21 **Broader Context (no more than 200 words)**

22 Metal halide perovskite solar cells are presently attracting immense interest due to the rapid rise

23 of their solar to electric power conversion efficiency from 3.8% to over 25.5% within the past

24 decade. The latest improvements have been achieved by compositional engineering.

25 Methylammonium iodide (MAI)-free perovskites are promising for their high stability compared

26 to those containing MAI, however, there is very little understanding on the role of phases and

27 structures on all properties of the materials and devices. Here we present a systematic study of the

28 compositional space of tunable formamidinium/cesium and iodide/bromide perovskites.

29 Employing advanced X-ray scattering techniques with grazing incidence we elucidate the type of

30 structures forming on the perovskites with 49 different compositions. Our findings give new sights

31 for MAI-free materials towards understanding the mechanisms that make these perovskites

32 efficient light harvesters and optimized compositions in perovskite solar cells towards long-term

33 durability.

34

Abstract

One of the organic components in the perovskite photo-absorber, the methylammonium cation, has been suggested to be a roadblock to long-term operation of organic-inorganic hybrid perovskite-based solar cells. In this work we systematically explore the crystallographic and optical properties of the compositional space of mixed cation and mixed halide lead perovskites, where formamidinium (FA^+) is gradually replaced by cesium (Cs^+), and iodide (I^-) is substituted by bromide (Br^-), i.e., $Cs_yFA_{1-y}Pb(Br_xI_{1-x})_3$. Higher tolerance factors lead to more cubic structures, whereas lower tolerance factors lead to more orthorhombic. We find that while some correlation exists between tolerance factor and structure, tolerance factor does not provide a holistic understanding of whether a perovskite structure will fully form. By screening 26 solar cells with different compositions, our results show that $Cs_{1/6}FA_{5/6}PbI_3$ delivers the highest efficiency and long-term stability among I-rich compositions. This work sheds light on the fundamental structure-property relationships in the $Cs_yFA_{1-y}Pb(Br_xI_{1-x})_3$ compositional space, providing vital insight to the design of durable perovskite materials. Our approach provides a library of structural and optoelectronic information of this compositional space.

Keywords: perovskite, methylammonium-free, compositional engineering

Introduction

Since they were first reported in 2009 with a power conversion efficiency (PCE) of 3.8% [1], organic-inorganic hybrid perovskites have witnessed an unprecedented efficiency progress over a decade, resulting in the most recent highest certified PCE of 25.5% [2], which is approaching the 33.7% Shockley-Queisser (SQ) limit of single-junction solar cells [3]. The large number of constituents that can be fit into the ABX_3 crystal formula provides a relatively broad material space to be explored, where A is a monovalent cation (methylammonium — MA^+, formamidinium — FA^+, or cesium — Cs^+) [4,5], B is a divalent metal cation (typically Pb^{2+} or Sn^{2+}) [6], and X is a halogen anion (Cl^-, Br^- or I^-) [7]. Due to the tunability of its composition and bandgap, lead halide perovskites carry promise as the top wide-gap absorbers in silicon tandem solar cells or to be assembled into pure perovskite tandem cells, enabling higher efficiencies and bypassing the theoretical efficiency limit on single-junction solar cells. In addition, these lead halide perovskite materials allow for a range of versatile processing methods and a variety of cell structures [5], making halide perovskites a major competitor for low-cost solar energy conversion whether as stand-alone cells or as top cells in tandem structure [7–10]. Thus, understanding the relation between compositional variations and changes in crystal structure and bandgap becomes paramount for the design of optimum materials for different applications.

Despite the success of perovskite solar cells (PSCs) in laboratory research, the most pressing issue to be solved before commercialization is long-term stability, which is limited by a variety of factors, including chemical decomposition, phase transitions, or phase segregation. The extensively studied $MAPbI_3$ undergoes a phase transition above 57℃, and decomposes into PbI_2 even in an inert atmosphere at 85℃ owing to degassing MA^+ [11]. Mixed I/Br perovskites $MAPb(Br_xI_{1-x})_3$ that enable wider bandgaps are prone to phase segregation into iodide-rich and bromide-rich domains under illumination [12,13]. In addition, mixed-halide perovskite compositions are prone to the formation of halide vacancies, which introduce sub-bandgap energy levels [14] that act as trap states fostering non-radiative recombination, limiting the open-circuit voltage (V_{oc}) of the PSCs, and affecting the device photostability [13,15,16].

FAPbI$_3$ and CsPbI$_3$ have higher thermal-decomposition temperatures with respect to $MAPbI_3$, and have emerged as compelling candidates for the commercialization of long-term operating devices [17,18]. FAPbI$_3$ has an optical bandgap of 1.48 eV [19], closer to the theoretically optimal bandgap 1.34 eV [3] for a single-junction solar cell than the 1.58 eV of $MAPbI_3$ [19,20]. CsPbI$_3$

84   is promising for application in tandems and for its inorganic nature, which allows it to tolerate high

85   temperatures without decomposition. Cs^+ has a considerably smaller radius (1.67 Å) than MA^+

86   (2.17 Å) and FA^+ (2.53 Å) [21,22], which results in a bandgap widened to 1.73eV for $CsPbI_3$ [19,23].

87   However, the black perovskite phases α-$FAPbI_3$ or α-$CsPbI_3$, which are suitable for efficient

88   photon absorption and electron transport, are prone to structural instability, spontaneously

89   converting into the undesirable non-photoactive yellow δ-phase in the ambient atmosphere [24–26].

90   Therefore, the main challenge on $FAPbI_3$ and $CsPbI_3$-based solar cells is to stabilize the black α-

91   phase at room temperature.

92   To boost thermal and structural stabilities, as well as to inhibit halide segregation, it has

93   been shown that mixing A-site cations in compositional engineering is essential [4,24,27]. Introducing

94   small amounts of MA^+ in FA^+-based compositions enables suppressing the formation of the yellow

95   δ-$FAPbI_3$ component due to stronger interaction via H…I–H (hydrogen bonding) or Coulomb

96   interaction between the more polar MA^+ and the PbI_6 octahedral cage [28], while enabling high PCEs

97   [7,24,29]. For mixed-cations with Cs^+ and MA^+, Niu et al. found a small addition of Cs^+ was

98   responsible for inducing oriented polycrystalline films, leading to reduced series resistance and

99   suppressing the formation of trap states, thus enhancing the PCE [30]. Introducing the small inorganic

100   cation Cs^+ in FA-based compositions has been shown to adjust the strain in the structure to stabilize

101   the α-$FAPbI_3$ [26]. The mixed-cation Cs^+/FA^+ perovskite showed an α phase even at room

102   temperature, which is in contrast to pure $FAPbI_3$ (165°C) and $CsPbI_3$ (315°C), as well as excellent

103   phase stability at high temperature or humidity conditions [8,26,31,32]. The obtained perovskite α-

104   phase with FA^+ and Cs^+ is entropically stabilized, stemming from the α-phase of $CsPbI_3$ and

105   $FAPbI_3$, which have similar structural features (corner-sharing PbI_6 octahedra) and volume [33].

106   Furthermore, mixed-cation Cs^+/FA^+ has been shown to lower the ionic mobility and suppress

107   halide segregation, in contrast to $MAPb(Br_xI_{1-x})_3$ [13] and $FAPbI_yBr_{3-y}$ [19,34], by enhanced crystallinity

108   to restrain the regions of short-range crystalline order, thus improving the compositional

109   photostability and V_{oc} [7–9,27]. Therefore, mixed-cation Cs^+/FA^+, i.e., MA-free composition, is highly

110   desired for the long-term operation.

111   Almost all high efficiency and phase-stable PSCs are fabricated by simultaneously

112   integrating mixed A-site cations with mixed X-site halogens [4,5,24,35,36]. However, the fundamental

113   understanding of the relation between composition variations and the structural and optoelectronic

114   properties have not been fully revealed in the $Cs_yFA_{1-y}Pb(Br_xI_{1-x})_3$ compositional space. This work

115 systematically explores the compositional space of the $Cs_yFA_{1-y}Pb(Br_xI_{1-x})_3$ perovskites by

116 simultaneously and independently changing the Cs^+/FA^+ and Br^-/I^- ratios. Our investigation

117 highlights the structure-property relationships in the $Cs_yFA_{1-y}Pb(Br_xI_{1-x})_3$ compositional space by

118 exploring optical and crystallographic properties through high throughput synthesis and

119 characterization. An empirical equation for $Cs_yFA_{1-y}Pb(Br_xI_{1-x})_3$ bandgap as a function of

120 composition is quantitatively determined, which contributes to tailor bandgaps suitable for single-

121 junction and tandem applications. The crystal structure and phases in the $Cs_yFA_{1-y}Pb(Br_xI_{1-x})_3$

122 compositional space are identified qualitatively based on the results from synchrotron-based

123 grazing incidence wide-angle X-ray scattering (GIWAXS). We find that tetragonal, cubic, and

124 unidentified structures can be synthesized with slight compositional changes of I-rich Cs_yFA_{1-}

125 $_yPb(Br_xI_{1-x})_3$ perovskites, and resulting in small effects to their electronic response in solar cells.

126 A tetragonal structure is majority FA and I-based yielded the highest performance, regardless of

127 annealing temperature (65°C and 150°C). The work illustrates the importance of the precise

128 composition of the perovskite for making devices with high performance and durability, and will

129 help to extend the compositional design of novel MA-free perovskite for various optoelectronic

130 applications.

131 **Results and Discussion**

132 A graphical illustration of the $Cs_yFA_{1-y}Pb(Br_xI_{1-x})_3$ composition space explored in this

133 work is shown in Fig. 1A. A full set of 49 perovskite compositions with varying ratios of Cs^+/FA^+

134 and Br^-/I^- was deposited via solution processing. The 49 films were prepared by combining

135 perovskite stock solutions in the appropriate molar ratio to obtain the desired $Cs_yFA_{1-y}Pb(Br_xI_{1-x})_3$

136 final composition. Four 0.4 M master solutions were prepared (i.e., $CsPbI_3$, $FAPbI_3$, $CsPbBr_3$, and

137 $FAPbBr_3$) in dimethyl sulfoxide (DMSO). The perovskite solution stoichiometries are correlated

138 with the respective sample numbers in Fig. 1A. A mild annealing temperature of 65°C was selected

139 to retain the perovskite phase of the Cs-rich films (Fig. S1) [9]. The annealing at 65°C is too low to

140 crystallize the perovskite phase in FA-only films (especially No.43-No.46), which, however, have

141 been studied extensively in previous reports [19,29]. The 49 perovskite films present markedly

142 different colors across the matrix of variations, as illustrated in a photograph in Fig.1B. I-rich films

143 are generally dark brown and Br-rich films are progressively more orange, then turning to yellow,

144 with increasing bromide content. The $FAPbI_3$ film does not show the dark brown color expected

145 for the α phase, as the annealing temperature selected is lower than the phase transition temperature

146   of 160°C [25]. All films (except the pure Cs-based compositions, No.1-No.7) annealed at 170 °C were

147   also prepared and are presented in Fig. S1, and it is important to note that these samples degraded

148   within minutes, and thus we excluded these samples from further characterization. Herein, all

149   characterizations on films are performed on perovskites annealed at 65 °C, except when otherwise

150   specified to ensure all conditions are kept constant in the study.

151

The numbers on the squares represent the key between the perovskite compositions and the corresponding
sample numbers. (B) Photograph of the full set of perovskite films arranged in the same order as in the
composition matrix of (A).

Crystallographic properties

157   Tuning the Goldschmidt tolerance factor (t) through compositional engineering is a

158   practical approach to tailor the crystallographic properties and structural stability of perovskite

159   materials [21,26,29]. The t is a reliable empirical index used to predict the structural phase of a

160   perovskite by evaluating its ionic size mismatch. The expression is $t = \dfrac{r_A + r_X}{\sqrt{2}\,(r_B + r_X)}$, where r_A, r_B

161   and r_X are the radii of the A cation, B cation, and X anion, respectively. Here, it is widely

162   understood that t equals 1 for a perfect cubic perovskite. Values of t in the range 0.9-1.0 mostly

163   result in cubic perovskites at room temperature. The t values between 0.8-0.9 favor distorted

164   corner-sharing octahedra configurations, which result in perovskite structures of lower symmetry

165   than cubic, e.g., orthorhombic or tetragonal [21,26,29]. The t values greater than 1.0, induce a

166   hexagonal non-perovskite structure with face-sharing octahedra. While this is the general

167   understanding in the field, in this study we attempt to explore, experimentally, the relationship

168   between t and different structures. For a composition such as $Cs_yFA_{1-y}Pb(Br_xI_{1-x})_3$, the weighted

169   average at the A- and X-site of the two different ions is used to define an effective ionic radius [26]

170   to compute the tolerance factor.

171    $$r_{X\text{-}effective} = xr_{Br^-} + (1-x)r_{I^-}$$

172    $$r_{A\text{-}effective} = yr_{Cs^+} + (1-y)r_{FA^+}$$

173    $$t_{effective} = \frac{r_{A\text{-}effective} + r_{X\text{-}effective}}{\sqrt{2}\,(r_{Pb^{2+}} + r_{X\text{-}effective})} \tag{1}$$

174   The computed $t_{effective}$ for the different compositions are summarized in Fig.2 assuming $r_{Cs^+}= 1.67$

175   Å, $r_{FA^+} = 2.53$ Å, $r_{Pb^{2+}} = 1.19$ Å, $r_{Br^-} = 1.96$ Å, $r_{I^-} = 2.20$ Å [21,22,37]. The $t_{effective}$ in Fig.2 could thus be

176   used to roughly predict the structure of the different perovskite compositions. The $t_{effective}$ values

177   of 47 of the 49 compositions fall into the range 0.8-1.0 suggesting that these perovskite structures

178   will form corner-sharing octahedra. $FAPbBr_3$ and $FAPbBr_{1/2}I_{5/2}$ have $t_{effective}$ slightly larger than

179   one, however, estimating the ionic radius of the organic FA^+ is complex and prone to errors [38],

180   making these two compositions still promising candidates to process perovskites with cubic

181   structure. Of the other 47 compositions, FA-rich compositions, i.e., No. 24-47, should be prone to

182   form a cubic structure, whereas Cs-rich compositions, i.e., No. 1-23, are likely to form perovskite

183   structures with low crystal symmetry.
184

185   **Fig.2.** Effective tolerance factor map for the $Cs_xFA_{1-x}Pb(Br_yI_{1-y})_3$ compositional space tuned by composition

186   engineering.

187   To reveal the correlation between composition and crystal phase, X-ray diffraction (XRD)
188   and GIWAXS were performed. Perovskite crystals exhibit polymorphism, different crystal phases
189   can thus be formed depending on the free energy of formation, preparation conditions, and
190   temperature. For instance, $CsPbI_3$ has three black photoactive perovskite phases - namely, the α-
191   (cubic), β- (tetragonal), and γ-phases (orthorhombic), and one yellow photoinactive non-
192   perovskite δ-phase (orthorhombic) made of edge-sharing PbI_6 octahedra, as illustrated in Fig. 3A-
193   D. Similar to $CsPbI_3$, $FAPbI_3$ exhibits two main phases: a black cubic perovskite α-phase and a
194   yellow hexagonal non-perovskite δ-phase with face-sharing 1D PbI_6 octahedra (Fig. 3E) [38]. The
195   α-, β-, and γ-phases are all composed of corner-sharing PbI_6 octahedra, but have decreasing crystal
196   symmetry as the distortion of the PbI_6 octahedra increases (Fig. 3A-C). The decrease in symmetry
197   is reflected in peak splitting and the appearance of additional peaks in the XRD pattern (Fig. 3F).
198   As an example, the $(100)_C$ reflection at around $q = 1.0$ Å^{-1} of the α-phase ($Pm\bar{3}m$) in Fig. 3F splits
199   into the $(110)_T$, $(001)_T$ reflections and $(110)_O$, $(002)_O$ reflections in the β-phase ($P\bar{4}mbm$) and γ-
200   phase ($Pbnm$), respectively [39]. Here, the subscript of the crystal plane represents the corresponding
201   crystal phase, i.e., C, T, and O represent cubic, tetragonal and orthorhombic, respectively. It is
202   notable that there is still the same number of splitting peaks when moving from tetragonal to
203   orthorhombic. In addition, the difference in d-spacing among cubic, tetragonal and orthorhombic
204   is usually sufficiently small that the splitting can be difficult to resolve. Hence, it is challenging to
205   identify the crystal phase by means of split peaks, especially for tetragonal and orthorhombic
206   structures. In the β-phase, the $(210)_T$ and $(211)_T$ reflections appear at around $q = 1.6$ Å^{-1}and
207   1.9 Å^{-1}, respectively, (shown in the red area of Fig. 3F), comparing to the α-phase with undistorted
208   PbI_6 octahedra. In the γ-phase with a second distortion in the orthorhombic structure, the crystal
209   symmetry is lower and a new reflections appears around $q = 1.7$ Å^{-1} (shown in the blue area of
210   Fig. 3F), corresponding to the $(211)_O$, $(121)_O$, $(103)_O$ planes. Hence, the characteristic peaks at
211   around $q = 1.6$ Å^{-1} and 1.9 Å^{-1} could be used to distinguish whether the tetragonal phase exists,
212   while the peak around $q = 1.7$ Å^{-1} could be used to identify if an orthorhombic phase is present
213   [40–43].
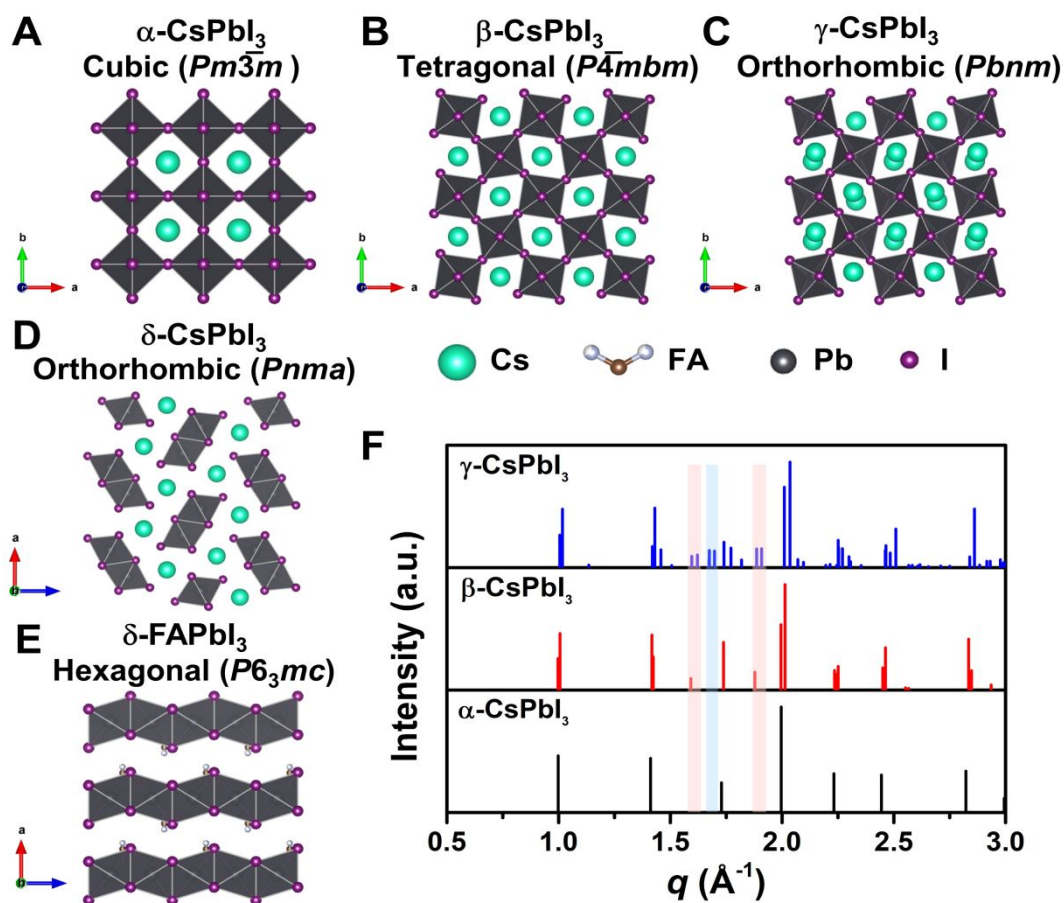

Fig.3. Crystal structure of three perovskite phases with corner-sharing octahedra for $CsPbI_3$, which are cubic α-$CsPbI_3$ (A), tetragonal β-$CsPbI_3$ (B), and orthorhombic γ-$CsPbI_3$ (C). (D) and (E) are crystal structure of non-perovskite δ-$CsPbI_3$ and δ-$FAPbI_3$, respectively. All the crystal structures in A-E were plotted by Vesta by using crystallographic information files extracting from references [25,44,45]. (F) Simulated powder XRD patterns for α-, β-, and γ- phases of $CsPbI_3$ plotted with vertical lines corresponding to the diffraction peaks. XRD patterns plotted with respect to scattering vector q, which is equivalent to $2*\pi/d$ where d is the d-spacing of the diffracting set of planes. The red area shows the positions of the extra XRD peaks discussed in the main text for tetragonal and orthorhombic structures compared with cubic structure. The blue area exhibits the position of the additional XRD peak discussed in the main text for orthorhombic structures compared with cubic and tetragonal structures. XRD pattern was simulated by Vesta.

Since I^- is larger than Br^-, there should be a lattice contraction when Br^- substitutes for I^-, thus giving rise to a smaller d-spacing. Based on Bragg's law, a corresponding shift in XRD peaks towards a larger diffraction angle is expected upon increasing bromine content. A shift towards a larger angle is likewise anticipated as smaller Cs^+ substitutes for FA^+. Such trends are indeed observed in the XRD diffraction patterns shown in Fig. 4. The XRD patterns for all compositions and peak-shifts for all subsets are available in Fig. S2-S3. The XRD peak at 14.0° shifts to a higher

231   angle with increasing Br⁻ content demonstrating the incorporation of Br⁻ in the perovskite lattice

232   (Fig. 4A-B). The XRD peak at 14.8° shifts to higher angle with increasing Cs⁺content reveals that

233   as FA⁺ is replaced with Cs⁺ (Fig. 4C-D). The XRD peak at ~14-15° for the compositions in the

234   matrix usually exhibits single peak, whereas some compositions show split peaks. For instance,

235    $Cs_{2/6}FA_{4/6}PbBr_3$ (No.35) in Fig. 4D shows a split peak at around 15.0°, which may be associated

236   with a decrease in crystal symmetry. In addition, $CsPbBr_{1/2}I_{5/2}$ (No.2) and $Cs_{4/6}FA_{2/6}Pb(Br_xI_{1-x})_3$

237   ($1/2\leq x \leq2$, i.e., No.16-19) also show apparent peak splitting (Fig. S2-S3), related to low crystal

238   symmetry. The films with high bromide content or high cesium content exhibit high texture by

239   having only a few dominant peaks (Fig. 4A and 4C).

240   The crystal symmetries of the four corner compounds (i.e., $CsPbI_3$, $CsPbBr_3$, $FAPbI_3$, and

241    $FAPbBr_3$) were then analyzed to further elucidate which crystal phases form depending on the

242   compositions studied. The as-deposited $CsPbI_3$ film in a nitrogen glovebox was dark brown (Fig.

243   1B), but converts to visible yellow in few minutes once exposed to ambient atmosphere. The XRD

244   pattern of $CsPbI_3$ film in Fig. S4A indicates that $CsPbI_3$ has mixed γ-$CsPbI_3$ perovskite phase and

245   orthorhombic δ-$CsPbI_3$ (*Pnma*) non-perovskite phase since it was measured at ambient condition,

246   in agreement with the reported structures and the metastability of γ-$CsPbI_3$ [25,44,46]. The peaks

247   located at 14.41°, 20.29°, and 28.90° are indexed as the (110), (112) and (220) planes in sequence

248   for the orthorhombic *Pbnm* γ-$CsPbI_3$ phase [44]. The characteristic diffraction peaks at 9.86° and

249   13.06° correspond to the (101) and (102) planes of yellow orthorhombic *Pbnm* δ-$CsPbI_3$ [25]. For

250   the $CsPbBr_3$ film, the two strong peaks at 15.25° and 30.74° in the XRD pattern (Fig. S4B)

251   matched well with the (110) and (220) planes of the standard orthorhombic perovskite structure

252   [9,47,48]. These two strong diffraction peaks dominate the XRD pattern of the $CsPbBr_3$ film,

253   underlining the presence of a high degree of texture. The XRD of the $FAPbI_3$ film (Fig. S4C) is in

254   good agreement with literature data for the hexagonal *P6₃mc* δ-$FAPbI_3$ structure at room

255   temperature and ambient conditions [25]. Likewise, $FAPbBr_3$ (Fig. S4D) exhibits a cubic $Pm\bar{3}m$

256   structure at room temperature that is in line with previous reports [19,29,49].
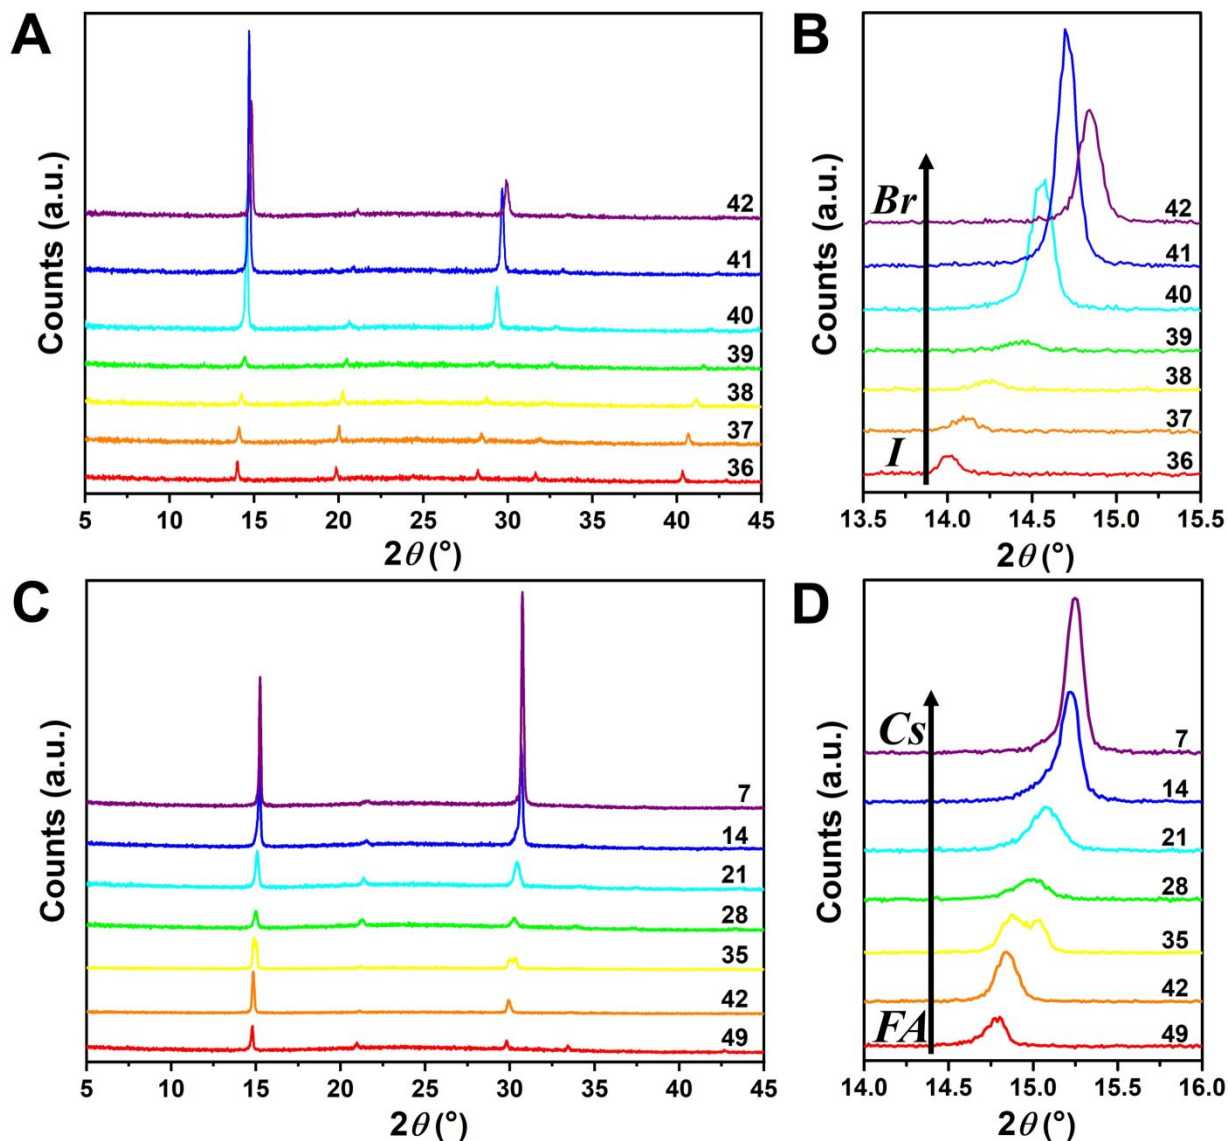

Fig.4. XRD patterns of $Cs_{1/6}FA_{5/6}Pb(Br_xI_{1-x})_3$ films as a function of Br content (A and B) and $Cs_yFA_{1-y}PbBr_3$ as a function of Cs content (C and D). B and D are zoom-ins of the peaks at ~14-15 degree in (A) and (B).

Although the presence of XRD peak splitting could give the information for the decreased crystal symmetry for some compositions, e.g., No.16-19 in $Cs_{4/6}FA_{2/6}PbBr_xI_{1-x}$, the films with high texture only show a few predominant signals, possibly hiding some characteristic peaks and making it hard to distinguish which crystal phases are present in the film. Due to its measurement geometry of grazing-incidence, GIWAXS technique provides signal that is independent from texture effects that can hide real peak signals, and thus it is perfectly suited for the investigation of the crystallographic information of thin films compared to conventional XRD. To better identify which crystal phases are present in the matrix, synchrotron-based GIWAXS was performed. The

268 GIWAXS results for identification of the crystal phase of the four corner compounds (Fig. S5-6)

269 are consistent with the XRD data, except the CsPbI$_3$, which only exhibits δ-CsPbI$_3$ phase due to

270 the phase transition that was induced during the measurements at ambient conditions. The four

271 characteristic peaks with low signal at q = 1.7-2.0 Å^{-1} of CsPbBr$_3$ shown in GIWAXS data (Fig.

272 S5) show that the as-deposited CsPbBr$_3$ is orthorhombic phase [9,47,48] while those subtle signals are

273 hidden in XRD (Fig. 4C) due to the high texture. Therefore, the GIWAXS data was used to

274 qualitatively identify the phase variation in the matrix. As revealed in Fig. 5A, there are two extra

275 peaks that appear for some compositions (i.e., No.36 and No. 40-42) in Cs$_{1/6}$FA$_{5/6}$Pb(Br$_x$I$_{1-x}$)$_3$ at

276 around q = 1.6 Å^{-1} and 1.9 Å^{-1} corresponding to the (210)$_T$ and (211)$_T$ reflections. The data then

277 suggests that composition No.36 and No. 40-42 have a tetragonal symmetry, while composition

278 No.37-39 in Cs$_{1/6}$FA$_{5/6}$Pb(Br$_x$I$_{1-x}$)$_3$ with mixed halide and low bromide content are cubic since

279 those two peaks are absent in their integrated GIWAXS patterns. Here, halide segregation could

280 be excluded because pure-Br Cs$_{1/6}$FA$_{5/6}$PbBr$_3$ (No.42) also has the characteristic peaks for a

281 tetragonal symmetry (Fig. 5a). It is also possible that No.36 and No. 40-42 are a mixture of

282 tetragonal and cubic phases. However, it is challenging to rigorously quantify the amounts of each

283 phase present with established techniques since our samples are thin films. Therefore, here we

284 discuss the lowest crystal symmetry that is present in the GIWAXS data. Furthermore, octahedra

285 tilting and the orthorhombic phase is present in Cs-rich compositions No.2, No.9, and No.16 of

286 Cs$_y$FA$_{1-y}$PbBr$_{1/2}$I$_{5/2}$ as shown by an extra reflection at around q = 1.7 Å^{-1}(Fig. 5B), assigned to

287 three reflections (211)$_O$, (121)$_O$, (103)$_O$. This decreased symmetry is also in accordance with the

288 split peaks observed in XRD and is in line with calculated tolerance factors predicting low

289 symmetry (Fig. 2). There are clear splitting peaks around 14.45° and 29.07° in the XRD pattern of

290 composition No.2 (Fig. S3). Composition No.9 shows the shoulder peaks closely near the high-

291 intensity peaks at 20.45° and 45.51° (Fig. S3). Composition No.16 grows clear splitting peaks

292 around 14.34°, 20.22°, 28.89° and 41.32° (Fig. S3). The full set of GIWAXS patterns could be

293 found in Fig. S5-6. In addition, the trends in GIWAXS are that the peaks will shift to higher q

294 values, which indicate the decreased lattice d-spacing and lattice contraction upon increasing in

295 the bromide content (Fig. 5A) or cesium content (Fig. 5B). This is in line with the observation in

296 XRD data, again corroborating the incorporation of halide and A-site cation into the crystal lattice.

297
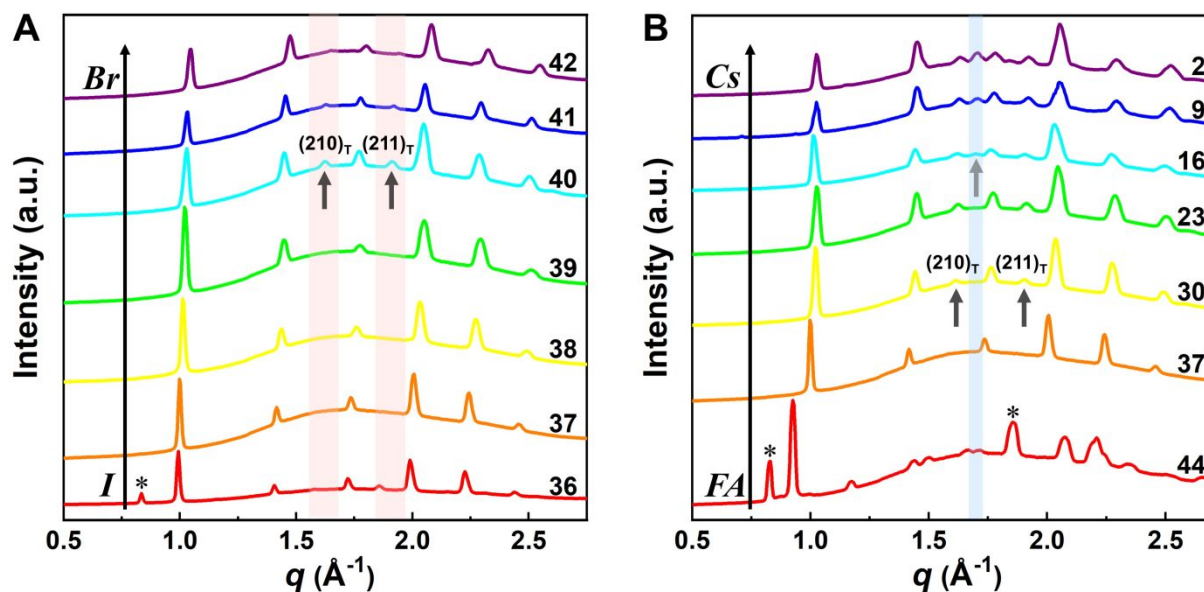

Fig.5. Integrated circular average of 2D GIWAXS patterns for $Cs_{1/6}FA_{5/6}Pb(Br_xI_{1-x})_3$ films as a function of Br content (A) and $Cs_yFA_{1-y}PbBr_{1/2}I_{5/2}$ as a function of Cs content (B). δ-$FAPbI_3$ was marked by *. The black arrows point to the characteristic peaks of tetragonal phase and the grey arrow refers to the characteristic peaks of orthorhombic phase, i.e., $(211)_O$, $(121)_O$, $(103)_O$.

The clear evidence for the variation of crystal symmetry motivates us to qualitatively establish the relationship between crystal symmetry and perovskite compositions. Combining the information retrieved from XRD and GIWAXS data, we identify the presence of perovskite and non-perovskite phases as a function of composition in Fig. 6A. We observe that iodine-pure compositions are prone to the formation of secondary non-perovskite phases. The $Cs_yFA_{1-y}PbI_3$, $FAPbI_3$ (No.43) and $Cs_{1/6}FA_{5/6}PbI_3$ (No.36) perovskite thin films have non-perovskite δ-$FAPbI_3$ phase, and the other five compositions with Cs ratio in the range of $2/6 \leqslant y \leqslant 1$ show signatures of the presence of the non-perovskite δ-$CsPbI_3$ phase (Fig. S6). The ratio of non-perovskite phase to perovskite phase for $Cs_yFA_{1-y}PbI_3$ compositions is estimated by calculating the intensity ratio of the characteristic peak at $q = 0.70$ Å^{-1} (δ-$CsPbI_3$) or $q = 0.83$ Å^{-1} (δ-$FAPbI_3$) for non-perovskite phase over the characteristic peak at q around 1.00 Å^{-1} of perovskite phase was calculated based on GIWAXS data in $Cs_yFA_{1-y}PbI_3$ compositions, as shown in Fig. S7. The content of δ-$FAPbI_3$ dramatically decreases when $1/6$ of FA^+ is replaced by Cs^+, i.e., $Cs_{1/6}FA_{5/6}PbI_3$ (No.36). As the ratio of Cs increases, so does the content of δ-$CsPbI_3$ in the range of $2/6 \leq y \leq 1$. The presence of different non-perovskite phases as a function of composition and the boundary at around $1/6 < y < 2/6$ might be explained by changes in the formation energy between the corresponding perovskite

318　　phases and two non-perovskite phases. It has been calculated that δ-CsPbI$_3$ has lower formation

319　　energy than that of δ-FAPbI$_3$ and the corresponding perovskite phase when the Cs ratio goes higher

320　　than ~30%, while δ-FAPbI$_3$ has lower formation energy than δ-CsPbI$_3$ and the perovskite phase

321　　for Cs ratios below ~30% [26,50]. The phase transition energy from the alloyed perovskite phase to

322　　the two different non-perovskite phases reaches a minimum at Cs ratio ~30% [26], which is in line

323　　with our experimental results in Fig. S7. The Cs$_{2/6}$FA$_{4/6}$PbI$_3$ (No.29) perovskite exhibits the lowest

324　　content of δ-CsPbI$_3$. The low phase transition energy for FA-rich composition in Cs$_y$FA$_{1-y}$PbI$_3$ is

325　　also associated with the availability of perovskite phases and gives rise to enhanced stability under

326　　our mild preparation conditions. However, Cs-rich ($3/6 \leq y \leq 1$) mixed perovskite phases are

327　　enthalpically significantly disfavored [50]. The distortion of the lattice reduces the antibonding

328　　overlap of the I p-orbitals with the s-orbitals of Pb of the valence band maximum (VBM) for Cs-

329　　rich composition in Cs$_y$FA$_{1-y}$PbI$_3$, leading to a less stable structure [33,50]. All of this is also in

330　　agreement with their high (FA-based) and low (Cs-based) tolerance factors (Fig. 2). Thus, in

331　　Cs$_y$FA$_{1-y}$PbI$_3$ ($2/6 \leq y \leq 1$) compositions the perovskite phase could be formed, but it is

332　　thermodynamically unstable at room temperature [26,50.31,50]. All of this is also in agreement with

333　　their high (FA-based) and low (Cs-based) tolerance factors (Fig. 2). Thus, in Cs$_y$FA$_{1-y}$PbI$_3$ ($2/6 \leqslant$

334　　$y \leqslant 1$) compositions the perovskite phase could be formed, but it is thermodynamically unstable

335　　at room temperature [26,50]. Such theoretical prediction is consistent with our experimental results.

336　　The crystallographic peaks of I-rich composition No.44-46 with FA$^+$ as the exclusive A-site cation

337　　deviate from other compositions. These films exhibit the characteristic peaks of δ-FAPbI$_3$. In

338　　addition, other crystal structures that are not well-defined can be formed (Fig. S2 and S5),

339　　originating from low annealing temperature and the formation of an amorphous phase [19,34].

340　　Composition No.44-46 are therefore referred to as an unknow region in our subsequent analysis.

341　　With the exception of the seven Cs$_y$FA$_{1-y}$PbI$_3$ compositions in the first column, No.44-46 and

342　　Cs$_{5/6}$FA$_{1/6}$PbBr$_{1/2}$I$_{5/2}$ (No.9), all other perovskite compositions, crystallize in the perovskite phase.

343　　The existence of characteristic peaks at around $q = 1.6$ Å^{-1} and 1.9 Å^{-1} corresponding to the (210)$_T$

344　　and (211)$_T$ reflections, respectively, are used to determine whether a tetragonal phase exists.

345　　Similarly, the presence of an additional characteristic peak at around $q = 1.7$ Å^{-1} indexed to the

346　　(211)$_O$, (121)$_O$, (103)$_O$ reflections, is utilized to distinguish whether an orthorhombic phase is

347　　present. The presence of different perovskite phases is summarized in Fig. 6B and the full set of

348　　GIWAXS patterns for all compositions showing the key peaks is given in Fig. S8. The low signal

349   region for phase identification overlaps with the δ-CsPbI$_3$, making it hard to assess the perovskite

350   phase for compositions No.8, 15, 22, and 29 in Cs$_y$FA$_{1-y}$PbI$_3$. Decreased symmetry stemming from

351   the PbX$_6$ octahedral tilting and distortion has been found in the Cs$_y$FA$_{1-y}$PbI$_3$ polycrystalline films

352   upon cesium ratio above 2/6 [33]. The symmetry variation has been well-established in Cs$_y$FA$_{1-}$

353    $_y$PbI$_3$ nanocrystals which could stabilize the perovskite phase at room temperature arising from the

354   higher surface/volume ratio, and the crystal symmetry lower from cubic to tetragonal to

355   orthorhombic upon increasing cesium content [43]. This variation of crystal structure conforms to

356   the tendency of tolerance factor which has been corroborated in the literature [26,33,43]. The variation

357   of crystal symmetry in the explored compositional space is consistent with the prediction from the

358   tolerance factors we computed (Fig. 2). Cs-rich compositions with lower tolerance factor (0.8-0.9)

359   have lower crystal symmetry deriving from the size mismatch between A-site cations and PbX$_6$

360   octahedra, which are mainly orthorhombic and tetragonal; FA-rich compositions with tolerance

361   factor ~0.9-1.0 have increased crystal symmetry, which are principally tetragonal and cubic.

362   Notably, composition No.36 is identified to have a tetragonal phase and a small amount of δ-

363   FAPbI$_3$ is detected, while composition No.37 forms cubic phase and there is no δ-phase found

364   under our mild preparation condition. This indicates that the incorporation of a small amount of

365   bromine into the crystal lattice can dramatically decrease the phase transition temperature and

366   contribute to the formation of the cubic phase. Hence the correlation between crystal structure and

367   the compositions with varying cesium ratio and bromine ratios is qualitatively established,

368   conducive to help understand the photophysical properties and photovoltaic performance in such

369   materials.

370   To complement the experimental studies, we have also conducted first-principles density-

371   functional theory calculations to assess the structure of the perovskites and their thermodynamic

372   stability. The optimized lattice constants for all compositions and for the three phases

373   orthorhombic, tetragonal and cubic are shown in Fig. S9. The calculated lattice constants also show

374   the lattice contraction with cesium ratio or bromine ratio increasing, as we observed in XRD and

375   GIWAXS results. Further, using the optimized structures, we compared the phase stability for each

376   composition based on total electronic energy. Results are summarized in Fig. S10. Given the small

377   energy differences between the three phases, we report the thermodynamic stability based on

378   Boltzmann distribution at T = 300°C. As seen from Fig. S10A, for most compositions, more than

379   one phase is thermodynamically stable at room temperature. This suggests that neglected higher

380   order effects including harmonic and nonharmonic vibrational [51] as well as entropic effects [52],

381   which are computationally non-trivial, can have a noticeable effect in determining the most stable

382   phase. Further, kinetic effects can also be important in determining the most stable phase observed

383   during synthesis.
384

385   **Fig.6** Color map of the presence of perovskite phases (A) and the presence of crystal symmetry for perovskite

386   phases (B) in the $Cs_xFA_{1-x}Pb(Br_yI_{1-y})_3$ compositional space based on the XRD and GIWAXS data. (B) only show

387   the crystal symmetry for perovskite phases in (A) and the empty square for $FAPbI_3$ (No.43) is non-perovskite

388   phase.

389   ***Surface morphology***

390   In addition to understanding the structural aspects of these materials, we need to understand

391   film morphology and coverage if we are to fabricate solar cells. Therefore, scanning electron

392   microscopy (SEM) was carried out to image the morphology of the perovskite films in the Cs_yFA_{1-}

393    $_yPb(Br_xI_{1-x})_3$ compositional space. The thickness of the as-deposited perovskite layer is

394   approximately 150-200 nm based on the cross-sectional SEM image (Fig. S11A). The full set of

395   top-view SEM images for the 49 compositions are displayed in Fig. 7. The SEM images at both

396   higher and lower magnifications are available in Fig. S12-S14. The surface morphology of the

397   films shows significant differences among different compositions. Cs-rich compositions (e.g., No.

398   8-10) exhibit a rough surface with a large degree of pinholes, acting as shunt and moisture

399   pathways, which are detrimental to the performance and stability of the devices [38]. Notably,

400   variations in the Cs^+/FA^+ ratio in $Cs_yFA_{1-y}PbI_3$ greatly impact the surface morphology. Cs-rich

401   compositions in $Cs_yFA_{1-y}PbI_3$, No.1, No. 8 and No.15, show poorly defined domains and have a

402   large number of pinholes. The δ-$FAPbI_3$ (No.43) presents a rod-like morphology and

403      $Cs_{1/6}FA_{5/6}PbI_3$ (No.36) show defined perovskite domains with average size of 200-300 nm, while

404      $Cs_{3/6}FA_{3/6}PbI_3$ (No.22) and $Cs_{4/6}FA_{2/6}PbI_3$ (No.29) present a combination of rod-shaped crystals

405   embedded among flat domains. The remarkable difference in surface morphology is likely to affect

406   device performances once these films are incorporated in complete solar cell stacks.

407   There are differences in domain size between the explored compositions. However, there is no

408   clear correlation with increasing bromine or cesium content in the films and domain size. The

409   compositions with high cesium content combined with high bromine content, e.g.,

410      $Cs_{5/6}FA_{1/6}PbBr_{3/2}I_{3/2}$ (No.11), $Cs_{5/6}FA_{1/6}PbBr_2I_1$ (No.12), and $Cs_{4/6}FA_{2/6}PbBr_{5/2}I_{1/2}$ (No.20),

411   generally appear to have small domain sizes of ~100 nm. A larger domain size can sometimes be

412   associated with the reduction of the nonradiative recombination and improvement of the charge

413   carrier transport, thus enhancing device performance [53,54]. The films deposited from compositions

414   with low cesium content combined with low bromine content, e.g., $Cs_{2/6}FA_{4/6}PbBr_{1/2}I_{5/2}$ (No. 30),

415      $Cs_{1/6}FA_{5/6}PbI_3$ (No.36), and $Cs_{1/6}FA_{5/6}PbBr_{1/2}I_{5/2}$ (No. 37), have fewer voids and present relatively

416   large domain size, which should lead to higher device efficiencies. The domain size of the film is

417   in line with the reported perovskite films with a similar composition deposited via an analogous

418   approach [27,41].

419
Fig.7. Top-view SEM images of the perovskite films in the $Cs_yFA_{1-y}Pb(Br_xI_{1-x})_3$ compositional space. The panels are arranged in the same order as in the composition matrix of Fig. 1A. The yellow scale bar on the right bottom is 1 µm.

Optical properties

To understand the variations in optical properties in $Cs_yFA_{1-y}Pb(Br_xI_{1-x})_3$ films, ultraviolet-visible absorbance and steady-state photoluminescence (PL) measurements were performed. The absorption and normalized PL as a function of wavelength are presented in Fig. 8 for a subset of the films. The full set of figures for the 49 perovskite films with varying ratios of Cs^+/FA^+ and Br^-/I^- are shown in Fig. S15-S18. The absorbance trends observed upon changing the Br^-/I^- ratio are indicated in Fig. 8A. All $Cs_{1/6}FA_{5/6}Pb(Br_xI_{1-x})_3$ films present sharp optical band edges, that will shift to a lower wavelength as the bromine content increases, resulting in bandgap tunability for solar cell application. In addition, the shape of the absorption curve varies with the Br^-/I^- ratio. With higher bromine content, the band edge of absorption becomes sharper and the excitonic absorption appears with the visual appearance of a peak, which is in good agreement with the higher exciton binding energy reported for the Br-rich perovskites [29,55,56]. Changing the Cs^+/FA^+ ratio has a

435   considerably smaller effect on absorbance than changing the halide ratio, as illustrated in Fig. 8B.

436   When the cesium content is increased, the optical band edges will shift to slightly higher

437   wavelengths. The markedly different impact on the absorbance of $Cs_yFA_{1-y}Pb(Br_xI_{1-x})_3$ thin films

438   when varying Cs^+/FA^+ and Br^-/I^- ratios could be clarified by looking at the contribution of the

439   energy levels of A and X to the electronic band structure of $APbX_3$ [56,57]. As the halide is substituted

440   from I (5p) to Br (4p), the energy of the halide p orbital decreases and Pb-X bond lengths decrease,

441   shifting the VBM toward more negative energy and shifting the CBM toward more positive energy,

442   thus increasing the bandgap [56,57]. Instead, the A-site cations introduce energy levels deep into the

443   bands, and thus do not directly contribute to the VBM and CBM. The A-site cations however have

444   an indirect impact on the bandgap by influencing the Pb-X orbital overlap through two competing

445   effects, i.e., lattice contraction and PbX_6 octahedral tilting [57]. Previous work has shown octahedral

446   tilting is the dominant effect in lead perovskites upon the substitution of the larger FA^+ with the

447   smaller Cs^+ [57]. Octahedral tilting and lowered symmetry reduce the Pb-X orbital overlap, moving

448   the bands to deeper energies and increasing the bandgap for Cs-rich compositions [57].
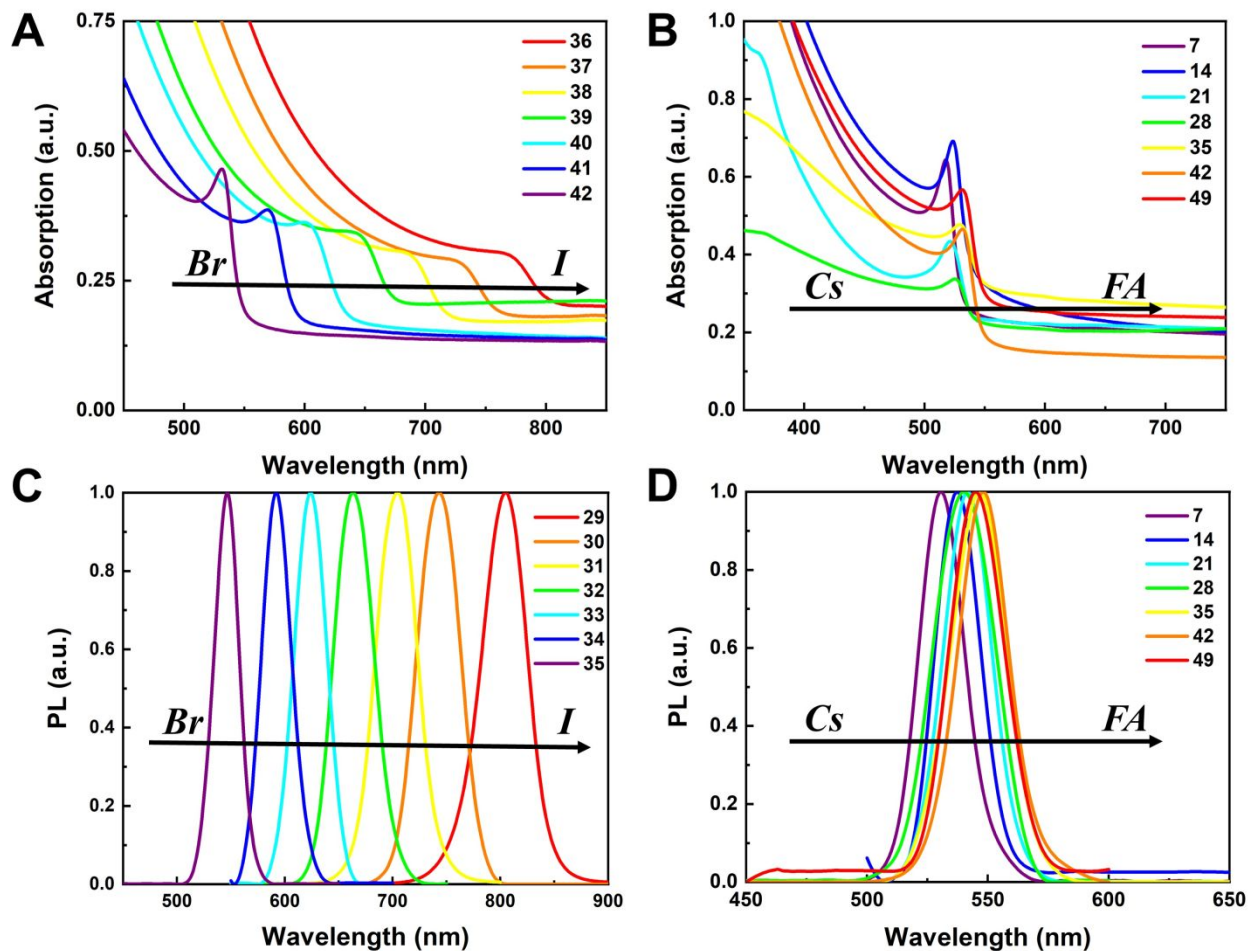

Fig.8. Ultraviolet-visible absorbance spectra of $Cs_{1/6}FA_{5/6}Pb(Br_xI_{1-x})_3$ (A) and $Cs_yFA_{1-y}PbBr_3$ (B) films. Normalized photoluminescence spectra of $Cs_{2/6}FA_{4/6}Pb(Br_xI_{1-x})_3$ (C) and $Cs_yFA_{1-y}PbBr_3$ (D) films.

The trends in PL are in good agreement with the shift of absorption onset, as displayed in Fig. 8C a clear blue shift of PL peak is observed upon increasing the bromine content. The PL peaks of Br-rich samples are narrower than that of I-rich compositions, which can be due to a more defined bandgap without electronic defects. As cesium content increases, the PL peak slightly blue shifts, as can be seen in Fig. 8D and this is consistent with the slight shift in their bandgap. It is worth noting that two PL peaks appear in Br-rich films, e.g., $CsPbBr_2I_1$ (No.5), $Cs_{5/6}FA_{1/6}PbBr_2I_1$ (No.40), and $Cs_{1/6}FA_{5/6}PbBr_{5/2}I_{1/2}$ (No.41) (Fig. S17-S18). From the two peaks, the one at higher energy corresponds to the direct emission from CBM to VBM, but there is also another peak at lower photon energy. This double peak behavior in the Br-rich perovskites is halide phase segregation, which has been reported in previous studies [9,13,29,34]. It was proposed that Br-rich compositions can phase-segregate into majority Br-rich domains with PL peaks at higher energy and minority I-rich domains with PL peak at lower energy upon illumination [9,13,29]. The I-rich

464   domains derive from stochastic composition fluctuations and local lattice strain induced by

465   localized polarons under illumination, which is detrimental to the device performance, especially

466   V_{oc} [15]. The Br-rich compositions with the sub-bandgap photoemission is potentially a problem for

467   the practical application under illumination. From the absorbance spectra, the bandgap energy (E_g)

468   for $Cs_yFA_{1-y}Pb(Br_xI_{1-x})_3$ compositions, as extracted by Tauc plots are summarized in Fig. 9A. The

469   fits used for the calculation are presented in Fig. S19 with the assumption that all compositions are

470   direct bandgap semiconductors. The difference in E_g between a pure iodide perovskite and a pure

471   bromide perovskite with a fixed Cs^+/FA^+ ratio is approximately 0.75 eV, whereas the difference

472   in E_g between a pure Cs perovskite and a pure FA perovskite with a fixed Br^-/I^- ratio is only

473   approximately 0.15 eV.

474   The PL peak positions (E_{PL}) are shown in Fig. 9B. If the composition showed two PL peaks, the

475   one at high energy is the one shown. The compositions with the secondary peak at low photon

476   energy are illustrated in Fig. 9C. A majority of E_{PL} for MA-free $Cs_yFA_{1-y}Pb(Br_xI_{1-x})_3$ matches well

477   to the E_g extracted from the UV-vis measurements, revealing the PL is predominantly from the

478   direct recombination from the CBM to the VBM rather than trap or sub-band states. The energy

479   loss from E_g to E_{PL} for some compositions indicates the emitted photon has less energy than the

480   absorbed photon and the energy loss derives from vibrational relaxation as well as internal

481   conversion, which is called the Stokes shift in PL [58]. Two compositions (i.e., No.6 and No.12)

482   have large energy differences since they exhibit phase segregation during a few minutes of beam

483   exposure during PL measurements (Fig. 9C). There is no second PL peak at low energy in the Br-

484   rich $Cs_yFA_{1-y}PbBr_{3/2}I_{3/2}$ compositions, while the appearance of a second PL peak is documented

485   to appear within a few minutes for $MA_yFA_{1-y}PbBr_{3/2}I_{3/2}$ in literature [29]. This observation possibly

486   aims at the existence of a broader range of photostable compositions for MA-free Cs_yFA_{1-}

487    $_yPb(Br_xI_{1-x})_3$ in comparison to $MA_yFA_{1-y}Pb(Br_xI_{1-x})_3$, though a full understanding of phase

488   segregation is beyond the scope of this initial study. The emitted photon has more energy than the

489   absorbed photon for some compositions and the extra energy comes from the dissipation of thermal

490   phonons in a crystal lattice, this is called up-conversion photoluminescence [58]. PL-peak centered

491   on energies slightly higher than the bandgap energy from absorption also was observed in our

492   previous research [29]. In addition, it has been reported that the perovskite materials show up-

493   conversion properties with phonon-assisted energy gain and potential applications in hot carrier

494   optoelectronic and energy-harvesting devices [59,60].

495   To quantitatively describe the dependence of E_g on the composition in the $Cs_yFA_{1-y}Pb(Br_xI_{1-x})_3$

496   space, we fitted an empirical equation to the experimental data. Compositions No.43-46 (I-rich in

497   $FAPb(Br_xI_{1-x})_3$), 8 ($Cs_{5/6}FA_{1/6}PbI_3$), 9 ($Cs_{5/6}FA_{1/6}PbBr_{1/2}I_{5/2}$), 15 ($Cs_{4/6}FA_{2/6}PbI_3$), 16

498   ($Cs_{4/6}FA_{2/6}PbBr_{1/2}I_{5/2}$) were excluded from the fit. The E_g of compositions No.43-46 follow a

499   different trend than other compositions (Fig. S20A-C), which can be also seen in their

500   crystallographic data. Compositions No.8-9 and No.15-16 show broad absorption without a clear

501   onset (Fig. S15-S16). Under these assumptions, the nonlinear variation of E_g with changing halide

502   ratio could be empirically described via a quadratic equation [12,29]. A quadratic equation also

503   describes the trend in E_g with changes in the ratio of Cs/FA. The E_g across the whole compositional

504   space can then be described with a second-order polynomial:

505
$$x = \frac{[Br]}{[Br + I]}, y = \frac{[Cs]}{[Cs + FA]}$$

506
$$E_g(x, y) = 1.50 + 0.56x + 0.08y + 0.19x^2 + 0.11y^2 - 0.10xy \tag{2}$$

507   The r-square and adjusted r-square of this equitation are 0.976 and 0.973, respectively. The

508   confidence intervals of the determined coefficients are reported in Table S1. Fig. 9D visualizes the

509   comparison between the experimental data of E_g and the empirical equitation of the fit. Notably,

510   the equation can be used to predict the bandgap of the perovskite phase of unexplored compositions.

511   If the equation is used to predict the E_g of $FAPbI_3$, i.e., $x = y = 0$ (composition No.43), which was

512   excluded from our fit being in the δ-phase in our experiment, the estimated E_g will be 1.50 eV,

513   which is in good agreement with the 1.48 eV value reported in literature for the α-phase. The

514   coefficients of the halide ratio variable x are always larger than those of y, again highlighting that

515   an increase in Cs content yields less shift in bandgap than an equivalent increase in Br content.

516   Overall, this equation can be used to estimate the E_g values across the compositional space of

517   $Cs_yFA_{1-y}Pb(Br_xI_{1-x})_3$, and would aid further tailoring E_g for various optoelectronic applications.
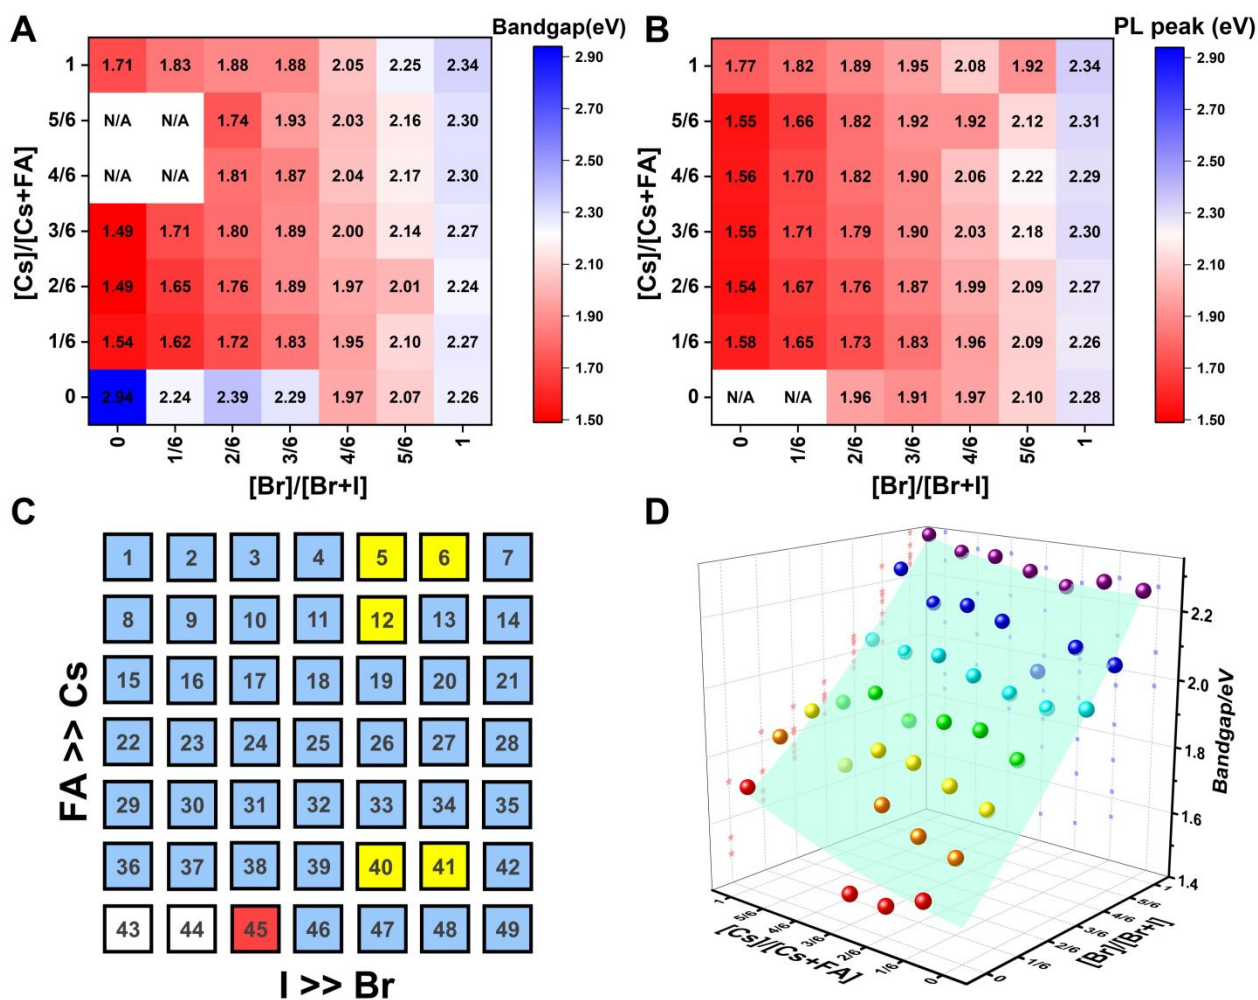

518

519 **Fig.9**. Heat maps of bandgaps extracted from Tauc plots based on absorption (A) and on the PL energy (B)

520 extracted from the wavelength of maximum emission. N/A means not available. Note: if the composition

521 incurred phase segregation and had two peaks, the position of the PL peak at low wavelength was selected. (C)

522 Color map of compositions with phase segregation summarized based on Fig. S16-S17. A blue square means

523 only one peak was observed during the measurement. Yellow square means a secondary PL peak co-exists.

524 Although $CsPbBr_{5/2}I_{1/2}$ (No.6) only has one peak, it is the result of evolving red-shifted PL at low wavelength

525 upon illumination [9]. The red square represents a split PL peak and the white one has no observable PL peaks.

526 (D) Bandgaps as a function of perovskite compositions for the $Cs_yFA_{1-y}Pb(Br_xI_{1-x})_3$ compositional space. The

527 colored dots are the experimental bandgaps calculated from Tauc plots based on absorption. The values predicted

528 from the fitted empirical equation belong to the light green plane in the plot.

529 ***Device performance***

530   The I-rich compositions usually yield the highest photovoltaic performance and stability

531 due to the suitable bandgap as photoabsorbers in single junctions solar cells [18,27]. Here, perovskite

532 solar cells for all I-rich compositions $Cs_yFA_{1-y}Pb(Br_xI_{1-x})_3$ ($0 \leq x \leq 3/6$), i.e., first four columns apart

533   from $CsPbI_3$ and $FAPbI_3$, were fabricated in the n-i-p FTO/c-TiO_2/m-TiO_2/perovskite/Spiro-

534   OMeTAD/Au architecture, where FTO is fluorine-tin-oxide coated glass and Spiro-OMeTAD is

535   2,2',7,7'-Tetrakis[N,N-di(4-methoxyphenyl)amino]-9,9'-spirobifluorene as the hole transport

536   layer. The perovskite layer in the solar cell was deposited by the same method as the characterized

537   perovskite films. Fig. 10 A-D shows the photovoltaic parameters short-circuit current (J_{sc}), V_{oc}, fill

538   factor (FF), and PCE for reverse scan attained from best devices of each perovskite composition.

539   The corresponding photovoltaic parameters for forward scan and stabilized power output at

540   maximum power point (MPP) are available in Fig. S21. The corresponding box plots, depicting

541   the performance distribution of multiple devices, are given in Fig. S22-S25. The 26 I-rich

542   compositions show a huge spread of device performances, with the reverse PCE varying from 1.30%

543   to 12.25%. Of the 26 I-rich compositions, $Cs_{1/6}FA_{5/6}PbI_3$ (No.36) yielded the best devices, with a

544   reverse PCE of 12.25% and a forward PCE of 12.55%. The best devices have compositions

545   clustered around No.36, involving No.29 ($Cs_{2/6}FA_{4/6}PbI_3$), No 30 ($Cs_{2/6}FA_{4/6}PbBr_{1/2}I_{5/2}$), and

546   No.37 ($Cs_{1/6}FA_{5/6}PbBr_{1/2}I_{5/2}$).

547   As illustrated in Fig. 10A, when the amount of bromine is increased, there is a decrease in

548   J_{sc} (barring the Cs-rich compositions), directly related to the blue-shift of absorption onset. As

549   cesium ratio increases, a reduction of J_{sc} is observed. This decline is remarkable for compositions

550   with iodide as the exclusive halogen. When the cesium ratio is increased, J_{sc} is significantly

551   decreased from 18.67 mA/cm^2 at $y = 1/6$ (No.36) to 3.35 mA/cm^2 at $y = 5/6$ (No.8) for the

552   compositions of $Cs_yFA_{1-y}PbI_3$, while J_{sc} is slightly decreases from 13.30 mA/cm^2 at $y = 1/6$ (No.38)

553   to 10.38 mA/cm^2 at $y = 1$ (No.3) for the compositions of $Cs_yFA_{1-y}PbBr_1I_2$. The difference can be

554   attributed to the poor surface morphology of No.8 and No.15 on the one hand, and the presence of

555   a large degree of non-perovskite δ-phase on the other. In light of our recent research work focusing

556   on preferred crystallographic orientation (texture) [61] and its effect on J_{sc}, we analyzed the

557   GIWAXS data, tracking the intensity variations of a specific plane with varying azimuthal angle,

558   as an indication of texture. Our analysis, summarized in Note 1 and Fig. S26-S28, suggests that

559   the impact of texture on the device performance is negligible in the face of other factors, e.g.,

560   bandgap, surface morphology, and the existence of lower symmetry phases.

561   The V_{oc} increases as a result of the widening bandgap with increasing bromine ratio in first

562   three columns (Fig. 10B). Nevertheless, the V_{oc} decreases as the cesium ratio increases, which is

563   in opposite trend to the bandgap. This means that there are additional factors besides the bandgap

564   that dominate V_{oc}. Besides the poor surface morphology and the presence of δ-phase in Cs-rich
565   compositions the decreased symmetry of Cs-rich compositions is hypothesized to favor non-
566   radiative recombination, inducing a loss in V_{oc}. The Cs-rich compositions have a small tolerance
567   factor, which is representative of a large mismatch in ionic size between the A-site cation and the
568   PbI_6 octahedra. This mismatch leads to lowered symmetry and increased lattice strain, which in
569   turn favors increased defect concentrations and non-radiative recombination, harmful to the V_{oc}
570   [16,62].

571   The FF of a solar cell is often the most difficult parameter to study and optimize, as it is
572   sensitive to a wide range of loss mechanisms including resistance losses. The FF does not show a
573   clear trend across the compositional space (Fig. 10C). The PCE exhibits a similar functional
574   dependence on the composition as the overall J_{sc} (Fig. 10D), despite the PCE being determined
575   from the products of J_{sc}, V_{oc}, and FF. Increasing the cesium or bromide content decreases the PCE
576   of devices. This suggests that the bandgap variations correlate with the trends in PCE to some
577   extent, which is also expected. Both FA-rich and I-rich compositions exhibit the highest device
578   performance in our study, which can also be attributed to their long carrier lifetime. Rehman et
579   al. extracted the carrier lifetime from photoluminescence decay transients in compositions similar
580   to the ones we report here [31]. The authors found that the region of $0.1 < y < 0.3$ Cs$^+$ content yielded
581   less non-radiative trap-assisted recombination as well as faster carrier mobility in
582    $Cs_yFA_{(1-y)}Pb(Br_{0.4}I_{0.6})_3$. The carrier lifetime varies from 191 ns for $Cs_{1/6}FA_{5/6}PbI_3$ (No.36) to 22 ns
583   for $Cs_{1/6}FA_{5/6}PbBr_3$ (No.42) perovskite thin films while the carrier diffusion lengths decreased
584   from 4.4 μm for No.36 to 0.8 μm for No.42 in the row of compositions $Cs_{1/6}FA_{5/6}Pb(Br_xI_{1-x})_3$. The
585   longer carrier lifetime in both FA-rich and I-rich compositions is beneficial to the performance of
586   solar cells, which is in line with our device results (Fig. 10).

587   However, a more insightful way to compare these materials is to normalize by the bandgap.
588   We calculated the ratio of experimental J_{sc}, V_{oc}, and FF, and PCE from the best devices to the
589   corresponding theoretical Shockley-Queisser limit (for each bandgap) of I-rich compositions (Fig.
590   S29) [3]. These ratios can be used to evaluate the loss of each photovoltaic parameter relative to their
591   theoretical value as a function of bandgap. The experimental vs. theoretical ratios in the J_{sc} shown
592   in Fig. S29 are lower than 70% due to reflection from the glass, parasitic absorption by the
593   FTO/TiO_2, and relatively thin layers in these unoptimized devices [63]. However, we plot these ratios
594   for all devices measured to understand trends of J_{sc}. Cs-rich samples, e.g., No.8 and No.9, show

595   only ~ 12% of the theoretical J_{sc}, mainly deriving from the large amounts of non-perovskite present

596   in the films (Fig. S7). The experimental vs. theoretical ratios in the V_{oc} are also lower than 80%

597   primarily due to trap-assisted non-radiative recombination in the perovskite bulk and interfaces as

598   well as the mismatch of energy level between the perovskite and charge transport layer [64]. Looking

599   at Fig. S29 we can see that moving away from I-rich compositions leads to lower normalized V_{oc},

600   which suggests that adding Br leads to increased recombination dynamics or a limit by the splitting

601   of the quasi-Fermi levels of the transport layers. These large V_{oc} deficits also occurred in other

602   reported wide-bandgap perovskites [64]. Chemical treatments could remarkably reduce this loss from

603   non-radiative recombination [63,65]. The perovskite fabrication process needs to be optimized

604   together with favorable energy alignment of the contact layers to overcome this loss. Similarly,

605   going from FA- to Cs-rich leads to a decrease in the V_{oc} ratios, which can be attributed to more

606   pinhole formation (Fig. 7). However, looking closer at compositions that have similar

607   morphological features with close bandgap and no non-perovskite phases (Fig. 9A), compositions

608   No. 37, 30, and 23, the V_{oc} decreases with the decrease in symmetry, even though No.23 (1.71eV)

609   has a wider bandgap than No.37 (1.62eV). The V_{oc} goes from cubic and a 70% of theoretical V_{oc}

610   to tetragonal and 61% of theoretical V_{oc} for compositions No. 37 and 23, respectively. It indicates

611   that lower symmetries alone in I-rich perovskites may be one of the factors that lead to lower V_{oc},

612   which is indicative of increased recombination dynamics. The crystal structure of the perovskite

613   phase seems to have an impact on the device performance and the lower symmetries might lead to

614   increased non-radiative recombination.

615   Given the promise of the FA-rich I-rich compositions and the thin nature of our films due

616   to poor solubility of CsBr used when processing the films, we set to increase the thickness of the

617   perovskite layer to maximize photon harvesting. Hence, a 1.0 M precursor solution was prepared,

618   and a higher annealing temperature of 150℃ was used to crystallize the deposited films, to

619   suppress the formation of the yellow δ-phase. Fig. 11A shows the champion current-voltage (J-V)

620   characteristic curves for the four compositions (No.29, 30, 36 and 37). The detailed photovoltaic

621   parameters as reported in Table 1. The corresponding box plots and MPP tracking are given in Fig.

622   S30. From the collected data it can be observed that the stabilized power output at MPP of

623   composition No.29 using 1.0 M precursor solution (10.22%) is almost the same as the 0.4 M

624   (10.21%). The negligible change in photovoltaic parameters for this composition, despite the

625   increased thickness and thus the increased GIWAXS signal from the perovskite phases, is to be

626   ascribed to the presence of a δ-CsPbI$_3$ secondary phase (Fig. S31A-C), which limits performances

627   in spite of the increased thickness and annealing temperature used. The composition PSCs based

628   on No.36 using 1.0 M precursor solution delivers a champion stabilized PCE of 18.62%, benefiting

629   from an improvement in each of the photovoltaic parameters, especially J_{sc} - which raises from

630   18.67 mA/cm^2 to 24.04 mA/cm^2. As illustrated in Fig.S32, the change in onsets of external

631   quantum efficiency (EQE) spectra for these four compositions match the bandgap extracted from

632   the absorbance onset, E_g (Table. S2). We attribute the enhancement to the absence of δ-phase (Fig.

633   S31A-B) for this composition. The stabilized PCE of composition No.30 and No.37 also raise to

634   15.13% and 17.13%, respectively. The increase in annealing temperature does not change the

635   preferred crystallographic orientation and crystal symmetry of No.30, No.36, and No.37, still

636   keeping the cubic, tetragonal and cubic structure, respectively (Fig. S31). The long-term

637   operational stability data obtained for PSC with composition No.36 and No.37 held at MPP under

638   1 sun irradiation in nitrogen atmosphere and at room temperature are shown in Fig. 11B. After 330

639   h, the solar cell with composition No.36 retained 94% of its initial efficiency. The major

640   contribution to the efficiency drop observed is attributed to a 5% decrease in V_{oc} and FF compared

641   to the initial values (Fig. S33). The solar cell with composition No.37 maintained 98% of the initial

642   efficiency exhibiting increased photostability, which is of promise to enable solar cells with long-

643   term stability. No.36 (1.54 eV) and No.37 (1.62 eV) not only have suitable bandgaps to absorb the

644   light illumination, but also exhibits less mismatch in crystal structure that gives rise to the

645   suppression of non-perovskite phase, thus leading to their high performance and durable among

646   the compositions explored. It is the structure and optoelectronic properties that determine the

647   optimized composition for making high performance devices.
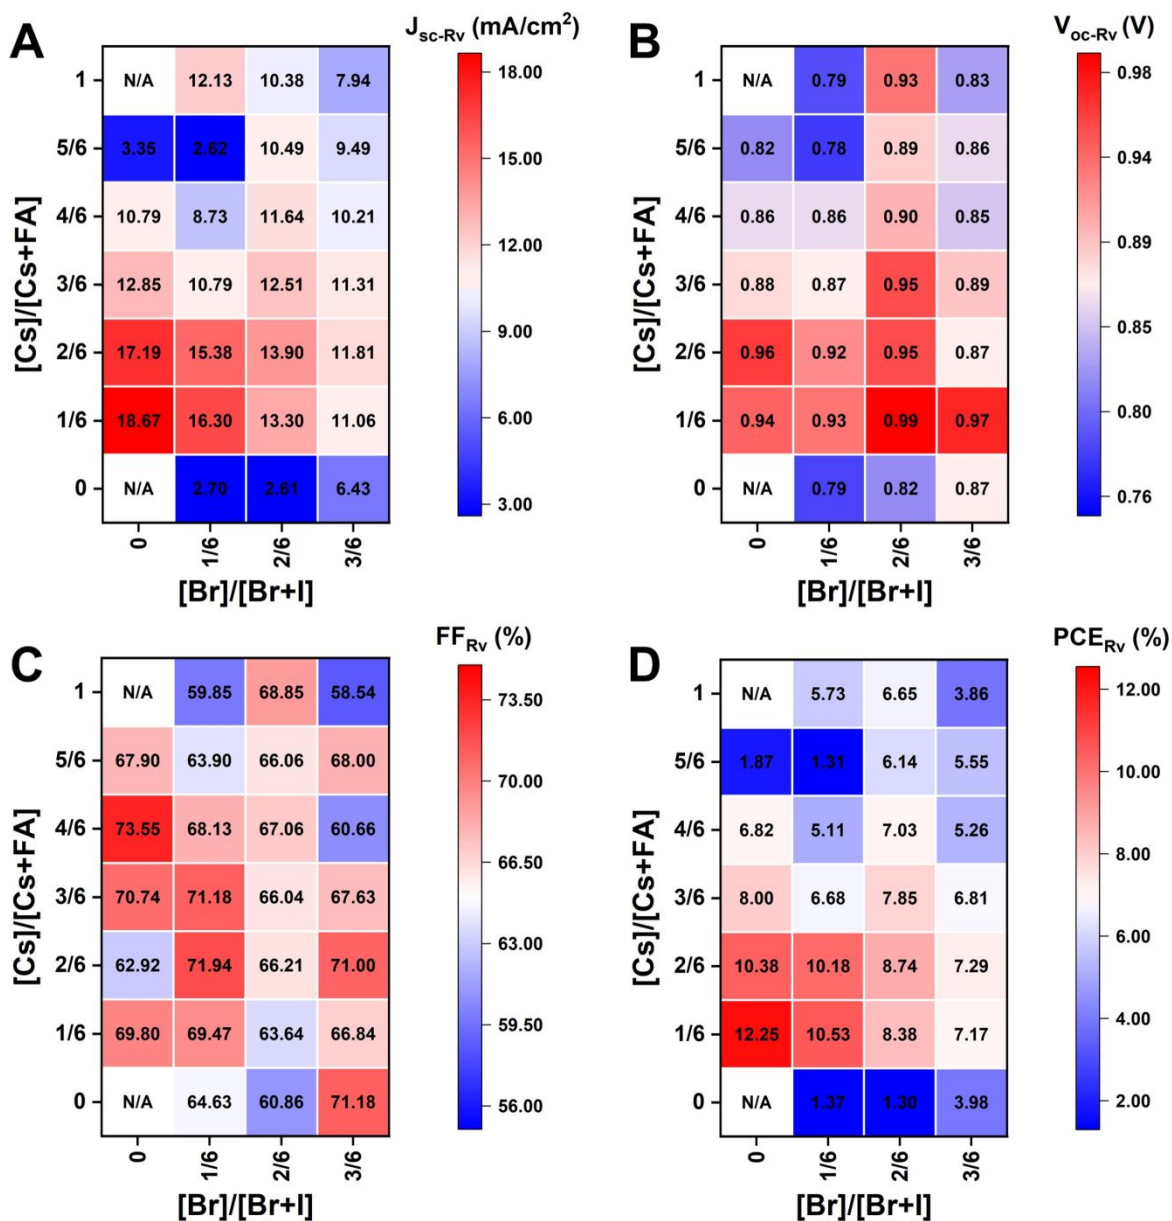

648

649 **Fig.10.** The photovoltaic parameters of J_{sc} (A), V_{oc} (B), FF (C), and PCE (D) for reverse scan attained from best

650 devices of I-rich compositions using 0.4 M perovskite precursor solutions.
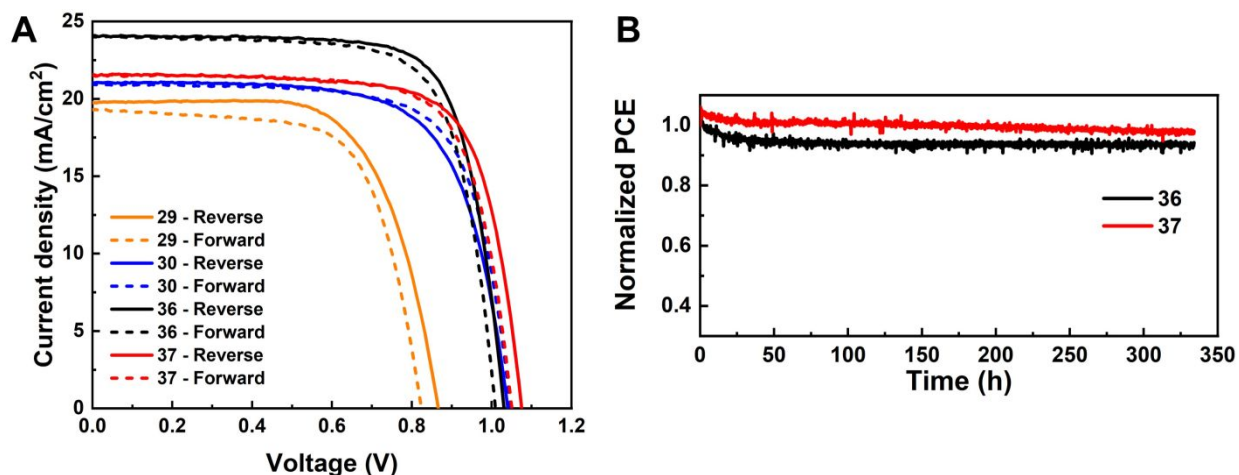

Fig. 11. (A) Reverse J-V curves of the champion PSCs of composition 29, 30, 36, and 37 using 1.0 M perovskite precursor solutions with 5% excess Pb^{2+}. (B) Continuous MPP tracking results under 1 sun irradiance at N_2 atmosphere of devices of composition 36 and 37.

Table 1. Photovoltaic parameters of champion devices based on composition 29, 30, 36 and 37 measured under AM 1.5G illumination

Composition	29	30	36	37
J_{sc-Rv} (mA/cm^2)	19.76	21.03	24.04	21.57
V_{oc-Rv} (V)	0.86	1.04	1.03	1.08
FF$_{Rv}$(%)	66.95	69.19	74.66	73.08
PCE$_{Rv}$(%)	11.38	15.13	18.49	17.03
J_{sc-Fw} (mA/cm^2)	19.30	20.94	24.02	21.55
V_{oc-Fw} (V)	0.83	1.05	1.01	1.05
FF$_{Fw}$(%)	66.79	71.62	73.03	73.52
PCE$_{Fw}$(%)	10.70	15.75	17.72	16.64
Stabilized MPP (%)	10.22	15.13	18.62	17.13

Our work illustrates the importance of the precise composition on structural integrity of the perovskite structure, including segretation into non-perovskite phases and Br- and I-rich perovskites. These are all important aspects for device operation. Compositional changes allow us to to tailor the crystallographic properties and improve the structural stability of perovskite materials. The phase separation phenomenon could be suppressed by incorporating Br$^-$ and limited Cs^+, as well as increasing the crystallization temperature. For instance, No. 37 ($Cs_{1/6}FA_{5/6}PbBr_{1/2}I_{5/2}$) with the incorporated Br$^-$ shows no δ-phase compared with No.36

665   ($Cs_{1/6}FA_{5/6}PbI_3$) annealed at 65 ℃ in Fig. 5A. Thus, the content of δ-$FAPbI_3$ in No.36 is

666   significantly decreased when the Cs^+ substitutes FA^+ and the films are annealed at 65 ℃ (Fig. S7).

667   In addition, the δ-$FAPbI_3$ is removed in composition No. 36 when the samples are annealed at 150

668   ℃. Moving away from pure iodine compounds ($x \geqslant 1/6$), no δ-phases detected, with the exception

669   of the $Cs_{5/6}FA_{1/6}PbBr_{1/2}I_{5/2}$ (No.9) and unknown No.44-46. Interestingly, the δ-$CsPbI_3$ still exists

670   for Cs-rich compositions (e.g. No.29) with I^- as the exclusive X-site halide even though annealed

671   at 150 ℃ (Fig. S31C). There is no appearance of the δ-phase in No.30 ($Cs_{2/6}FA_{4/6}PbBr_{1/2}I_{5/2}$) with

672   the incorporation Br^- compared with No.29 ($Cs_{1/6}FA_{5/6}PbI_3$) even when annealed at 65 ℃ (Fig.

673   6A). Thus, the thermodynamic stability of the perovskite material itself at room temperature is

674   critical to its properties. Concerning the optical and crystallographic properties for solar cell

675   applications, the optimal Br ratio needs to include a analysis of the trade-off between the opposing

676   effects, i.e., the widening of the bandgap and the enhanced structural stability, which believe is in

677   the compositions No.36 and No.37.

678   **Conclusions**

679   Through the systematic exploration of the MA-free $Cs_yFA_{1-y}Pb(Br_xI_{1-x})_3$ compositional space, we

680   have revealed structure-property relationships by combining crystallographic and optoelectronic

681   characterization. We qualitatively discussed the correlation between the Goldschmidt tolerance

682   factor and experimentally identified crystal structures. We showed that Cs-rich compositions

683   exhibit significant phase separation into perovskite phase and non-perovskite δ-phase alongside

684   poor surface morphology, which resulted in low efficiencies once the layers were incorporated in

685   full solar cell stacks. However, there are indications that lower symmetries alone in Cs-rich

686   perovskites lead to lower open-circuit voltages, which is indicative of increased recombination

687   dynamics. In I-rich perovskite compositions, it was found that the bandgap, phase purity and

688   surface morphology of the perovskite phase dominate the performance. Of the explored perovskite

689   compositions, $Cs_{1/6}FA_{5/6}PbI_3$ and $Cs_{1/6}FA_{5/6}PbBr_{1/2}I_{5/2}$ yield the highest efficiencies and

690   operational stability, showing the greatest promise as a material for optoelectronic devices. A

691   concomitant tuning of the charge selective layers for proper energy level alignment to these

692   optimized perovskites may be required in future applications. This work highlights the significance

693   of compositional design to improve the optoelectronic performances of perovskite films, and

694   shows how the analysis of the structure-property relationship for a class of materials can be used

695   to provide deeper insight of their optoelectronic properties.
