Photocatalytic CO<sub>2</sub> reduction to value-added chemicals is appealing but challenging, especially under dilute CO<sub>2</sub> conditions. Herein, we present a molecular modulation strategy for porous metal–salophen organic frameworks (M-SOFs), involving cooperative regulation of the catalytically active metal centers and their local coordination environments for selective photocatalytic CO<sub>2</sub> reduction across a wide range of CO<sub>2</sub> concentrations. The optimal Ni-SOF shows a remarkable photocatalytic CO production rate of 16 908 μmol h<sup>-1</sup> g<sup>-1</sup> and near-unity selectivity under a pure CO<sub>2</sub> atmosphere, along with excellent structural stability. More impressively, it largely preserves the catalytic activity and selectivity even when exposed to dilute CO<sub>2</sub> (5–20 vol%). Both experimental and theoretical analyses support that the specific Ni–N<sub>2</sub>O<sub>2</sub> coordination environment in the Ni-SOF endows it with strong CO<sub>2</sub> binding capacity. This, coupled with nanoporous skeletons, enhances local CO<sub>2</sub> enrichment and facilitates its subsequent conversion at the catalytic centers, thereby leading to superior photocatalytic performances at various CO<sub>2</sub> concentrations.

## Broader context

Solar-driven CO<sub>2</sub> conversion has been considered as an ideal approach for reducing atmospheric CO<sub>2</sub> concentration while producing value-added chemicals and fuels. Over the past decades, tremendous progress has been made in the development of high-performance photocatalysts. Unfortunately, most of them are only operable under high-purity CO<sub>2</sub> conditions. Direct photoreduction of dilute CO<sub>2</sub> is appealing, given that industrial exhaust gases typically contain low concentrations of CO<sub>2</sub>; however, it remains a formidable challenge. The key obstacles lie in the inadequate CO<sub>2</sub> capturing ability of the photocatalysts and unfavourable interactions between catalytic sites and CO<sub>2</sub> molecules. Here, we demonstrate the unique capability of metal–salophen organic frameworks – with properly engineered metal centers and coordination environments – to facilitate the local enrichment and subsequent conversion of CO<sub>2</sub>. The optimal sample shows exceptional photocatalytic performance and near-unity CO<sub>2</sub>-to-CO selectivity across a wide range of CO<sub>2</sub> concentrations.

## Introduction

Excessive CO<sub>2</sub> emissions from fossil fuel combustion have been recognized as the dominant cause of global warming and climate change, posing a significant threat to our economic and environmental sustainability.<sup>1</sup> Several strategies have been proposed to reduce the atmospheric CO<sub>2</sub> concentration, either through physical sequestration or chemical conversion.<sup>2,3</sup> Among them, solar-driven CO<sub>2</sub> reduction to valuable chemicals (e.g., CO, CH<sub>4</sub>, CH<sub>3</sub>OH, and HCOOH) offers a particularly attractive approach by transforming solar energy into chemical energy while neutralizing CO<sub>2</sub> emissions.<sup>4,5</sup> Nevertheless, current investigations are primarily based on pure CO<sub>2</sub> feedstocks. Given that a major source of CO<sub>2</sub> emissions is industrial exhaust gases which contain relatively low CO<sub>2</sub> concentrations typically in the range of 5–20%, the direct conversion of low-concentration CO<sub>2</sub> is more practically relevant and highly

desirable.<sup>6</sup> Unfortunately, limited attempts so far have shown that diluted CO<sub>2</sub> concentrations usually compromise the activity and/or selectivity.<sup>7</sup> This is mainly attributed to inefficient CO<sub>2</sub> capture and unfavorable binding interactions between catalytic sites and substrates.<sup>8</sup> As a result, the rational design of photocatalysts with optimized catalytic centers and CO<sub>2</sub> binding capacity is crucial.

In nature, enzymes can catalyze complicated redox reactions with high activity and specificity towards target products.<sup>9</sup> Their active sites are typically composed of metal cations bound to the amino acid residues of the proteins containing nitrogen (N), sulfur (S), and oxygen (O) atoms. For instance, galactose oxidase is a well-known mononuclear oxidoreductase, in which the Cu center is ligated by two pyrrolic N atoms and two phenolic O atoms.<sup>10</sup> Such a Cu–N<sub>2</sub>O<sub>2</sub> site can efficiently catalyze the two-electron oxidation of primary alcohols to corresponding aldehydes. Inspired by these biocatalysts, great efforts have been devoted to exploiting artificial enzymes in order to mimic the functions of natural molecules.<sup>11–14</sup> Salen or salophen compounds are a type of Schiff-base ligands with planar tetradentate N<sub>2</sub>O<sub>2</sub> sites, capable of accommodating various transition metal ions.<sup>15</sup> By judiciously varying metal catalytic centers and ancillary organic ligands, it is possible to fine-tune their catalytic performances. Benefiting from their structural diversity and easy accessibility, metal–salen/salophen complexes have been widely used as enzyme mimics for different catalytic reactions.<sup>16,17</sup> Nevertheless, their potential in photocatalytic CO<sub>2</sub> reduction has not been explored. This may be partly attributed to the unsatisfactory long-term stability of molecular salen/salophen catalysts during photocatalytic reactions as a result of their aggregation or degradation.<sup>18</sup>

Immobilizing molecular catalysts onto suitable porous hosts offers a potential solution to the above issue. Previous investigations have demonstrated that porous skeletons could enhance the robustness of catalytic sites, and facilitate the enrichment of CO<sub>2</sub> molecules in their vicinity.<sup>19,20</sup> This is of great significance for durable and efficient CO<sub>2</sub> conversion, particularly under diluted CO<sub>2</sub> concentrations.

To this end, here we synthesize a new type of metal–salophen organic framework (M-SOF, M = Co, Ni, Cu, and Zn) by covalently incorporating metal–salophen nodes into porous architectures for the efficient and durable photoreduction of CO<sub>2</sub> at varying concentrations. By tuning the pre-designed organic precursors and metal species, the activity and CO selectivity of the resulting catalysts could be readily modulated. Of particular note is that the Ni-SOF containing Ni–N<sub>2</sub>O<sub>2</sub> centers is the most photocatalytically active; across a wide range of CO<sub>2</sub> concentrations (5–100 vol%), it exhibits an extremely high photocatalytic activity of up to 16 908 μmol h<sup>−1</sup> g<sup>−1</sup> and near-unity selectivity for CO production. Experimental and theoretical studies show that the outstanding catalytic activity of the Ni-SOF originates from its porous frameworks and favorable binding towards CO<sub>2</sub> and reaction intermediates.

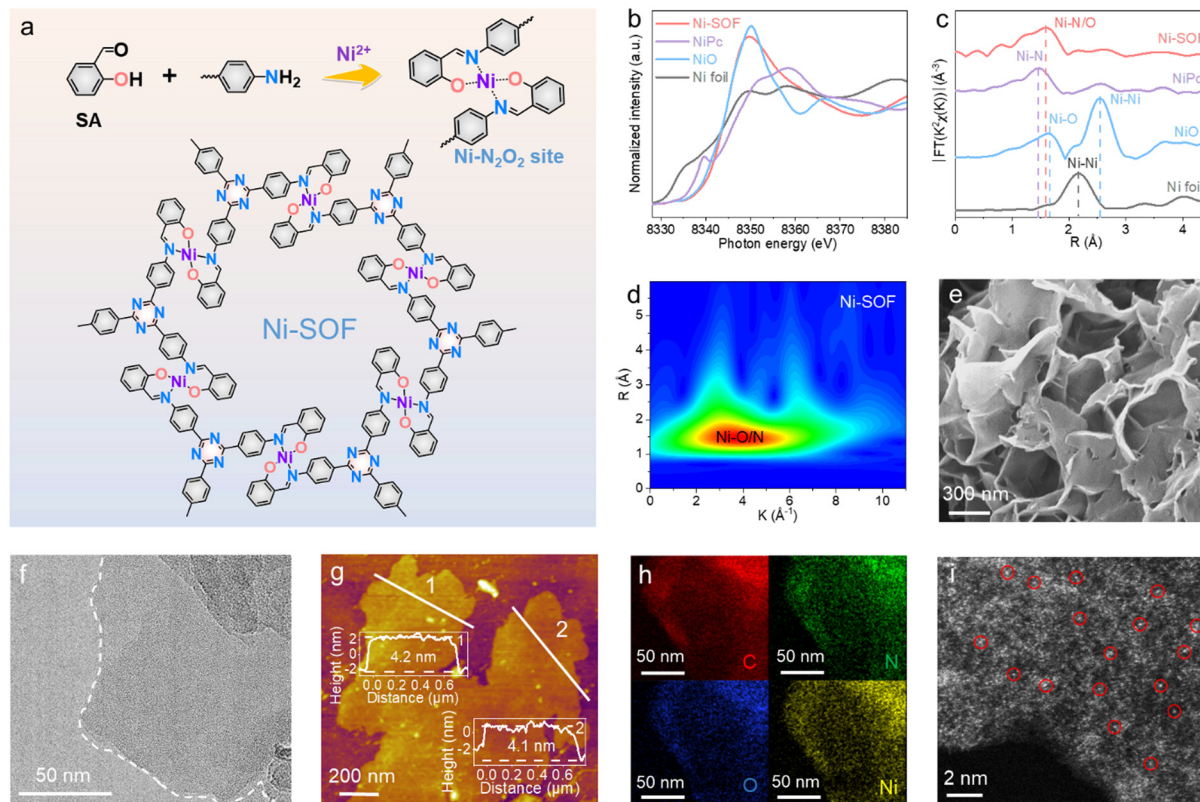

## Results and discussion

Fig. 1a schematically illustrates the synthetic procedure of Ni-SOFs *via* a metal-template-assisted Schiff-base reaction between

salicylaldehyde and 1,3,5-tris(4-aminophenyl)triazine (TAPT) in *N,N*-dimethylformamide (DMF). During the synthesis, salicylaldehyde and nickel acetate were first mixed in DMF at room temperature to form a soluble O-coordinated Ni intermediate (Ni–O<sub>4</sub>), as evidenced by the change in solution color from light green to yellow.<sup>21</sup> The subsequent addition of TAPT initiated the condensation reaction with the aldehyde functionalities of Ni–O<sub>4</sub> at elevated temperatures and ultimately gave rise to an extended coordination polymer with Ni–N<sub>2</sub>O<sub>2</sub> nodes. It is worth noting that such a stepwise synthetic procedure is crucial in order to achieve the desired metal–N<sub>2</sub>O<sub>2</sub> coordination. TAPT is employed as the building block because of its nitrogen-rich composition, which would result in nitrogen-rich porous skeletons to facilitate CO<sub>2</sub> capture. Other samples with different metal centers (Co-SOFs, Cu-SOFs, and Zn-SOFs) were synthesized by adding corresponding metal salts under otherwise identical conditions. To investigate the effect of coordination environments on photocatalysis, N-coordinated Ni–N<sub>4</sub>, and N/S-coordinated Ni–N<sub>2</sub>S<sub>2</sub> were also synthesized by replacing salicylaldehyde with 2-pyridinecarboxaldehyde and 2-mercaptobenzaldehyde, respectively.

The chemical structures of our samples were first interrogated by Fourier transform infrared (FT-IR) and X-ray photoelectron spectroscopy (XPS). For the sake of clarity, the following discussion will be focused on Ni-SOF as a representative unless otherwise specified. From its FT-IR spectrum, the successful condensation between salicylaldehyde and TAPT is evidenced by the disappearance of the –NH<sub>2</sub> stretching vibrations at 3209 and 3321 cm<sup>−1</sup> as well as the emergence of a new peak at 1621 cm<sup>−1</sup> attributed to –CH=N (Fig. S1, ESI<sup>†</sup>).<sup>22</sup> The presence of two peaks at 1361 and 1508 cm<sup>−1</sup>, characteristic of triazine, also signifies the incorporation of TAPT within the coordination networks.<sup>23</sup> Moreover, two weak bands corresponding to Ni–O and Ni–N are observed at 589 and 458 cm<sup>−1</sup>, respectively.<sup>24</sup> They suggest that the coordination nodes in Ni-SOF are formed through the interactions between Ni cations and surrounding imine/hydroxyl groups. Fig. S2 (ESI<sup>†</sup>) summarizes the XPS results of Ni-SOFs. The N 1s spectrum of the Ni-SOF could be deconvoluted into three peaks assigned to pyridinic N in the triazine unit (398.0 eV), C=N (398.8 eV) and Ni–N (399.8 eV).<sup>22</sup> Its O 1s spectrum shows two peaks at 528.3 and 531.6 eV, corresponding to Ni–O and C–O, respectively.<sup>25</sup> The Ni center in the Ni-SOF is determined to be in the divalent state based on its Ni 2p spectrum.<sup>26</sup>

The electronic state and coordination environment of the Ni-SOF were further examined by synchrotron X-ray absorption spectroscopy (XAS). Fig. 1b illustrates its X-ray absorption near-edge structure (XANES) spectrum at the Ni K-edge. The white-line peak of Ni-SOFs is similar to that of NiO, corroborating the divalent state of Ni centers in Ni-SOFs. The corresponding Fourier transform extended X-ray absorption fine structure (EXAFS) spectrum of Ni-SOFs exhibits a prominent peak at 1.60 Å, which is a value between the bonding length of Ni–N in nickel phthalocyanine (NiPc) (1.46 Å) and that of Ni–O in NiO (1.65 Å) (Fig. 1c). This again supports the mixed Ni–N/O first-shell coordination.<sup>27</sup> No Ni–Ni scattering is observed,

**Fig. 1** Synthesis and characterizations of Ni-SOFs. (a) Schematic illustration of the synthetic procedure of Ni-SOFs. (b) XANES and (c) EXAFS spectra of Ni-SOFs, NiPC, NiO and Ni foil. (d) Wavelet transform of the EXAFS spectra of Ni-SOFs. (e) SEM, (f) TEM, (g) AFM, (h) EDS elemental mapping and (i) HAADF-STEM images of Ni-SOFs.

confirming the atomic dispersion of  $\text{Ni}^{2+}$  cations in Ni-SOFs. Further evidence is obtained from the wavelet transform (WT) of the EXAFS spectra (Fig. 1d and Fig. S3, ESI<sup>†</sup>). The maximum WT position of Ni-SOFs apparently differs from those of Ni-N in NiPC and Ni-O in NiO, but partially overlaps with them.

To fully unveil the steric structure of Ni- $\text{N}_2\text{O}_2$  nodes in Ni-SOFs, a model molecule (denoted as Ni-salophen) was synthesized as its mimic and analyzed by single-crystal X-ray diffraction (XRD) measurement (Fig. S4 and Table S1, ESI<sup>†</sup>). It is shown to possess a four-coordinated Ni center with the first coordination sphere consisting of two phenolic O atoms and two imine N atoms. The bond length of Ni-O is calculated to be 1.83 Å, slightly shorter than that of Ni-N (1.91 Å) as a result of the higher electronegativity of O atoms. Two pairs of *trans*-coordinated O and N atoms around the central Ni atom form a nearly planar rhomboid geometry owing to the small differences in bond lengths and bond angles. It is believed that such an open metal center with exposed axial coordination is advantageous for  $\text{CO}_2$  binding and activation.<sup>28</sup>

Scanning electron microscopy (SEM) and transmission electron microscopy (TEM) imaging show that the Ni-SOF consists of crumpled and stacked nanosheets (Fig. 1e and f). Individual nanosheets are estimated to have a size ranging from 200 nm to 1 μm. From atomic force microscopy (AFM) height profiles at multiple locations, the nanosheet thickness is measured to be approximately 4 nm (Fig. 1g). Such an ultrathin nanosheet

geometry is desirable for catalytic applications as it promotes the exposure of inner active sites and maximizes atom utilization. Energy dispersive X-ray spectroscopy (EDS) mapping under scanning transmission electron microscopy (STEM) reveals the uniform distribution of C, N, O and Ni on Ni-SOF nanosheets (Fig. 1h). The aberration-corrected high-angle annular dark-field STEM (HAADF-STEM) image shows discrete bright spots (some marked with red circles) corresponding to heavy Ni atoms, corroborating the atomic dispersion of Ni sites throughout the examined region (Fig. 1i). Moreover, the Ni content in Ni-SOFs is found to be 10.5 wt% as analyzed by inductively coupled plasma mass spectrometry (ICP-MS), which is in good agreement with the theoretical value (10.2 wt%).  $\text{N}_2$  isotherm sorption measurements show that the Ni-SOF has a specific surface area of  $116 \text{ m}^2 \text{ g}^{-1}$  (Fig. S5, ESI<sup>†</sup>). In addition to Ni-SOFs, the structures of other samples with different metal sites and coordination environments were also characterized, and results are summarized in the ESI<sup>†</sup> (Fig. S6–S8 and Table S2).

We evaluated the photocatalytic performance of our samples under pure  $\text{CO}_2$ . The reactions were conducted in a mixed solution of acetonitrile and water under visible light irradiation ( $\lambda > 420 \text{ nm}$ ) using  $[\text{Ru}(\text{bpy})_3]\text{Cl}_2$  as the photosensitizer and triisopropanolamine (TIPA) as the hole scavenger. Gaseous products (e.g.,  $\text{CO}$  and  $\text{H}_2$ ) were analyzed and quantified by gas chromatography (GC) based on their calibration curves (Fig. S9, ESI<sup>†</sup>). We explored different solvent ratios, catalyst

frameworks with improved structural robustness and catalytic stability. The excellent stability of Ni-SOFs is also supported by the cycling experiment showing no noticeable performance loss after a total of 40 h illumination (Fig. 2e). In addition, the ICP-MS analysis of the reaction filtrate after the cycling test reveals a negligible Ni concentration (0.264 ppm), thus ruling out the possibility of Ni leaching out of Ni-SOFs during photocatalysis. Spectroscopic and microscopic analyses of the recovered Ni-SOF disclose no discernable structural changes (Fig. S15, ESI<sup>†</sup>).

Effective charge transfer from the photosensitizer to the catalytic sites is a prerequisite for initiating redox reactions. To probe the charge transfer behavior between  $[\text{Ru}(\text{bpy})_3]^{2+}$  and Ni-SOFs, steady-state and time-resolved photoluminescence (PL) spectroscopy studies were conducted. As shown in Fig. S16 (ESI<sup>†</sup>), the steady-state PL peak intensity of  $[\text{Ru}(\text{bpy})_3]^{2+}$  gradually decreases as the Ni-SOF concentration increases, while the TIPA concentration has no significant effect on the

PL intensity. Corresponding Stern–Volmer plots show the much higher quenching efficiency of Ni-SOFs than TIPA. These results reveal that the electron transfer from the photosensitizer to the catalyst is the initial step of the photocatalytic cycle.<sup>32</sup> The time-resolved PL spectrum of  $[\text{Ru}(\text{bpy})_3]^{2+}$  follows a single exponential decay with an average PL lifetime of 237 ns, consistent with literature results (Fig. 3a).<sup>50</sup> In the presence of Ni-SOFs, a double-exponential decay is observed with fitted lifetimes of 0.49 ns and 225 ns (Fig. 3b). The former is attributed to the charge transfer between  $[\text{Ru}(\text{bpy})_3]^{2+}$  and Ni-SOFs. Compared to those measured in the presence of other M-SOFs (M = Co, Cu, and Zn), the shorter lifetime observed with Ni-SOFs at the early stage suggests more efficient electron transfer (Fig. S17, ESI<sup>†</sup>).<sup>51</sup> Moreover, electron paramagnetic resonance (EPR) spectroscopy was conducted (Fig. 3c). Upon irradiation, a sharp EPR signal ascribed to  $\text{Ni}^+$  is observed at  $g = 2.06$ ,<sup>52</sup> while it becomes significantly attenuated upon  $\text{CO}_2$

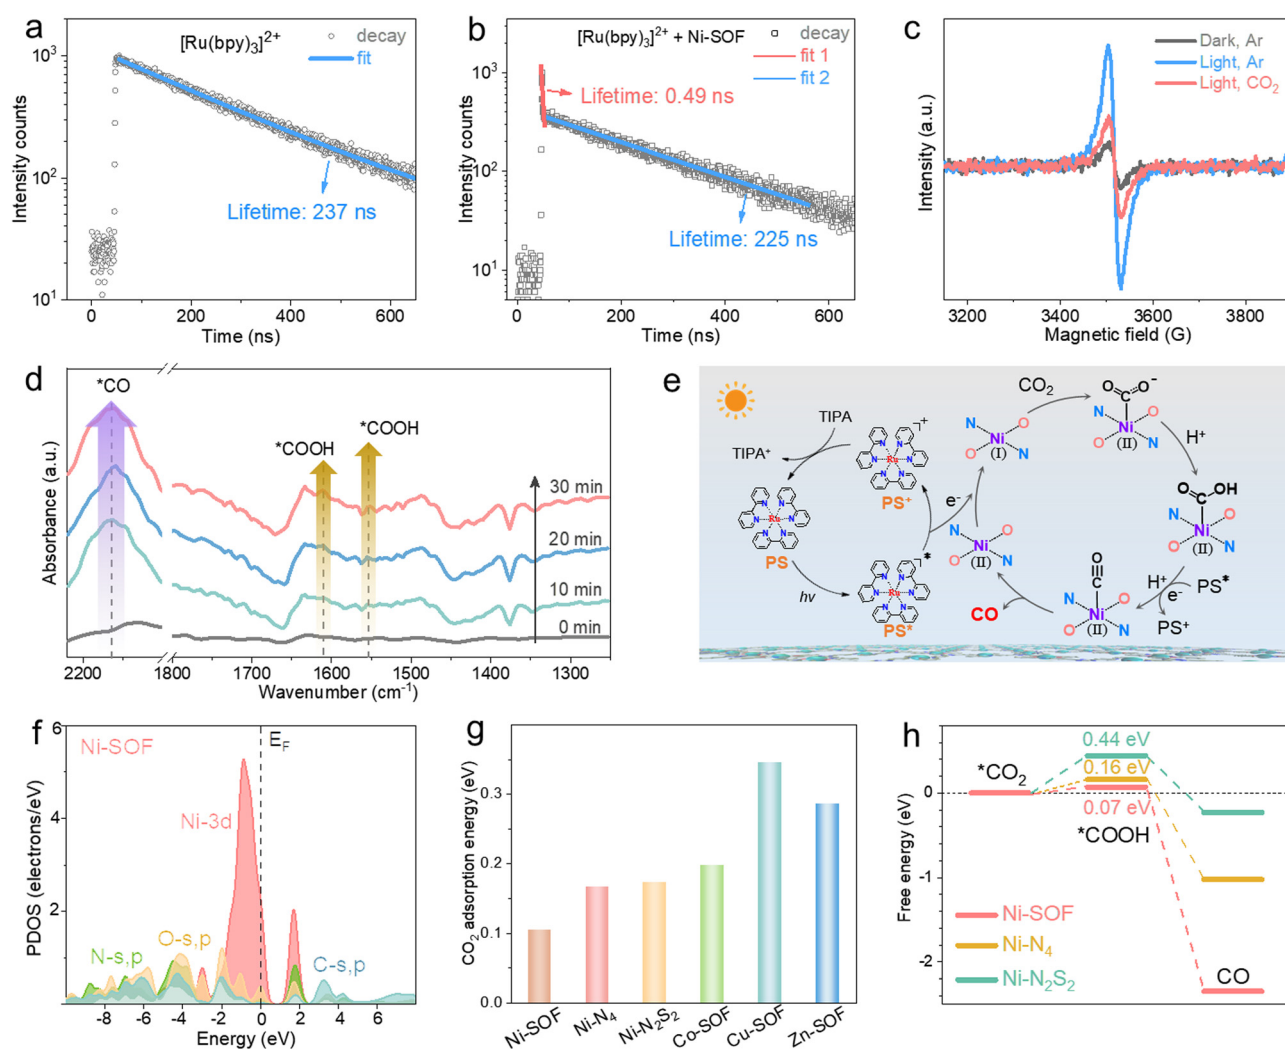

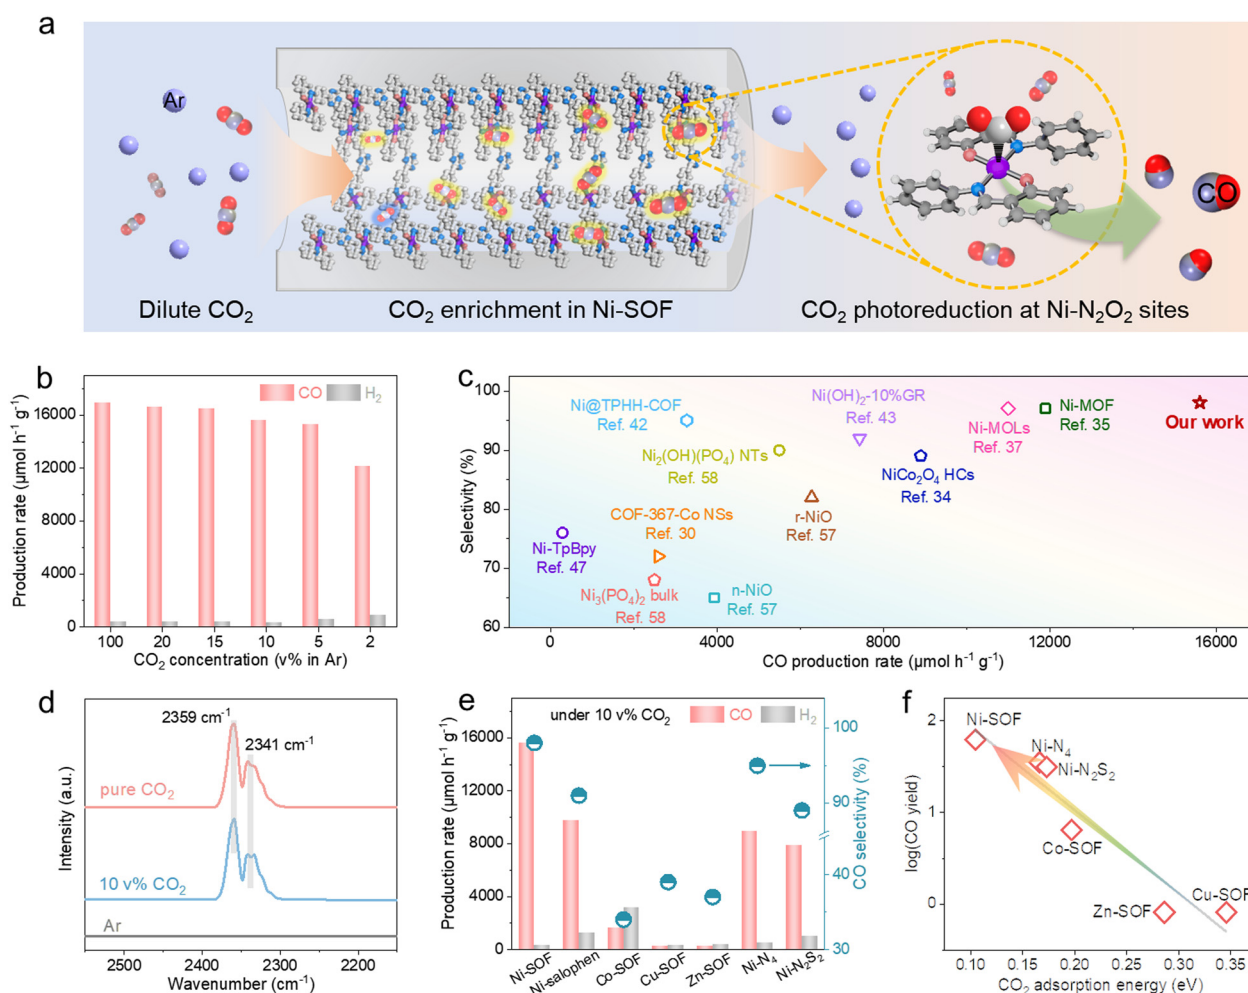

Fig. 3 Charge transfer kinetics and possible reaction mechanism. (a) and (b) Time-resolved PL spectra of (a)  $[\text{Ru}(\text{bpy})_3]\text{Cl}_2$  and (b)  $[\text{Ru}(\text{bpy})_3]\text{Cl}_2$  + Ni-SOF in acetonitrile. (c) EPR spectra of Ni-SOFs under different conditions. (d) *Operando* DRIFTS spectra of Ni-SOFs under irradiation for different durations of time. (e) Schematic illustration of the proposed catalytic cycle. (f) PDOS spectra of Ni-SOFs. (g)  $\text{CO}_2$  adsorption energy on different catalysts. introduction. Considering that  $\text{Ni}^{2+}$  is EPR-silent, this observation indicates that  $\text{Ni}^{2+}$  sites can readily accept electrons from the excited photosensitizer, and subsequently transfer them to  $\text{CO}_2$  to initiate the reduction reaction. The  $\text{CO}_2$  reduction process was then be tracked by *in situ* diffuse reflectance infrared Fourier transform spectroscopy (DRIFTS). Fig. 3d clearly shows the vibration bands from intermediates within a 30-minute irradiation period. The two peaks at  $1611$  and  $1552\text{ cm}^{-1}$  are characteristic of the  $\text{*COOH}$  intermediate, and their peak intensity increases as the irradiation continues.<sup>53</sup> In the meantime, a pronounced  $\text{*CO}$  adsorption peak at  $2163\text{ cm}^{-1}$  is also observed, indicating a high  $\text{*CO}$  surface coverage under irradiation.<sup>54</sup>

Based on the above spectroscopic results, a possible mechanism for  $\text{CO}_2$  photoreduction is proposed and illustrated in Fig. 3e. Upon visible light irradiation,  $[\text{Ru}(\text{bpy})_3]^{2+}$  (PS) is promoted to its excited state ( $\text{PS}^*$ ). Subsequently, photoexcited electrons are transferred to the  $\text{Ni}^{2+}$  sites of Ni-SOFs within a

short time scale, generating catalytically active  $\text{Ni}^+$  centers. The oxidized photosensitizer ( $\text{PS}^+$ ) is then reduced back to its ground state by accepting electrons from TIPA. Electrons located on the  $\text{Ni}^+$  centers are further transferred to adsorbed  $\text{CO}_2$ , initiating the reduction reaction which involves the sequential formation of  $\text{*COOH}$  and  $\text{*CO}$  intermediates. At the end,  $\text{*CO}$  desorbs from the catalyst surface, thus stopping the reaction cycle.

To gain more insights into the catalytic mechanism, density functional theory (DFT) calculations were performed. The electronic distribution diagrams of Ni-SOFs,  $\text{Ni-N}_4$ , and  $\text{Ni-N}_2\text{S}_2$  near the Fermi level ( $E_F$ ) are depicted in Fig. S18 (ESI<sup>†</sup>). The maximum bonding orbital distribution is located closer to Ni in Ni-SOFs compared to those in  $\text{Ni-N}_4$  and  $\text{Ni-N}_2\text{S}_2$ , suggesting the electron-rich feature of Ni sites in Ni-SOFs. The electronic modulation of metal centers by the coordination environment is evident from the projected partial density of states (PDOS) analysis. As shown in Fig. 3f, the Ni-3d orbitals of Ni-SOFs

exhibit a sharp peak near  $E_F$  at  $E_v - 0.88$  eV ( $E_v = 0$  eV). The s, p orbitals of O and N sites have good overlaps with the Ni-3d orbitals, indicating their strong binding interactions with central Ni atoms are necessary for the formation of a stable coordination configuration and efficient site-to-site electron transfer.<sup>55</sup> By comparison, the metallic 3d orbitals of other catalysts (Ni-N<sub>4</sub>, Ni-N<sub>2</sub>S<sub>2</sub>, Co-N<sub>2</sub>O<sub>2</sub>, Cu-N<sub>2</sub>O<sub>2</sub>, and Zn-N<sub>2</sub>O<sub>2</sub>) are located at more negative positions related to their  $E_F$  with obviously decreased overlaps with the s and p orbitals of surrounding heteroatoms (Fig. S19, ESI†). The d-band center and optical absorption comparisons also confirm the improved catalytic activity and optical properties of Ni-SOFs to promote the photocatalytic performances of CO<sub>2</sub> reduction (Fig. S20, ESI†).

Furthermore, CO<sub>2</sub> adsorption energies on different catalysts were calculated and compared (Fig. 3g). The Ni-SOF has the lowest adsorption energy, suggesting its strongest binding with CO<sub>2</sub>. This result is corroborated by the temperature programmed CO<sub>2</sub> desorption (TPD) measurements showing that the Ni-SOF has the largest CO<sub>2</sub> desorption capacity and highest desorption temperature (Fig. S21, ESI†). Favorable CO<sub>2</sub> binding ability is believed to be conducive to CO<sub>2</sub> capture and enrichment around the catalytic sites, thereby accelerating CO<sub>2</sub> conversion.<sup>56</sup> In addition, the free energy profiles of different catalysts during CO<sub>2</sub> reduction were simulated. The conversion from \*CO<sub>2</sub> to \*COOH is found to be the rate-determining step (RDS) for all the catalysts (Fig. 3h and Fig. S22, ESI†). Among them, the Ni-SOF shows the smallest energy barrier of 0.07 eV, indicating that the redox reaction on the Ni-SOF is the most favorable. Further conversion from \*COOH to CO is exothermic and thereby spontaneous once \*COOH is formed.

Encouraged by the great catalytic capacity and favorable CO<sub>2</sub> binding of the Ni-SOF, we moved on to assess its catalytic performance at dilute CO<sub>2</sub> concentrations. Fig. 4a schematically illustrates the local enrichment and subsequent photo-reduction of diluted CO<sub>2</sub> within the porous skeletons of Ni-SOFs. As demonstrated in Fig. 4b and Fig. S23 (ESI†), the Ni-SOF exhibits an exceptional catalytic performance at varying CO<sub>2</sub> concentrations. Both the CO production rate and selectivity remain largely stable across a wide range of CO<sub>2</sub> concentrations from 5 to 20 vol% in Ar. At a CO<sub>2</sub> concentration as low as 2 vol%, the mass-specific CO production rate is measured to be 12 100  $\mu\text{mol h}^{-1} \text{g}^{-1}$ , retaining 72% of the value achieved under pure CO<sub>2</sub> as well as a high CO selectivity of 93%. Moreover, the AQE value at 10 vol% CO<sub>2</sub> is 2.7% at 450 nm, which is very close to that obtained under pure CO<sub>2</sub> (2.8%) (Fig. S24, ESI†). To the best of our knowledge, such high activity and selectivity have rarely been achieved before under dilute CO<sub>2</sub> (Fig. 4c and Table S4, ESI†),<sup>37,43,57,58</sup> exceeding those of other organic and inorganic candidates, even measured under pure CO<sub>2</sub>.<sup>34,42</sup> The DRIFTS spectra of Ni-SOFs under pure and diluted (10 vol%) CO<sub>2</sub> show two identical absorption bands at 2359 and 2341  $\text{cm}^{-1}$ , assigned to adsorbed CO<sub>2</sub> with the end-on configuration (Fig. 4d).<sup>59</sup> Importantly, their peak intensity and integrated areas are found to be largely independent of the CO<sub>2</sub> concentration. This implies that Ni-SOFs can enrich local CO<sub>2</sub> concentration when the feedstock becomes much diluted and may rationalize

the exceptional photocatalytic activity measured under low-concentration CO<sub>2</sub>.

The great photocatalytic performance under low-concentration CO<sub>2</sub> appears to be unique to Ni-SOFs. Ni-salophen presents considerably lower activity despite its similar coordination environment with Ni-SOFs (Fig. 4e). Replacing the central Ni with Co results in a decreased mass-specific activity of 2167  $\mu\text{mol h}^{-1} \text{g}^{-1}$  (more than 4 times lower than that under pure CO<sub>2</sub> on Co-SOFs) and low CO selectivity of 34%. More strikingly, CO<sub>2</sub> photoreduction on Cu-SOFs and Zn-SOFs becomes almost quenched under the same conditions. Furthermore, both Ni-N<sub>4</sub> and Ni-N<sub>2</sub>S<sub>2</sub> exhibit about half of the activity of Ni-SOFs under 10 vol% CO<sub>2</sub>. We note that the measured activity here is roughly correlated with the CO<sub>2</sub> binding energy predicted in Fig. 4f. The strongest binding affinity of Ni-SOF affords our catalyst with the most appealing activity by enriching CO<sub>2</sub> local concentration and facilitating its subsequent conversion.

## Conclusions

In summary, we synthesized a new class of M-SOF materials *via* facile metal-assisted Schiff-base reactions for efficient photocatalytic CO<sub>2</sub> reduction. All the samples are composed of atomically dispersed metal sites and controlled local coordination environments, both of which could be precisely modulated *via* varying the pre-designed organic moieties and metal species. The optimal sample, the Ni-SOF with Ni-N<sub>2</sub>O<sub>2</sub> nodes, showed the highest CO production rate of 16 908  $\mu\text{mol h}^{-1} \text{g}^{-1}$  with an excellent selectivity up to 98%. Impressively, the Ni-SOF was able to maintain its photocatalytic performance across a wide range of CO<sub>2</sub> concentrations (5–20 vol% in Ar) without reducing the selectivity. Experimental and theoretical studies revealed that the superior catalytic performance of Ni-SOFs mainly originated from the favorable d-band electronic modulation of the coordinated Ni atoms and optimal binding strength with the intermediates. In particular, the strong CO<sub>2</sub> affinity of Ni-SOFs is identified as the key factor for the efficient conversion of diluted CO<sub>2</sub>. Our study demonstrates a promising strategy for rationalizing the chemical and electronic configurations of metal catalytic centers toward the direct utilization of diluted CO<sub>2</sub> from industrial exhaust gas.

## Author contributions

Y. L. and W. H. conceived the project and designed the experiments. X. Y. synthesized the catalysts and conducted the structure analysis and photocatalytic tests. B. H. and M. S. performed the theoretical calculations. T. Y. and L. Z. conducted the X-ray absorption measurements. L. J. carried out TEM characterization studies. M. C. performed TPD measurements. X. Y., M. S., W. H., B. H., and Y. L. co-wrote the paper. All authors discussed the results and commented on the manuscript.
