- β antagonists, have yielded substandard results.⁹ Renal replacement therapies such as haemodialysis and peritoneal dialysis can only partially replace the functioning of the kidneys. They do not fully mimic normal physiological processes, and long-term reliance on these therapies may have a serious impact on the quality of life of patients. In addition, renal replacement therapy carries the risk of complications, such as cardiovascular problems and infections. Drug delivery challenges are a major contributor to the struggle to meet expectations for renal fiber therapy.

A set of technologies known as “drug delivery technology” controls all aspects of the distribution of medication in an organism, including its location, timing, and dosage. Drug delivery can be achieved by improving drug stability, addressing controlled release, and battered drug delivery in the delivery category. Incorporating drug delivery into renal anti-fibrotic therapy enhances drug targeting to the kidneys, improves bioavailability, and reduces damage to other organs.¹⁰ More importantly, the use of drug delivery technology holds the promise of developing a novel clinical treatment strategy for renal fibrosis (Fig. 1). This review focuses on research advances in drug delivery-based therapeutic strategies for renal fibrosis. It focuses on the drug delivery strategies for renal antifibrosis, as well as the methods of administrating medications to the kidneys and renal fibrosis. We also present

these summaries to guide research on drug delivery strategies for renal fibrosis treatment.

2 Mechanisms of renal fibrosis

Fibrosis is a pathological extension of the normal healing method for wounds, marked by damage, inflammation, myofibroblast activation and migration, deposition of the matrix, and remodeling. Much of the pathophysiology of renal fibrosis is the same as that of other fibrotic diseases, such as cirrhosis,¹¹ cardiomyopathy,¹² and idiopathic pulmonary fibrosis.¹³ However, there are currently no clinically approved targeted antifibrotic therapies for the kidneys, possibly since there is still much to learn about the intricate processes that create and propel fibrosis. Among the key mechanisms of renal fibrosis that have increased more agreements are the heterogeneousness and procedures involved in myofibroblast formation, and the role of immune cells and injured epithelial cells and the mechanisms of their interaction (Fig. 2).⁸

The main source of resident fibroblasts, pericytes, and their subpopulations is myofibroblast-derived tissue. Smooth muscle cells—mainly reactive cells found in pathological circumstances like injury or cancer—combine characteristics of fibroblasts and myofibroblasts. Alpha-smooth muscle actin (α -SMA), which generates stress fibers – bunches of myofilaments, is the greatest indicator of the myofibroblasts. These fibers under stress are essential for attaching myofibroblasts to the extracellular matrix (ECM), and excessive deposition of the ECM is characteristic of renal fibrosis. The extracellular matrix (ECM) is a complex reticular dynamic structure composed of macromolecules secreted by cells into the extracellular mesenchyme; under normal physiological conditions, ECM catabolism and synthesis are in dynamic equilibrium; under pathological

conditions, there is an increase in synthesis and a decrease in catabolism, with an eventual overdeposition of the ECM and an accompanying up-regulation of myofibroblast activity, resulting in a chronic macrophage- and immune-cell infiltrating inflammatory environment with infiltration of macrophages and immune cells. As the structure of the matrix changes and hardens with excessive ECM deposition, mechanical forces are exerted on the matrix as the cells contract, causing reorganisation and wound closure during the healing process. PDGFR- β , the receptor for the platelet-derived growth factor, is expressed by all myofibroblasts. Furthermore, one important regulator of myofibroblast development during fibrosis is transforming growth factor-beta 1 (TGF- β 1). Researchers have demonstrated the major role of myofibroblasts in renal fibrosis by deleting α V integrins and cutting off signaling that transmits pro-fibrotic TGF- β using the PDGFR- β -Cre driver, which led to the observation of a significant reduction in renal fibrosis.¹⁴

In addition to myofibroblasts, renal tubulointerstitial fibrosis in the kidneys is caused by a variety of cells, including tubular epithelial cells, mesenchymal stromal cells, endothelial cells, and inflammatory cells. The formation and progression of renal fibrosis is coordinated by these cells' intimate communication.¹⁵ One of the main processes causing renal fibrosis in these many cellular components is believed to be crosstalk between the injured renal tubular epithelial cells and mesenchyme. The researchers observed renal fibrosis driven by specific damage to the renal tubules of model mice, suggesting that damaged tubules are a critical component in the progress of renal fibrosis. The fibrosis is greatly influenced by the potential interaction between the injured tubules and the immune cells or mesenchyme.^{16,17} Vascular damage and capillary thinning are also major contributors to renal fibrosis. Renal damage in humans due to chronic kidney disease is characterized by peritubular capillary thinning. Tissue oxygenation measurements in several CKD experimental models validate hypoxia.^{18,19}

Hypoxia-inducible factor-1 α promotes pro-fibrotic signaling pathways and is up-regulated in hypoxic renal tubular epithelial cells, especially those in patients with chronic kidney disease.^{20,21} Loss of peritubular capillaries from acute or chronic injury results in local hypoxia, further damage to nearby tubules, up-regulation of pro-fibrotic pathways, and a self-reinforcing vicious cycle.

3 Drug delivery in renal fibrosis

Among the most significant treatment-related obstacles of kidney disease is the selective delivery of drugs to achieve therapeutically relevant concentrations in the target organ to reduce the amount of drugs required and minimize side effects. In 1994, a targeted drug delivery method was reported for glomerular mesangial cells using actinomycin D-loaded poly (isobutylcyanoacrylate) nanoparticles that are concentrated in rat mesangial cells. Since the beginning of the 1990s, research has been conducted on kidney-targeted drug delivery systems.²² Currently, renal drug delivery mainly targets tubules and glomeruli, in addition to targeting giant proteins, tubules, *etc.*²³ However, glomerular filtration makes drug delivery to renal cells difficult. Podocytes, glomerular endothelial cells, and glomerular basement membranes make up the glomerular filtration barrier. Nanoparticles with a hydrodynamic diameter of less than 10 nm can pass *via* the glomerulus and be removed, however particles larger than 150 nm cannot cross the glomerular filtration barrier and collect in diseased areas.²⁴ More importantly, podocytes in the glomeruli were the target of nanoparticles that could pass through the glomerular filtration barrier at a certain size of 5–30 nm.²⁵ Studies have shown that nanoparticle accumulation is limited to the glomerular tunica and the extracellular matrix of the kidneys, and that maximum glomerular deposition can be achieved with about 80 nm size of the nanoparticles.^{26,27} Furthermore, one crucial factor for renal

Fig. 3 Renal drug delivery system.

targeting is charge selectivity. Long circulation durations and little macrophage uptake are observed in nanoparticles with a surface charge of 15 mV.²⁸ Cells within the mononuclear phagocyte system quickly eliminate highly positively charged nanoparticles from the bloodstream, whereas anionic nanoparticles are also eliminated by these cells.

Renal therapy has demonstrated encouraging results using nanosystems that have diverse physicochemical qualities (dimension, form, surface, and charge) and biological attributes (high cellular internalization, low cytotoxicity, regulated pharmacokinetics, and biodistribution). Nanomaterial-derived drug delivery systems based on anti-renal fibrosis trigger extensive research discussions among researchers (Fig. 3).²⁹ Among many nanomaterials, metal organic frameworks (MOFs) have attracted wide attention due to their porosity, large specific surface area, stable results and modifiability. MOFs are a class of porous materials formed by metal ions or metal clusters connected with organic ligands through strong coordination bonds. They are widely used in gas storage, separation, catalysis, drug release, sensing and other fields. In biological applications, MOFs are mainly used in drug carriers, bioimaging technology, and biosensing technology and as antimicrobial materials. Among them, the most promising is the drug carrier technology of MOFs, which often outperforms the therapeutic effect of drugs alone by carrying anti-tumour drugs and so on. In addition to the field of drug delivery, MOFs have been extensively studied in other fields, especially in battery storage and sewage treatment, where they have been practically applied and have high economic potential.

4 Drug delivery strategies for renal antifibrosis

Due to the special physiological structure and physiological function of the kidneys, drug delivery systems for delivery to the kidneys are often on the nanoscale. Different nanomaterials,

such as microcapsules, lipid bilayers, nanocopolymers, *etc.*, are modified and adapted to improve their biocompatibility and renal targeting. Thus, anti-renal fibrosis therapeutic agents, including peptides, medicines, active ingredients of traditional Chinese medicines, *etc.* can be efficiently delivered to the damaged kidneys (Table 1).

4.1 Gene therapy

4.1.1 Delivery of siRNA-based therapeutics. A family of double-stranded non-coding RNAs known as small interfering RNAs (siRNAs) is commonly utilized to control gene expression both *in vivo* and *in vitro*. siRNAs are very promising as a disease modifier. However, *in vivo* delivery beyond hepatic effectiveness and non-specific innate immune stimulation of siRNAs are limiting factors in the development of siRNA therapy.^{52–54} A common mode of management of siRNA-derived therapeutics is systemic fluid dynamics injection. However, this process involves huge amounts of drug solution and high-pressure injections, and the drug may not be injected repeatedly at the same site because of the ensuing tissue damage. To cure renal fibrosis, intravesical siRNA injections have been employed in many investigations. Furthermore, enhancement of their targeting and specificity by modification or piggybacking is expected to result in better renal fibrosis treatments. To facilitate the selective gene silencing of target proteins, siRNA can destroy regions of complementary RNA molecules. Raval *et al.*³⁰ reported an encapsulated, stabilized, and passively delivered siRNA containing albumin polymer nanocomplexes. The approach for the delivery of histone deacetylase 4 (HDAC4) siRNA is specifically to kidney podocytes *via* $\alpha_v\beta_3$ integrin (Fig. 4). In this strategy, siRNA nanocomplexes with fluid dynamics dimension of particles of 65.31 ± 1.83 nm and zeta potentials of 17.4 ± 1.08 mV were able to enter the glomerulus efficiently. The siRNA nanocomplexes possessed significantly high siRNA encapsulation and showed good stability in serum. There is no significant cytotoxicity when compared to free HDAC 4 siRNA and other controls, demonstrating their good biocompatibility. In cellular uptake experiments, siRNA-associated green fluorescence was observed in the intracellular compartment of podocytes, indicating effective cellular uptake and intracellular siRNA delivery. In an *in vitro* DN podocyte model, siRNA nanocomplexes efficiently target the silencing of the HDAC 4 gene. In the diabetic nephropathy (DN) mouse model, siRNA nanocomplexes exhibited excellent antifibrotic effects compared to controls following intraperitoneal injection of siRNA nanocomplexes.

Amphiregulin (AREG) is a transmembrane glycoprotein recently found to be associated with renal fibrosis. Son *et al.*³¹ demonstrated *in vivo* suppression of amphiregulin using a new and efficient renal fibrosis through self-assembled micelle (SAM) inhibitory RNA. This self-assembled micelle inhibitory RNA can be blocked with epidermal growth factor receptor (EGFR) signaling. After injection of SAMiRNA-AREG into two types of renal fibrosis mice produced by unilateral ureteral obstruction (UUO) and adenosine diet (AD), due to the small nanoparticle size, it is easier for it to enter into tumours, inflamed or fibrotic

Table 1 Drug delivery strategies for delivering antifibrotic therapeutics to the kidneys

Drug delivery strategy	Therapeutic agent	Delivery vehicle	Particle size (nm)	Route of drug delivery	Target site	Ref.
Cyclo(RGDfC)	siRNA	cyclo (RGDfC)-polymeric	65.31 ± 1.83	Peritoneal injection	Renal podocytes	30
SAMiRNA-AREG	siRNA	Self-assembling micelles	—	Intravenous injection	Renal tubules	31
miR-146a-PEI-NPs	miRNA	Polyethyleneimine nanoparticles	—	Caudal vein injection	UUO Kidneys	32
DTmiAnp-cRGD-30 a mm	miRNA-30a	Cyclo (RGDfC)-gated polymeric-nanoplexes	73.51 ± 1.43	Peritoneal injection	Renal podocytes	33
CTLA-4-Ig	CTLA-4-Ig	Microbubbles	—	Peritoneal injection	Renal podocytes	34
TKI-LZM	TGF-β type-I receptor kinase inhibitor	Protein lysozyme	—	Intravenous injection	Renal tubules	35
PTRAS EPLP-VEGF	Vascular endothelial growth factor	Elastin-like polypeptide	—	Renal Endovascular Implant	Renal parenchyma	36
SAP-TNF-α/HGF	Anti-TNF-α, hepatocyte growth factor	Self-assembling peptides/heparin hydrogel	10–20	Intrarenal injection	Renal tubules	37
IL-10@PLT	Interleukin-10	Platelets	965	Caudal vein injection	Inflammatory renal cells	38
MV-DEX	Dexamethasone	RAW 264.7 macrophage cell-derived MVs	140.7 ± 4.8	Intravenous injection	Inflammatory renal cells	39
RDYH58-NP	Sorafenib	Lactic- <i>co</i> -glycolic acid	76.0 ± 13.7	Intravenous injection	Myofibroblasts	40
DXMS/CAP@PLGA-ILs	Dexamethasone, captopril	Liposome-nanoparticle hybrid	119.1 ± 2.31	Caudal vein injection	Glomerulus	41
KGM/PBA-PGA hydrogel	Insulin, liraglutide	Glucose-responsive hydrogel	—	Hypodermic injection	Renal tubules	42
SMEDDS	Emodin	Self-microemulsifying drug delivery systems	18.31 ± 0.12	Oral administration	Renal tubules	43
CPP/PEG-NPs	Emodin, tanshinone IIA	Microcapsules	156.3 ± 2.4	Oral administration	UUO Kidneys	44
PPP-RH-NPs	Rhein	Polyethyleneglycol- <i>co</i> -polycaprolactone- <i>co</i> -polyethylenimine triblock	75 ± 25	Intravenous injection	Diabetic kidneys	45
Plum pudding	Celastrol	Self-assembled triblock polymeric micelles and injectable hydrogels	35.6	Intravenous injection	Glomerulus	46
PLGA-Gyp XLIX	Gypenoside	Polylactic acid- <i>co</i> -glycoside (PLGA)	35.6	Intravenous injection	Renal tubules	47
BBR-BC 12-NPs	Berberine	Brij-grafted-chitosan	102.0 ± 0.7	Oral administration	Glomerulus	48
NTCC	CoCl ₂	50% <i>N</i> -acetylation-thiolated chitosan	50–100	Peritoneal injection	Renal tubules	49
GLAuNPs-Co	Co, AuNPs	GLAuNPs-Co	22.97 ± 7.43	Peritoneal injection	Renal tubules	50
ZnONPs	Zinc oxides	Nanoparticles	—	Peritoneal injection	Renal podocytes	51

tissues. The SAMiRNA-AREG accumulates in damaged kidneys and exhibits excellent renal therapeutic and fibrotic effects through passive targeting by enhanced permeability and retention effects. Finally, it was confirmed that the upregulation of AREG in UUO or AD replicas was largely localized to the distal tubules.

4.1.2 Delivery of miRNA-based therapeutics. MicroRNAs (miRNAs) are a group of small non-coding RNAs, usually 19–25 nucleotides, which usually adjust gene expression *via* degradation or translational repression of target mRNA.⁵⁵ The miRNAs are associated with many downstream effects that regulate a variety of biological processes.^{56–58} The miRNAs have significant roles in proper renal function and have significant impacts on mesangial cells, podocytes, and tubular epithelial cells. The miRNA-192 produces tubular interstitial fibrosis and glomerular mesangial cell fibrosis through many mechanisms.⁵⁹ It has been shown that the transfer of exogenous miRNA-30a to podocytes may ameliorate albuminuria and podocyte injury. However, lack of miRNA solidity, deprived

targeting, and short *in vivo* specificity have been constraints. Morishita *et al.*³² developed a strategy to deliver miR-146 against renal fibrosis using polyethyleneimine nanoparticles (PEI-NPs). The UUO mice were injected with miR-PEI-NPs *via* the tail vein, and the obstructed kidneys of mice were primarily found in the tubular and interstitial fibrotic areas. The PEI-NPs containing miR-146 significantly increased the expression of miR-146 in the obstructed kidneys when compared to the control group, but also inhibited the infiltration of F4/80-positive macrophages, the renal fibrotic area, and α-smooth muscle actin expression.

The miRNA-30a is mainly accountable for podocyte homeostasis. In diabetic nephropathy (DN), miRNA-30a is mainly directly inhibited by the hyperglycaemic kidney-induced notch signaling trail, leading to podocyte injury and apoptosis. Thus, delivery of exogenous miRNA-30a to podocytes is expected to ameliorate proteinuria as well as podocyte damage, thus acting as an antifibrotic agent. Raval *et al.* reported the targeted and effective administration of miRNA-30a mimic by dendrimer-

Fig. 4 Schematic illustration of the nanoconstruction of cyclo-RGD truncated polymers for the HDAC4 gene silencing target in a mouse with diabetic nephropathy.³⁰ Reproduced with permission. Copyright 2021 American Chemical Society.

templated cyclo (RGDfC)-gated polymeric nanoplexes to improve podocyte conditions.³³ DTmiAnp-cRGD-30a nm had a fluid dynamics dimension of particles of about 73.51 ± 1.43 nm, and a zeta potential of 20.32 ± 1.03 mV. DTmiAnp-cRGD-30a nm was efficiently delivered to podocytes and up-regulated miRNA 30 compared to controls and protected the miRNA-loaded therapeutic agent from the deprivation by RNA enzymes in the process (Fig. 5). The kidney's glomerular region had less fibrosis and glomerular dilatation after its delivery.

4.2 Protein and peptide therapy

4.2.1 Delivery of protein-based therapeutics. Protein-based therapeutic agents have made a big splash in the treatment of several diseases in recent years, thanks to their excellent specificity. More and more researchers are investigating the therapeutic mechanisms and effects of protein-based therapeutics on different diseases. However, their constancy, immunogenicity, and nonexistence of abdominal absorption are some of the limitations of therapeutic proteins.⁶⁰ Fortunately, drug delivery technologies allow therapeutic proteins to be targeted to target sites with high efficacy. In antirenal fibrosis therapy, therapeutic proteins can be delivered to different targets to work. Wang *et al.*³⁴ reported a cytotoxic T lymphocyte-corresponded antigen 4 immunoglobulin (CTLA-4-IG) combined with an ultrasound microbubble strategy against renal fibrosis (Fig. 6). The microbubbles are composed of an outer shell with a gaseous interior, which under ultrasound can produce a cavitation effect to enhance the efficiency of drug penetration through the physical barriers of the body. It can be stably loaded with genes or drugs for targeted delivery.⁶¹ Moreover, in rodents with diabetic kidney disease, microbubbles increased

renal interstitial capillary permeability.^{62,63} CTLA-4-IG's capacity to penetrate the glomerular basement membrane and get close to podocytes is enhanced by ultrasound microbubble exposure. Thus, CTLA-4-IG can effectively prevent podocyte injury and inhibit inflammation and fibrosis.

Myofibroblasts are one of the key factors in the progression of renal fibrosis, and myofibroblasts are the foremost source of ECM in the process of renal fibrosis. Thus, the inhibition of myofibroblast production is expected to inhibit the progression of renal fibrosis. Albumin is an abundant multifunctional plasma protein synthesized mainly by hepatocytes.⁶⁴ The activated stellate cells (SCs) did not naturally express albumin. However, the phenotype of myofibroblasts reverted to that of early activated cells, along with the reappearance of cytoplasmic lipid droplets and decreased expression of collagen type I and α -SMA when forced to express it.⁶⁵ Cha *et al.*⁶⁶ reported an anti-fibrotic recombinant fusion protein (called R-III) that was created by fusing the C-terminus of retinol-binding protein (RBP) with the albumin domain III. RBP can be used to target SCs for delivery, based on which R-III can be targeted to renal stellate cells (Fig. 7). R-III action induced phenotypic reversal of activated/myofibroblast to a fat storage phenotype, but had no substantial effect on renal fibroblasts. Chronic tubular damage has been demonstrated to be a symptom of mitochondrial diseases, including structural and functional deficits, which progresses to fibrosis.⁶⁷ The regulatory element of the mitochondrial permeability transition pore (MPTP) that controls MPTP opening and MPTP-dependent necrotic cell death is identified as the mitochondrial matrix protein cyclophilin D (CypD). This exhibits *cis-trans* peptidyl prolyl isomerase activity. Jang *et al.* showed that CypD in renal tubular injury,

Fig. 5 (A) Analysis of HG-treated podocytes using flow cytometry following treatment with free cRGD, DTAnp-cRGD-FITC (+) and DTAnp-cRGD-FITC (–). (B) Quantitative assessment of cell uptake using MFI $p < 0.001$ in comparison to cRGD + DTAnp-cRGD-FITC. (C) When miRNA-30a mimic loaded nanoplexes were treated, the qRT-PCR data show a relative upregulation of miRNA-30a; in this case, U6snRNA was taken into account as an endogenous control (healthy podocytes). The results show that $***p < 0.001$ for both DTmiAnp-cRGD-30a mm and DTmiAnp-cRGD-30a mm vs. free miRNA-30a mimic. (D) Following the incubation of free miRNA-30a mimic, DTmiAnp-30a mm-scramble, DTmiAnp-30a mm, and DTmiAnp-cRGD-30a mm, Notch-1 expression was measured by western blot analysis. The endogenous control used was β-actin. Both $**p < 0.01$ and $***p < 0.001$, respectively, compare DTmiAnp-cRGD-30a mm to DTmiAnp-30a mm and free miRNA-30a mimic.³³ Reproduced with permission. Copyright 2021 Elsevier B.V.

which is a key aspect contributing to renal fibrosis in UUO,⁶⁸ and the results of this study may provide a new paradigm for targeted treatment of fibrotic diseases.

4.2.2 Delivery of peptide-based therapeutics. Peptides are molecules consisting of amino acids as the basic unit, with molecular weights generally below 10 kDa, and are widely used in the treatment of a variety of diseases such as diabetes, tumours, chronic pain, and multiple sclerosis. A variety of peptides have been found to have important effects on renal fibrosis, including transforming growth factor-β (TGF-β), bone morphogenetic protein 7 (BMP-7), connective tissue growth factor (CTGF), interleukin 1 (IL-10), *etc.*⁶⁹ Due to the inherent lack of targeting of peptides, high doses or multiple administrations are often required to achieve therapeutic efficacy. High doses may cause immunological side effects. Therefore, peptide-based antirenal fibrosis therapeutics are often investigated in combination with drug delivery technologies.

TGF-β is a multifunctional cytokine that serves an important part in the pathogenesis of several diseases related to renal, leading to renal fibrosis.⁷⁰ TGF-β activates renal tubular epithelial cells, leading to their alteration into fibroblasts

via epithelial-mesenchymal transdifferentiation,⁷¹ and ultimately the conversion of fibroblasts into myofibroblasts and construction of extracellular matrix (ECM) proteins.⁷² Prakash *et al.*³⁵ developed a renal drug delivery system that inhibits TGF-β receptors (TKI-LZM). The system consists of an inhibitor integrated into renal carrier protein lysozyme (LZM), which targets the TGF-β kinase inhibitor to renal tubular cells and provides sustained delivery of the active substance in the target cells over several days. TKI-LZM accumulated rapidly in renal tubular cells within 1 h after intravitreal injection and no accumulation was observed in the heart, spleen, and lungs. The degradation half-life of TKI-LZM conjugate in the kidney was about 37.7 h. The degradation of TKI-LZM was also observed in the kidneys, and the degradation of the TKI-LZM conjugate in the kidneys was also observed in the heart and spleen. Following binding to its type-II receptor, TGF-β interacts to another type-I receptor called activin receptor-like kinase-5 (ALK5).⁷³ By controlling the deposition of the extracellular matrix, ALK5 triggers downstream signaling cascades, and therefore contributes to the establishment of renal fibrosis.⁷⁴

Fig. 6 Therapeutic mechanism of CTLA-4-Ig in DN model rats.³⁴ Reproduced with permission. Copyright 2021 Wang *et al.*

Vascular endothelial growth factor (VEGF) is a pro-angiogenic cytokine that plays a crucial role in neovascularisation, healing, and conservation of the MV matrix throughout the body. The bioavailability of the VEGF is reduced in stenotic kidneys with renal vascular disease.⁷⁵ In a model of progressive renal failure, VEGF treatment improves kidney injury and protects renal microcirculation.⁷⁶ Guise *et al.*³⁶ developed a bioengineered fusion of drug delivery carriers with renal targeting. Adjuvant targeted administration of ELP-VEGF enhances the effectiveness of plastic and stenting in renovascular disease (RVD), and has a better therapeutic effect on renal injury such as renal fibrosis.

Self-assembling peptides (SAPs) are designer biomaterials readily available from naturally occurring amino acids that instinctively form cross-linked nanofibers, and are transformed into nanoscale hydrogels.^{77,78} Liu *et al.*³⁷ reported the hepatocyte growth factor (HGF) and the TNF- α neutralizing antibody (anti-TNF- α) co-delivered using an injectable, self-assembling peptide/heparin (SAP/Hep) hydrogel (Fig. 8). KLD 2 R/Hep hydrogels are only 10–20 nm in diameter and sequentially release the drug and accumulate in the kidneys after injection into the body. Animal studies have shown that SAP-drug hydrogels are more effective in lowering apoptosis and inflammation, enhancing tubular regeneration and renal function, and thus reducing chronic fibrosis after ischemia-reperfusion I/R hurt, compared to SAPs or free drugs.

The development of both acute and chronic renal illness has been linked to inflammatory agents, which are now recognized as important pathogenic molecules, yet interleukin-10 (IL-10) deficiency in damaged kidneys affects its anti-inflammatory effects. To address this issue, Gong *et al.*³⁸ developed a platelet (PLT)-activated IL-10 (IL-10@PLT), which was experimentally demonstrated to target IL-10@PLT to concentrate in the renal tubules of damaged kidneys, reduce inflammatory response,

improve renal function, and ameliorate renal fibrosis during the recovery phase of UUO treatment.

4.3 Pharmacotherapy

Current drugs for the treatment of renal fibrosis mainly alleviate renal fibrosis with multi-targets and numerous pathway trails. Among them, angiotensin-converting enzyme inhibitors and glucocorticoids are the main drugs for treating renal diseases, but these drugs generally lack targeting and adverse effects that vary with dosage limiting their clinical application to a large extent. Enhancing the renal targeting of chemical drugs through drug delivery techniques is expected to reduce toxic side effects and improve the therapeutic effect on renal fibrosis.

Exosomes and microvesicles are examples of extracellular vesicles (EVs), which are membrane particles generated from host cells and have an inherent means of intercellular communication.^{79–81} EVs can serve as effective carriers for drugs, RNA drugs and anti-inflammatory agents.^{82–84} Tang *et al.*³⁹ used RAW 264.7 macrophage cell-derived MVs as a vehicle for targeted delivery of dexamethasone (DEX) to inflamed kidneys (Fig. 9). The emulsive dosages of MV-DEX considerably reduced renal injury in murine models of LPS- or ADR-induced nephropathy, with improved therapeutic efficacy against renal inflammation and fibrosis, when compared to free DEX treatment. More importantly, the delivery of DEX in MV expressively abridged the consequences of long-term glucocorticoid treatment.

Liposomes are tiny lipid vesicles, usually encapsulated by one or more lipid layers, employed to deliver drugs or other active ingredients. Liposomes can improve drug solubility, stability, and to some extent targeting. Cheng *et al.*⁴⁰ created lipid-coated poly(lactic-co-glycolic acid) nanoparticles with sorafenib, a powerful anti-tumor multikinase inhibitor, encapsulated in the core and fibrotic kidney homing peptides on the

Fig. 7 Renal fibrosis caused by unilateral ureteral obstruction (UUO) is lessened by R-III. (A) PAS and MT were used to stain kidney sections from sham, UUO, and UUO + R-III-treated animals. The semiquantitative score for tubulointerstitial fibrosis is displayed in the right panel. (B) TGF- β 1, PAI-1, collagen type I and type IV, and kidney sections from sham, UUO, and UUO + R-III-treated mice were immunohistochemically examined. Each research group's representative photographs are displayed. The staining intensity semiquantitative analysis for each group is displayed (right). The data are shown as means \pm SD (p -value; Kruskal–Wallis test, then DSCF multiple comparison test). * p < 0.05, ** p < 0.01, and *** p < 0.001.⁶⁶ Reproduced with permission. NPs in reaching UUO-induced fibrotic kidneys, and significantly ameliorated the progression of renal fibrosis when given intravenously to mice suffering from UUO-induced renal fibrosis. In addition, Zhou *et al.*⁴¹ coated a phospholipid bilayer on the surface of PLGA-NPs to create a liposome-nanoparticle hybrid (PLGA-LNH). Afterwards, PLGA-LNH was co-modified with PEG and $\alpha 8$ integrin antibodies to create PLGA immunoliposomes (PLGA-ILs). The loading of dexamethasone (DXMS) and captopril (CAP) resulted in the DXMS/CAP@ PLGA-IL nanoparticles. The prepared nanoparticles contained a core-shell design with a uniform and suitable size (119.1 ± 2.31 nm), $10.22 \pm 1.00\%$ for DXMS and $6.37 \pm 0.25\%$ for CAP. The DXMS/CAP@ PLGA-IL possesses low cytotoxicity and good tethered cell entry capacity for successful aggregation in the glomerular MC zone. *In vivo* pharmacodynamic studies showed that DXMS/CAP@PLGA-ILs were effective in ameliorating pathological changes in the glomerular tunica albuginea region and positive expression of glomerular proliferating cell nuclear antigen (PCNA), decreasing the manifestation of factors that cause inflammation, fibrosis, and reactive oxygen species (ROS). Other researchers have used hydrogels, virus-mimetic nanoparticles, *etc.* loaded with chemical drugs to obtain better renal delivery capacity and renal fibrosis treatment.^{42,43}

4.4 Herbally active compound therapy

4.4.1 Delivery of quinone-based therapeutics. Unsaturated cyclic diketones with *p*- or *o*-benzoquinone structures are known as quinone compounds. Medical researchers have focused a lot of attention on the use of quinones, particularly anthraquinones, in antifibrotic therapy. Emodin (EMO) is a common anthraquinone compound with antifibrotic effects in a variety of organs, particularly on renal cell proliferation, apoptosis, and phenotypic change. Emodin reduces TGF- $\beta 1$ and SMAD-specific E3 ubiquitin protein ligase 2 (Smurf 2)

levels to enhance renal function and prevent renal fibrosis,⁸⁵ inhibiting the proliferation of renal fibroblasts and decreasing the levels of fibronectin (FN), collagen I, and Smad 2/3 protein and gene expression.⁸⁶ The EMO has low oral bioavailability and is acutely toxic in overdose. Precise delivery of EMO to the kidney is expected to further enhance the antirenal fibrosis effect. Huang *et al.* have prepared an emodin self-microemulsifying drug delivery system (SMEDDS).⁸⁷ The particle size of SMEDDS was only $\sim 18.31 \pm 0.12$ nm, and it was demonstrated by *in vivo* experiments. The self-microemulsifying drug delivery system could enhance the oral bioavailability and cellular uptake of emodin. Specifically, when mice are orally administered SMEDDS, the spontaneously formed emulsion of the self-microemulsifying drug delivery system dissolves the drug in the gastrointestinal tract and accelerates absorption. In addition, self-microemulsifying formulations may enhance oral bioavailability by promoting lymphatic absorption. Ultimately, digestion products are preferentially prepared and ultimately secreted into the mesenteric lymph to promote absorption. The SMEDDS protects the kidneys by decreasing the expression of FN, TGF- $\beta 1$, and ICAM-1 in the cells in which they are present (Fig. 10).

Tanshinone IIA (Tan IIA) is a component of Danshen. By blocking the activity of glycogen synthase kinase (GSK) 3 β , fibroblast recruitment, and tubular epithelial cell fibrosis, Tan IIA reduces renal fibrosis.⁸⁸ Tan IIA may act as an antirenal fibrosis agent along with emodin; nevertheless, inadequate oral absorption, unforeseen drug-drug interactions, and their potential to modify individual pharmacokinetic profiles when combined significantly restrict their utilization. To alleviate these limitations, Sun *et al.*⁴⁴ devised a novel nanomicrosystem-based co-delivery method by embedding Tan IIA-loaded nanoparticles (Tan IIA-NPs) into EMO-containing microcapsules with cell-penetrating peptides (CPPs) and polyethylene glycol (PEG)

Fig. 10 SMEDDS loaded with emodin reduced the expression of FN, TGF-β1, and ICAM-1 in GMCs and NRK-52E cells treated with AGEs. For twenty-four hours, AGEs were used to activate GMCs and NRK-52E cells in the presence or absence of crude emodin (Crude) or SMEDDS. (A) Impact of crude emodin (Crude) and SMEDDS at the same 2 μMEMO (emodin) concentration on FN, TGF-β1, and ICAM-1 expression in GMCs; excipients served as the solvent control. (B) How SMEDDS containing 0.1, 1, 3, and 10 μMEMO affects the expression of TGF-β1, ICAM-1, and FN in GMCs. (C) Impacts of crude emodin (Crude) with 10, 20 μMEMO and SMEDDS with 1 μMEMO on GMC expression of FN, TGF-β1, and ICAM-1. (D) Impact of crude emodin (Crude) and SMEDDS at the same 2 μMEMO(emodin) concentration on FN, TGF-β1, and ICAM-1 expression in NRK-52E cells; excipients served as the solvent control. **P* 0.05, ****P* 0.001 versus control, #*P* 0.05, ##*P* 0.01, ###*P* 0.001 versus AGEs, Compared to crude emodin, ^S*P* 0.05 and ^{SSS}*P* 0.001.⁸⁷ Reproduced with permission. Copyright 2016 Elsevier B.V.

modifications to obtain CPP/PEG-NPs (Fig. 11). This nanomicrosystem exhibited significant sequential drug release. In addition, *in vivo* tests showed that Tan IIA and EMO had improved oral bioavailability and possessed noteworthy therapeutic effects in UUO rats.

All traditional Chinese medicine uses rhine, a lipophilic anthraquinone molecule, as the primary absorbable anthraquinone derivative that enters the bloodstream following the oral treatment. Through a mechanism that inhibits the toll-like receptor 4 (TLR 4) and TGF-β1 release in the kidneys, rhine dramatically improves glomerular disease and tubule interstitial fibrosis. However, clinical administration of Rhine is restricted by adverse effects, low bioavailability, poor solubility, and decreased transport into the kidneys. Chen *et al.*⁴⁵ produced polyethyleneglycol-*co*-polycaprolactone-*co*-polyethylenimine triblock amphiphilic polymers to create RH-loaded PPP-RH-NPs. PPP-RH-NPs were about 80 nm in size with a zeta potential of 10 mV. The most popular and well-researched

gene transfer carrier is polyethylenimine (PEI). It demonstrates renal dispersion for gene delivery to some extent and includes 15–20% protonatable amine groups under physiological conditions. In the streptozotocin (STZ)-induced DN model, PPP-RH-NPs displayed upright renal dispersal and exhibited improved renal function, and antirenal fibrosis effects.

4.4.2 Delivery of terpene-based therapeutics. With an isoprene unit (C₅ unit) serving as the fundamental structural unit of the molecular skeleton, terpenoids are substances and their derivatives that are generated from mevalonate. Terpenoids exhibit a variety of health impacts, including antitumour,⁸⁹ anti-inflammatory,⁹⁰ antibacterial,⁹¹ and antifibrotic activities.⁹² The role of terpenoids in antirenal fibrosis has gradually attracted the attention of researchers. Therapeutic strategies based on the delivery of terpenoids using drug-delivery technologies have also received attention.

Celastrol (CLT) is a naturally occurring chemical that was isolated from *Tripterygium wilfordii*. Because of its potent

Fig. 11 Schematic illustration of hierarchically organized microcapsules.⁴⁴ Reproduced with permission. Copyright 2022 Elsevier B.V.

anti-inflammatory and antiproliferation properties, Celastrol was chosen as a model therapy for patients with RIF. Qin *et al.*⁴⁶ developed a topical drug delivery platform with controlled-release and long-acting characteristics *via* injectable hydrogels cross-linked by self-assembled triblock polymer micelles and piggy-backed with CLT, which enables long-term release of CLT at the renal site. Gypenosides (Gyp) are a class of dammarane type saponins extracted from five-leafed gynostemma. Among them, Gyp XLIX is one of the most active components, with anti-inflammatory,⁹³ anticancer,⁹⁴ and anti-hepatic fibrosis effects.⁹⁵ Studies related to the use of Gyp in the treatment of renal diseases have been continuously reported,^{96,97} but direct administration of Gyp XLIX is not ideal due to its low solubility and bioavailability, high molecular weight, and significant barriers to absorption in the body. To solve the problems related to limiting the clinical application of Gyp XLIX, Liu *et al.*⁴⁷ obtained PLGA-Gyp XLIX nanoparticles using a poly(lactic acid)-glucoside copolymer (PLGA) loaded with Gyp XLIX. The PLGA-Gyp XLIX nanoparticles possessed a particle size of ~ 120 nm and could be targeted to UUO kidneys. In contrast to Gyp XLIX, the PLGA-Gyp XLIX nanoparticles can lessen tubular necrosis, decrease collagen deposition, and limit renal fibrosis (Fig. 12).

4.4.3 Delivery of alkaloid-based therapeutic agents. A class of simple chemical molecules called alkaloids is extensively distributed throughout nature. The majority of alkaloids have nitrogen rings arranged in complicated ring configurations. Because of their anti-inflammatory properties, alkaloids have great antagonistic effects on organ fibrosis. Recently, flavonoids were extensively employed in the treatment of RF, especially in the treatment of DN. Studies have shown that other alkaloids, such as picloram, berberine, *etc.*, also have anti-renal fibre effects.^{98,99}

By inhibiting NF- κ B activation, dampening the Notch/Snail pathway, upregulating Nrf2 signaling, downregulating

the TGF- β /Smad/EMT pathway, reducing α -SMA levels, boosting E-cadherin levels, and inhibiting RhoA/ROCK, berberine prevents ECM buildup and lowers RF.^{100–103} Because of P-glycoprotein-mediated drug efflux and first-pass effects, BBR has a very limited oral bioavailability. To address this issue, Xiong *et al.*⁴⁸ developed a Brij-grafted-chitosan (BC) nanocarrier technology to improve oral bioavailability of berberine, and therapeutic efficacy in diabetic nephropathy. The BBR-BC 12-NP was spherical in shape and had a size of 102.0 ± 0.7 nm. The comparative oral bioavailability (FRel) of the BBR-BC 12-NP was demonstrated by *in vivo* experiments. The relative oral bioavailability (FRel) of BBR was determined to be 440.8% (Fig. 13). In a STZ-induced diabetic rat model, BBR-BC 12-NP was efficiently distributed in the renal fraction and exerted therapeutic effects.

4.5 Other antirenal fibrosis drug delivery systems

Metal ions provide important functions in biological systems such as regulation of electrolyte balance, oxygen transport, electron transfer, catalysis, *etc.* Many transition metal ions (Mn, Fe, Cu, Co, *etc.*) are involved in many redox reactions in the body due to their variable and physiologically accessible oxidation states. Metal nanoparticles are often made to give full play to the therapeutic effect of metal ions *in vivo* and are widely used in anticancer, anti-microbial, imaging, diagnostic and other applications. Therapies based on metal nanoparticles have also been proposed such as photothermal therapy,¹⁰⁴ chemodynamic therapy,¹⁰⁵ photodynamic therapy,¹⁰⁶ and ultrasound-dynamic therapy.¹⁰⁷ In recent years, the strategy of using metal nanoparticles against renal fibrosis has been continuously proposed by numerous researchers.

Cobalt chloride is one of the utmost extensively employed hypoxia inducible-factor activators in biomedicine, and HIF activators protect the kidneys by ameliorating renal hypoxia in

Fig. 12 Mouse UUO kidney is the target of PLGA-DiR NPs. (A) The fluorescence signal image of the primary organs removed from UUO mice (heart, liver, spleen, lung, and kidneys) at 0, 3, and 7 days following surgery when PLGA-DiR and Free DiR were administered. (B) The average intensity of fluorescence for every organ in (A). For six to eight separate mouse experiments, the data show the mean \pm S.D. Comparing the fibrotic kidney to the contralateral kidney, $***P < 0.001$ was found. $###P$ is less than 0.001. Comparison between PLGA-DiR and Free DiR. PLGA-DiR refers to PLGA nanoparticles loaded with DiR.⁴⁷ Reproduced with permission. Copyright 2021 Elsevier B.V.

chronic kidney disease. Unfortunately, unfavorable side effects and limited renal targeting of cobalt chloride severely restrict its therapeutic uses. Cobalt nanomaterials possessed numerous advantages of low preparation cost, low toxicity, high photo-thermal conversion ability, and high drug-carrying capacity. They have been proved to have a promising application in anticancer and anti-infection therapy. Li *et al.*⁴⁹ designed *N*-acetylated-thiolated chitosan cobalt (NTCC) nanocomposites. Cobalt will be liberated from biomaterials in acidic environments, whereas NTCC has exceptional stability in typical physiological circumstances. The NTCC showed a particle size of about 50–100 nm. Upon injection of NTCC into the UUO mouse model, the NTCC targets and accumulates in the kidneys, where it is released within 8 h. Compared with cobalt chloride particles, NTCC had a significant antirenal fibrosis effect.

Excellent biocompatibility, simplicity of surface modification, tunable features, and several uses of Au nanoparticles (AuNPs) in drug delivery, animal and cell imaging, and disease treatment have generated a lot of interest. However, Au nanoparticles have

low drug-carrying ability, and poor capability to embed drugs. Providentially, the Au nano-assemblies with greater surface areas and self-assembly possessions were able to address the challenges of Au nanoparticles. Tan *et al.*⁵⁰ demonstrated novel stimuli-responsive drug release nanoplat-forms. The nanoplat-forms involved the self-assembly of GLAuNPs (glutathione-modified Au nanoparticles) and Co²⁺ into nano-assemblies (GLAuNPs-Co) through coordinated interactions among empty orbitals and lone pair glutathione. GLAuNPs exhibited high drug loading capacity upon assembly with Co²⁺ and triggered drug release in renal fibrotic tissues. Furthermore, the cytotoxicity of Co²⁺ in renal tubular cells was significantly decreased by Co²⁺ ions enclosed in GLAuNPs. Histofluorescence imaging revealed that the kidneys, and particularly the proximal tubules, were the site of a specific accumulation of GLAuNPs-Co.

Elemental Zn plays important roles in biological processes, such as a catalytic cofactor, in immune responses, and as a structural functionality of many proteins. Studies have shown that a high prevalence of diabetes and progressive DN have

Fig. 13 Pictorial representation of BBR-BC-NPs improving the intestinal absorption of berberine (BBR) via transiently and reversibly adjusting the intercellular tight junctions and Pgp-mediated drug efflux.⁴⁸ Reproduced with permission. Copyright 2021 Elsevier Ltd.

been linked to systemic zinc deficiency.^{108–110} In addition, the TGF- β /Smad 2/3 pathway activates renal interstitial fibroblasts.¹¹¹ Alomari *et al.*⁵¹ studied the therapeutic consequence of zinc oxide nanostructures on STZ-induced DN rats. The results showed that ZnONPs ameliorated renal injury by ameliorating

podocyte damage, oxidative stress, inflammation, and aberrant angiogenesis, as well as by enhancing renal function. The experimental DN rat model is more effectively utilized (Fig. 14). This demonstrated that ZnONP nanoparticles were operative in ameliorating the development of renal fibrosis.

5 Summary and outlook

Drug delivery technologies can effectively deliver antifibrotic therapeutics to the kidneys, which not only enhances therapeutic efficacy, but more importantly reduces the total dose and mitigates toxic side effects. Currently, NP-based delivery systems that overcome barriers to enter into the kidneys have been extensively studied, such as self-assembling micelles, polyethyleneimine nanoparticles, liposome–nanoparticle hybrids, *etc.* Numerous studies have shown that nanoparticles can effectively piggyback on antifibrotic therapeutics and target the injured kidneys. Through nanomaterial drug delivery strategies, it is possible to concentrate RNA, TGF- β , *etc.* in the kidneys. Thus, they can act on organ-specific targets. For chemical drugs, drug delivery technology can not only target them to damaged kidneys but also reduce toxic side effects and provide therapeutic effects. In addition, drug delivery technology has even enhanced the use of herbal extracts for the treatment of renal fiber. Due to poor bioavailability, toxic side effects, and other disadvantages of some Chinese medicine extracts, it is difficult to achieve anti-renal fibrosis effects by direct use. However, through drug delivery technology, they can efficiently and safely reach the target site and exert their effect. These studies bring new hope to overcome the challenges of renal fibrosis treatment, but more relevant studies for overcoming some challenges are still needed.

The first is that the safety of drug delivery vehicles cannot be fully convincing. In many experiments, the biotoxicity of nanomaterials was observed only for a short period after they were injected or orally administered into a mouse model. There were fewer studies on whether prolonged use triggered the accumulation of toxicity. Secondly, the degradation and metabolism of many nanotherapeutic agents after entering the body have not been described. Moreover, now that the study population is almost exclusively mice with damaged kidneys, elucidating the distinctions between the experimental models of animals and humans with healthy and diseased kidney states may result in a more reliable transition from preclinical to clinical research. Understanding pharmacokinetic characteristics, biodistribution, and potential immunogenicity has become crucial, as has the biosafety of various nanomaterials for clinical usage. Currently, there are still drug delivery strategies whose mechanisms have not been clarified, especially nano-formulations based on active ingredients of herbal medicines. Even though it is well acknowledged that botanical substances are effective in treating RF, there are no standard diagnostic or therapeutic criteria, and the mechanisms of action of several natural compounds are unclear or inconclusive. Natural remedies do not work as quickly as western medications, and their clinical applications. The safety of nano formulations based on metal ions is difficult to be extensively recognized due to the possibility of triggering problems such as metal accumulation.

In conclusion, using a nanoscale therapeutic delivery system is a new approach to renal fibrosis treatment that effectively controls drug release, enhances targeting and improves therapeutic efficacy. Future research on drug delivery for the

treatment of renal fibrosis should focus on the drug loading capacity, targeting function, biocompatibility, and pharmacokinetics of drug delivery systems. When the shortcomings and challenges of nanoscale therapeutic delivery systems are overcome one by one, it is believed that they can shine in the clinical renal fibrosis treatment.
