Mechanisms and applications of cyclometalated Pt(II) complexes in photoredox catalytic trifluoromethylation†

Won Joon Choi,^a Sungkyu Choi,^b Kei Ohkubo,^c Shunichi Fukuzumi,^{*c} Eun Jin Cho^{*b} and Youngmin You^{*a}

The incorporation of a trifluoromethyl group into an existing scaffold can provide an effective strategy for designing new drugs and agrochemicals. Among the numerous approaches to trifluoromethylation, radical trifluoromethylation mediated by visible light-driven photoredox catalysis has gathered significant interest as it offers unique opportunities for circumventing the drawbacks encountered in conventional methods. A limited understanding of the mechanism and molecular parameters that control the catalytic actions has hampered the full utilization of photoredox catalysis reactions. To address this challenge, we evaluated and investigated the photoredox catalytic trifluoromethylation reaction using a series of cyclometalated Pt(II) complexes with systematically varied ligand structures. The Pt(II) complexes were capable of catalyzing the trifluoromethylation of non-prefunctionalized alkenes and heteroarenes in the presence of CF₃I under visible light irradiation. The high excited-state redox potentials of the complexes permitted oxidative quenching during the cycle, whereas reductive quenching was forbidden. Spectroscopic measurements, including time-resolved photoluminescence and laser flash photolysis, were performed to identify the catalytic intermediates and directly monitor their conversions. The mechanistic studies provide compelling evidence that the catalytic cycle selects the oxidative quenching pathway. We also found that electron transfer during each step of the cycle strictly adhered to the Marcus normal region behaviors. The results are fully supported by additional experiments, including photoinduced ESR spectroscopy, spectroelectrochemical measurements, and quantum chemical calculations based on time-dependent density functional theory. Finally, quantum yields exceeding 100% strongly suggest that radical propagation significantly contributes to the catalytic trifluoromethylation reaction. These findings establish molecular strategies for designing trifluoromethyl sources and catalysts in an effort to enhance catalysis performance.

Introduction

The recent development of visible light-driven photoredox catalysis has attracted renewed interest in radical-mediated organic syntheses.^{1–21} A wide variety of radical transformations that have been difficult to accomplish using conventional initiators can be carried out through photoredox catalysis. The most notable example of photoredox catalysis, which highlights the value of the reaction, is trifluoromethylation. While trifluoromethylation significantly improves the activities of drugs and agrochemicals, such as their metabolic stabilities, binding selectivities, and bioavailabilities,^{22–26} its high electron deficiency precludes reactions based on substitution methodologies. Trifluoromethylation has thus relied on the use of toxic transition metal catalysts, such as those containing Pd^{27–37} and Cu.^{38–51} Photoredox catalytic trifluoromethylation provides a promising alternative to these existing methods, as it utilizes the environmentally benign photon.⁵² The mild reaction

conditions tolerate a variety of functional groups and, thus, are amenable to the post-modification of bioactive molecules.^{53–55}

Photoredox catalysed trifluoromethylation reactions typically employ coordinatively saturated 4d or 5d transition metal complexes, such as Ru(II) polypyridine complexes^{53–66} and cyclometalated Ir(III) complexes,^{64,67–70} as the catalysts. Photoexcitation of these complexes promotes the formation of a long-lived triplet metal-to-ligand charge-transfer (³MLCT) transition state, in which the one-electron oxidized metal core and the one-electron reduced ligand act as the oxidant and reductant, respectively. A variety of reagents, such as CF₃I,^{55,60–62,64,67,71,72} silver trifluoroacetate,⁷³ triflyl chloride (CF₃SO₂Cl),^{54,69} the Langlois reagent,⁷⁴ the Togni reagent,^{56,58,59,65,70} the Umemoto reagent,^{53,57,63,68,70} and the Shibata reagent,⁶⁶ can serve as trifluoromethyl radical ([•]CF₃) sources,⁷⁵ and the key step involves the reductive cleavage of these reagents under photoirradiation of the catalyst. Two possible routes to the reductive generation of [•]CF₃ are available (Scheme 1). The photoexcited catalyst can directly deliver an electron to the [•]CF₃ source (oxidative quenching pathway), followed by the reductive regeneration of the catalyst by an electron donor. Alternatively, the photoexcited catalyst may be preferentially reduced by an electron donor to a one-electron reduced species that subsequently transfers an extra electron to the [•]CF₃ source (reductive quenching pathway). Although the net reactions are identical (*i.e.*, CF₃X + donor → [•]CF₃ + donor⁺⁺ + X[–]), each of two pathways involves reductants with distinct stabilities and thermodynamic driving forces for reductive cleavage. As shown in Scheme 1, the oxidative and reductive quenching pathways involve the photoexcited catalyst

and one-electron reduced catalyst, respectively, as the reductants. In most cases, photoredox catalysts, such as [Ru(bpy)₃]²⁺ and *fac*-Ir(ppy)₃ (bpy = 2,2'-bipyridine and ppy = 2-phenylpyridinate), can promote both oxidative^{53,54,56–59,63,65,68–70} and reductive^{55,60–62,64,67,74} quenching cycles, due to the positive driving forces for electron transfer to typical [•]CF₃ sources and from electron donors.⁷ The presence of two competing pathways hampers the elucidation and optimization of the molecular parameters associated with the catalysis. Further developments are needed to identify photoredox catalysts that select a single quenching process. This need prompted us to employ cyclometalated Pt(II) complexes as photoredox catalysts for trifluoromethylation reactions. The cyclometalated structure between a Pt(II) core and an anionic cyclometalating (C^N) ligand can cathodically shift the excited-state redox potentials. This effect provides the thermodynamic conditions needed to suppress excited-state reduction while enabling excited-state oxidation of the Pt complex. Thus, the resulting photoredox catalysis reaction strictly follows an oxidative quenching cycle. The additional benefits of using Pt(II) complexes are enormous. The complexes can be easily modified, allowing the molecular parameters to be synthetically tailored. Control over the substituents in the C^N ligands provides a viable approach to tuning the excited-state redox potentials and lifetimes of the complexes. Molecular design efforts can benefit from the rich knowledge established in previous studies of Pt(II) complexes in the context of electrophosphorescence and sensors.^{76–79} Taking advantage of these properties, photoredox catalytic applications of Pt(II) complexes in polymerization,^{80,81} hydrogen

production,⁸² and oxidation reactions^{83,84} have been demonstrated. It is, however, noted that trifluoromethylation by a Pt(II) complex has yet to be established.

Here, we report the first demonstration of photoredox catalytic trifluoromethylation using cyclometalated Pt(II) complexes. Key intermediates in the photoredox catalytic cycle were monitored directly using spectroscopic techniques. The spectroscopic identification of catalytic intermediates in the visible light-driven trifluoromethylation reaction is unprecedented. Mechanistic studies revealed that the photoredox catalysis involves an oxidative quenching pathway. The kinetic parameters associated with each step of the catalytic cycle were determined, providing novel insights into enhancing the catalysis performance.

Results and discussion

Synthesis and properties of the Pt(II) complex catalysts

A series of prototypical Pt(II) complexes having CAN ligands with different electron densities, 2-(2,4-difluorophenyl)pyridinate, 2-phenylpyridinate, and 2-(3-methoxyphenyl)pyridinate (Ptddfpy, Ptppy, and PtOMe, respectively, in Scheme 1), were tested here.⁸⁵ The ligand environment around the Pt(II) center

was completed by non-photoactive acetylacetonate ancillary ligands. The complexes were prepared through a modified procedure based on the protocol reported by Zhao and co-workers.⁸⁶ All compounds were characterized using standard spectroscopic methods, including ¹H, ¹³C, and ¹⁹F NMR spectroscopy, mass spectrometry, and elemental analysis. The spectroscopic identification data agreed fully with the proposed structures (see ESI†).

The UV-vis absorption spectra of the Pt(II) complexes (10 μM in CH₃CN) featured characteristic MLCT transition bands at 380 nm (log ε = 3.76; Ptddfpy), 386 nm (log ε = 3.91; Ptppy), and 420 nm (log ε = 3.78; PtOMe), with tails that approached the visible regions (Fig. 1a).^{85,87,88} Strong photoluminescence emission was observed upon photoexcitation of the MLCT bands at room temperature (see ESI, Fig. S1† for the photoluminescence spectra). The photoluminescence lifetimes (τ_{obs}) of the emission were on the order of submicroseconds or microseconds, indicating phosphorescence (Fig. 1b). It should be noted that the τ_{obs} value increased by two orders of magnitude as the electron richness of the CAN ligand was increased (*i.e.*, in PtOMe). The slow decay was indicative of weak MLCT contributions to the spin-forbidden electronic transition. Indeed, the MLCT character estimated by time-dependent density functional theory (CPCM(CH₃CN)-TD-B3LYP/LANL2DZ:6-311+G(d,p)//B3LYP/LANL2DZ:6-311+G(d,p)) was significantly smaller in the PtOMe complex (15%) than in the Ptddfpy complex (28%) (Table 1). Therefore, the triplet state responsible for phosphorescence emission can be best described as an admixture of the MLCT, ligand-centered (LC) π - π^* , and intra-ligand charge-transfer (ILCT) transitions. The large variations in τ_{obs} were useful for examining the notion of whether a long-lifetime catalyst could exhibit better photoredox catalytic performance (*vide infra*). The photophysical data, including the photoluminescence quantum yields (PLQY) and the triplet-state energies (ΔE_{T}) of the Pt(II) complexes are summarized in Table 1.

The ground-state redox potentials of the Pt(II) complexes were determined by cyclic voltammetry (CV), and were further verified using differential pulse voltammetry (DPV). Quasi-reversible (Ptddfpy) and irreversible (Ptppy and PtOMe) oxidation waves were measured at 0.52–0.62 V vs. SCE (see ESI,

^a 10 μM in acetonitrile solutions, 298 K. ^b Photoluminescence quantum yields determined relative to the fluorescein standard (0.1 N NaOH (aq), PLQY = 0.79). ^c MLCT contribution to the triplet transition estimated using AOMix based on the TD-DFT (CPCM(CH₃CN)-TD-B3LYP/LANL2DZ:6-311+G(d,p)//B3LYP/LANL2DZ:6-311+G(d,p)) results. ^d Triplet-state energy determined from the phosphorescence spectra. ^e Determined using cyclic and differential pulse voltammetry. Conditions: scan rate = 100 and 0.4 mV s^{−1} for CV and DPV, respectively; 1.0 mM Pt complex in Ar-saturated acetonitrile containing the 0.10 M Bu₄NPF₆ supporting electrolyte; a Pt wire counter electrode and a Pt microdisc working electrode; the Ag/AgNO₃ couple as the pseudo-reference electrode; qr = quasi-reversible; irr = irreversible. ^f Estimated using $E_{\text{red}} = E_{\text{ox}} - \Delta E_{\text{g}}$, where ΔE_{g} is the optical band gap energy: Ptddfpy, 3.08 eV; Ptppy, 2.95 eV; PtOMe, 2.72 eV. ^g $E_{\text{ox}}^g = E_{\text{ox}} - \Delta E_{\text{T}}$. ^h $E_{\text{red}}^h = E_{\text{red}} + \Delta E_{\text{T}}$. ⁱ Photoluminescence lifetimes observed at λ_{em} = 465 nm (Ptddfpy), 483 nm (Ptppy), and 543 nm (PtOMe). The measurements were collected in triplicate.

Fig. S2† for the voltammograms), corresponding to the $\text{Pt}^{\text{III/II}}$ redox couple.⁸⁸ These oxidation potentials (E_{ox}) were more positive than the E_{ox} value (0.47 V vs. SCE) of N,N,N',N' -tetramethylethylenediamine (TMEDA), a sacrificial electron donor. Because reduction was not observed until -1.8 V vs. SCE, the reduction potentials (E_{red}) for the $\text{Pt}(\text{II})$ complexes were calculated according to the relationship, $E_{\text{red}} = E_{\text{ox}} - \Delta E_{\text{g}}$, where ΔE_{g} is the optical band gap energy. As summarized in Table 1, the E_{red} value shifted cathodically as the electron density of the C \equiv N ligand decreased. The same trend was observed in the excited-state oxidation potential ($E_{\text{ox}}^* = E_{\text{ox}} - \Delta E_{\text{T}}$), whereas the excited-state reduction potential ($E_{\text{red}}^* = E_{\text{red}} + \Delta E_{\text{T}}$) remained relatively unchanged across the series of the $\text{Pt}(\text{II})$ complexes (Table 1). The changes in the E_{ox}^* values were dominated by ΔE_{T} rather than E_{ox} , as inferred from $\Delta \Delta E_{\text{T}}$ (0.28 eV) $>$ $e \Delta E_{\text{ox}}$ (0.10 eV; e is the elementary charge). The E_{ox}^* values (-2.11 to -1.93 V vs. SCE),⁸⁹ determined by DPV (ESI, Fig. S3†), indicating that the photoexcited Pt complexes could donate an electron to CF_3I under the driving force for the photoinduced electron transfer ($-\Delta G_{\text{PET}} = e[E_{\text{ox}}^*(\text{Pt}) - E_{\text{red}}(\text{CF}_3\text{I})]$) of 1.02–1.20 eV. The photoexcited complexes could not be reduced by TMEDA, as indicated by the negative driving force ($-\Delta G_{\text{PET}} = e[E_{\text{ox}}(\text{TMEDA}) - E_{\text{red}}(\text{Pt})] = -0.20 \sim -0.22$ eV).

Trifluoromethylation of non-prefunctionalized alkenes and heteroarenes

The $\text{Pt}(\text{II})$ complexes were evaluated for their activity in the photoredox catalytic trifluoromethylation of non-prefunctionalized sp^2 carbons. We employed CF_3I as a $^{\cdot}\text{CF}_3$ source. Trifluoromethylation of 0.50 mmol terminal alkenes was carried out in a deaerated acetonitrile solution (2.0 mL) containing 1.0 mol% Pt catalyst, 1.0 mmol DBU and 1.5 mmol CF_3I . The reaction mixture was photoirradiated using blue LEDs (450 nm,

^a An oven-dried resealable test tube equipped with a magnetic stirrer bar was charged with an alkene (0.50 mmol), sealed with a screw-cap, and degassed by alternating between putting under vacuum and backfilling with argon. A solution of Ptppy (1.0 mol%, 0.0050 mmol) in CH_3CN (2.0 mL, 0.25 M) and DBU (1.0 mmol) was then added to the tube under argon. CF_3I (1.5 mmol) was then delivered to the reaction mixture using a gastight syringe. The test tube was placed under blue LEDs (7 W) at room temperature for 5–10 h, and the progress of each reaction was monitored by TLC or gas chromatography. ^b The given yields are isolated yields reported as the average of two runs, except for **2b** (entry 2), which was monitored using ^{19}F NMR due to the volatility of the product. ^c The E/Z ratio was determined by ^1H NMR spectroscopy and gas chromatography.

Fig. 2 Photoredox catalytic trifluoromethylation of 1-dodecene (circles) and N -methylpyrrole (triangles) by Ptddppy (blue), Ptppy (green), and PtOMe (red). Empty and filled symbols correspond to the substrates and the trifluoromethylated products, respectively. Conditions: 2.0 mL of a deaerated acetonitrile solution containing 0.50 mmol substrate, 0.010 mmol Pt catalyst, 1.0 mmol TMEDA (or 1.0 mmol DBU), and 1.5 mmol CF_3I was photoirradiated under blue LEDs (450 nm, 7 W) at room temperature. The progress of the reaction was monitored using gas chromatography, with dodecane as the internal standard.

7 W) at room temperature, and the progress of the reaction was monitored using gas chromatography or thin-layer chromatography. The same method was applied to the trifluoromethylation of heteroarenes, except that 1.0 mmol TMEDA was used in place of DBU. The reaction conditions were optimized by testing several bases, DIPEA, TEA, K_3PO_4 , K_2HPO_4 , and KO^tBu , and by testing several solvents, DMF, CH_3OH , and CH_2Cl_2 . The optimization results revealed that the protocols described above worked best (ESI, Tables S1 and S2†). As demonstrated in Fig. 2, the trifluoromethylation of 1-dodecene

^a An oven-dried resealable test tube equipped with a magnetic stirrer bar was charged with an acetonitrile solution (2.0 mL) containing heteroarene (0.50 mmol), TMEDA (1.0 mmol), and Ptppy (2.0 mol%), and sealed with a screw-cap. The reaction mixture was degassed by alternating between putting under vacuum and backfilling with argon, after which CF₃I (1.5 mmol) was delivered using a gastight syringe. The test tube was placed under blue LEDs (7 W) at room temperature for 10–24 h, while the progress of each reaction was monitored by TLC. ^b The given yields are isolated yields obtained by taking the average of two runs, except for **4a** (entry 1), which was monitored using ¹⁹F NMR due to the volatility of the product. ^c Trifluoromethylation at the phenyl moiety of indole occurred at <10% (¹⁹F NMR and GC).

and *N*-methylpyrrole went to completion within 6 h and 30 h, respectively. The trifluoromethylated products were not detected without the Pt catalyst nor photoirradiation (ESI, Tables S1–S3†), confirming that the photoexcited catalysts were responsible for the observed reactivities. Under the optimized conditions, the Pt(II) complexes exhibited catalytic activities comparable to the well-established photoredox catalysts, such as [Ru(bpy)₃]Cl₂ and [Ir(ppy)₂(dtbbpy)]PF₆ (dtbbpy = 4,4′-di(*t*-butyl)-2,2′-bipyridine). The scope of the Pt(II) complex-mediated trifluoromethylation was investigated over a range of alkenes and heteroarenes (Tables 2 and 3). The isolated yields of the trifluoromethylated alkenes exceeded 82%, whereas moderate yields were obtained from the trifluoromethylation of heteroarenes. The trifluoromethylation reaction was highly tolerant of the presence of a variety of functional groups, including hydroxyl (**2c**), silylether (**2d**), ester (**2e**, **2f** and **4b**), amide (**2g** and **2h**), carbonate (**2i**), and sulfonate (**2j**) groups. Spectroscopic data for the trifluoromethylated alkenes and heteroarenes listed in Tables 2 and 3 are summarized in the ESI.† These results

successfully demonstrate that the cyclometalated Pt(II) complexes are promising alternatives to conventional photoredox catalysts based on Ir(III) and Ru(II) complexes for trifluoromethylation.

Scheme 2 illustrates the proposed mechanism underlying the photoredox catalytic trifluoromethylation reaction in the presence of the cyclometalated Pt(II) complex (Pt^{II}(C \wedge N) hereafter) catalysts. Photoexcitation of Pt^{II}(C \wedge N) promoted an electronic transition to a singlet MLCT (¹MLCT) state, which underwent ultrafast intersystem crossing to a ³MLCT state (*i.e.*, ³[Pt^{III}(C \wedge N)]⁺). Diffusional collision of ³[Pt^{III}(C \wedge N)]⁺ with CF₃I led to the reversible formation of an encounter complex ([³[Pt^{III}(C \wedge N)]⁺ CF₃I]; path B in Scheme 2). Oxidative electron transfer from the Pt catalyst to CF₃I in the encounter complex generated a geminate radical ion pair, [[Pt^{III}(C \wedge N)]⁺ CF₃I^{•−}]. It should be noted that ligand oxidation (*i.e.*, [Pt^{II}(C \wedge N)]⁺) could not be excluded, because the triplet state of the Pt(II) complex contained significant LC character (*vide supra*). An encounter complex formed between the photoexcited catalyst and an electron donor, such as TMEDA, could also have been generated (path A in Scheme 2); however, the negative driving force abrogated the formation of a geminate radical ion pair (*vide supra*). Two pathways were available to the [[Pt^{III}(C \wedge N)]⁺ CF₃I^{•−}] species: the first pathway involved quenching to the original species (*i.e.*, Pt^{II}(C \wedge N) and CF₃I) by back electron transfer (BeT), and the other pathway involved dissociation into [Pt^{III}(C \wedge N)]⁺ and CF₃I^{•−}. In the latter path, prompt cleavage of the C–I bond in CF₃I^{•−} resulted in the formation of [•]CF₃. Radical addition of [•]CF₃ to substrates formed trifluoromethylated radical species. The photocatalytic cycle was completed by the reductive regeneration of Pt^{II}(C \wedge N) with sacrificial electron donors, such as TMEDA and DBU. Alternatively, Pt^{II}(C \wedge N) was recovered through the radical-polar mechanism, which involved oxidation of radical species of the trifluoromethylated substrate to the cation (path C in Scheme 2). In this case, the resulting cationic species of the trifluoromethylated substrate was trapped by the strong nucleophile, I[−]. It should be noted that the compound bearing both iodide and trifluoromethyl groups could also be produced by radical propagation between the CF₃I and radical species of the trifluoromethylated substrate (path D in Scheme 2). In both cases (*i.e.*, paths C and D), E2 elimination assisted by TMEDA or DBU furnished the desired product, with the stoichiometric generation of ammonium iodide salts.

The photoredox catalytic cycle described above involved three key electron-transfer steps: forward photoinduced electron transfer (PeT), BeT, and reductive regeneration of the catalyst. The electron-transfer processes and their intermediate species generated during the photoredox catalytic trifluoromethylation reaction had not been directly observed to date. No kinetic information about electron transfer was available in the literature.

Spectroscopic observation of the photoredox catalytic cycle

The electron transfer reactions in each step of the photoredox catalytic cycle were investigated using time-resolved photoluminescence and laser flash photolysis measurements after

Scheme 2 Proposed mechanism for the trifluoromethylation of alkenes and heteroarenes.

nanosecond pulsed photoexcitation. Photoluminescence quenching experiments using time-correlated single photon counting (TCSPC) techniques were performed to monitor the oxidative PeT from $^3[\text{Pt}^{\text{III}}(\text{CAN})]^{*-}$ to CF_3I . Attempts to detect the rise signals of the transient absorption spectrum of the oxidized catalyst, $[\text{Pt}^{\text{III}}(\text{CAN})]^+$, were unsuccessful, because the significant overlap between the absorption spectra of $[\text{Pt}^{\text{III}}(\text{CAN})]^+$ and $^3[\text{Pt}^{\text{III}}(\text{CAN})]^{*-}$ (ESI, Fig. S4†) did not permit spectral resolution. Fig. 3a shows the photoluminescence decay traces ($\lambda_{\text{obs}} = 543 \text{ nm}$) for the deaerated acetonitrile solutions of $50 \mu\text{M}$ PtOMe after nanosecond pulsed photoexcitation at 377 nm . The decay trace followed a monoexponential decay model. τ_{obs} was as long as $11.6 \mu\text{s}$, but the incremental addition of CF_3I (0 – 20 mM) to the solution significantly shortened τ_{obs} . Other Pt complexes show similar photoluminescence quenching behaviors (ESI, Fig. S5†). Photoluminescence quenching accompanied the generation of $\cdot\text{CF}_3$, as evidenced by a weak photoinduced ESR signal with a g value of 2.004 , corresponding to a free radical,^{90,91} although the broad ESR spectrum hindered

resolution of the hyperfine coupling due to the fluorine nuclei (ESI, Fig. S6†). These results unambiguously indicate the occurrence of oxidative quenching of $^3[\text{Pt}^{\text{III}}(\text{CAN})]^{*-}$ by CF_3I . As inferred from the negative driving force (*vide supra*), reductive quenching was not observed, even at 20 mM TMEDA (ESI, Fig. S7†). The oxidative PeT rates were calculated from $1/\tau_{\text{obs}}(\text{CF}_3\text{I}) - 1/\tau_{\text{obs}}$, where $\tau_{\text{obs}}(\text{CF}_3\text{I})$ and τ_{obs} are the photoluminescence lifetimes in the presence and absence of CF_3I , respectively. The rate constants of PeT (k_{PeT}), determined by the pseudo-first order fit of the PeT rates *vs.* the CF_3I concentrations, were $8.8 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$, $7.9 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$, and $4.4 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ for Ptddppp, PtpPy, and PtOMe, respectively (Fig. 3b). Apparently, k_{PeT} increased in proportion to $-\Delta G_{\text{PeT}}$, indicating electron transfer in the Marcus normal region (*vide infra*). The fraction (f) of $^3[\text{Pt}^{\text{III}}(\text{CAN})]^{*-}$ that underwent oxidative quenching was estimated based on the empirical relationship, $f = (k_{\text{PeT}} \times 1 \text{ mM}) / (k_r + k_{\text{nr}} + k_{\text{PeT}} \times 1 \text{ mM})$, assuming that 1 mM CF_3I was present and other conditions, including diffusion, were held constant. In this relationship, k_r and k_{nr} are the rate constants

Fig. 3 Determining the rate constants for photoinduced electron transfer (k_{PeT}). (a) Phosphorescence decay traces of 50 μM PtOMe (deaerated CH_3CN ; $\lambda_{\text{obs}} = 543 \text{ nm}$) over the range of CF_3I concentrations (0–20 mM). (b) Plot of the electron transfer rates ($1/\tau_{\text{obs}}(\text{CF}_3\text{I}) - 1/\tau_{\text{obs}}$) as a function of the concentration of CF_3I . The k_{PeT} values were determined based on the pseudo-first order fits of the electron transfer rates. Standard deviations were determined from three independent measurements.

Fig. 4 Determination of the rate constant for back electron transfer (k_{BeT}) by nanosecond laser flash photolysis ($\lambda_{\text{ex}} = 355 \text{ nm}$) for a deaerated acetonitrile solution containing 100 μM PtOMe (O.D. at 355 nm = 0.52) and 50 mM CF_3I . (a) Transient absorption spectra recorded at 4 μs (red), 8 μs (blue), and 252 μs (black) after photoexcitation. The dotted grey line and grey bars are the simulated (CPCM(CH_3CN)-TD-B3LYP/LANL2DZ:6-311+G(d,p)//B3LYP/LANL2DZ:6-311+G(d,p)) absorption spectrum and calculated absorbance, respectively, of the one-electron oxidized species of PtOMe. (b) Plot of $\epsilon/\text{absorbance}$ of the 770 nm band vs. time. The k_{BeT} value was determined from the second-order linear fit (red). The results obtained from other Pt(II) complexes are shown in the ESI, Fig. S8†.

for the radiative transition and non-radiative transition, respectively, which compete with PeT (Table 4). The corresponding f values are 0.25, 0.74, and 0.84 for Ptdfppy, Ptpy, and PtOMe, respectively. This trend agreed with the order of τ_{obs} , suggesting that a photocatalyst with a long excited-state lifetime was likely to undergo oxidative quenching.

After oxidative quenching by PeT, BeT could occur in the geminate radical ion pair to restore $[\text{Pt}^{\text{II}}(\text{CAN})]$ and CF_3I . The BeT process was monitored according to the $[\text{Pt}^{\text{III}}(\text{CAN})]^+$ decay signals in the microsecond regime. Fig. 4a presents the transient absorption spectra of a deaerated acetonitrile solution containing 100 μM PtOMe and 50 mM CF_3I after nanosecond photoexcitation at 355 nm (O.D. = 0.52). The spectra display a visible absorption band at 770 nm, and similar visible absorption signatures are also observed for Ptdfppy (740 nm) and Ptpy (730 nm) (ESI, Fig. S8†). These absorption bands can be reasonably ascribed to $[\text{Pt}^{\text{III}}(\text{CAN})]^+$ because chemical oxidation of 50 μM Ptdfppy by 50 μM $[\text{Fe}^{\text{III}}(\text{bpy})_3]^{3+}$ produced a visible absorption band around 700 nm ($\epsilon = 3200 \text{ M}^{-1} \text{ cm}^{-1}$; ESI, Fig. S9†), although the irreversible oxidation of Ptpy and PtOMe hampered our ability to measure the visible absorption bands. As shown in Fig. 4a, the visible absorption spectrum of $[\text{Pt}^{\text{III}}(\text{CAN})]^+$ can be reproduced using quantum chemical simulation methods based on time-dependent density functional theory (CPCM(CH_3CN)-TD-B3LYP/LANL2DZ:6-

311+G(d,p)//B3LYP/LANL2DZ:6-311+G(d,p)). The molar absorbances (ϵ) of the one-electron oxidized species of PtOMe and Ptpy were thus estimated based on the simulated spectra. The decay trace of the one-electron oxidized species of PtOMe was monitored at 770 nm, and the rate constant for BeT (k_{BeT}) was determined from the second-order linear fit of the decay traces to be $2.2 \times 10^{10} \text{ M}^{-1} \text{ s}^{-1}$ (Fig. 4b; see ESI, Fig. S8† for other complexes). The k_{BeT} value was approximately one order of magnitude greater than the k_{PeT} values (Table 4), and was comparable to the diffusion rate constant (k_{diff}) in CH_3CN at 298 K, $1.93 \times 10^{10} \text{ M}^{-1} \text{ s}^{-1}$, calculated according to the Stokes–Einstein–Smoluchowski equation, $k_{\text{diff}} = (8k_{\text{B}}N_{\text{A}}T)/(3\eta)$, where k_{B} , N_{A} , T , and η are the Boltzmann constant, Avogadro's number, the absolute temperature, and the viscosity of the solvent, respectively. A significant fraction of the CF_3I^- species returned to CF_3I via BeT prior to escaping the solvent cage. This result revealed the importance of controlling the molecular structure to suppress BeT.

The photoredox cycle was completed by the one-electron reduction of $[\text{Pt}^{\text{III}}(\text{CAN})]^+$. Regeneration was accomplished primarily by electron transfer from a sacrificial electron donor, such as TMEDA, as determined based on the positive driving force ($-\Delta G_{\text{eT}} = e[E_{\text{ox}}(\text{TMEDA}) - E_{\text{ox}}(\text{Pt})] = 0.05\text{--}0.15 \text{ eV}$). This

Table 4 Rate constants for the photophysical and photoelectrochemical processes of the Pt(II) complexes

	$k_{\text{r}}^a (10^4 \text{ s}^{-1})$	$k_{\text{nr}}^b (10^4 \text{ s}^{-1})$	$k_{\text{PeT}}^c (10^8 \text{ M}^{-1} \text{ s}^{-1})$	$k_{\text{BeT}}^d (10^{10} \text{ M}^{-1} \text{ s}^{-1})$	$k_{\text{regen}}^e (10^8 \text{ M}^{-1} \text{ s}^{-1})$

^a Radiative rate constant. ^b Non-radiative rate constant. ^c Rate constant for photoinduced electron transfer. ^d Rate constant for back electron transfer. ^e Rate constant for regeneration of the Pt(II) complex photocatalyst by reductive electron transfer from TMEDA.

Fig. 5 Determination of the rate constants for the regeneration (k_{regen}) of the Pt(II) complex catalysts. (a) Decay traces of the 770 nm absorption band of the one-electron oxidized PtOME (100 μM in deaerated CH_3CN , O.D. at 355 nm = 0.52) in the presence (50 μM) or absence of TMEDA after nanosecond pulsed photoexcitation at 355 nm. (b) Plots of the regeneration rate ($1/\tau(\text{TMEDA}) - 1/\tau$, where $\tau(\text{TMEDA})$ and τ are the half-lives of the 770 nm traces in the presence and absence of TMEDA, respectively) vs. the concentration of TMEDA. The k_{regen} values were determined according to the single exponential curve fitting.

Fig. 6 Plots of the $\log(\text{rate constant})$ ($\log k_{\text{ET}}$) vs. the driving force for oxidative photoinduced electron transfer (k_{PeT} , filled triangles), back electron transfer (k_{BeT} , empty triangles), and regeneration of the Pt(II) complex (k_{regen} , filled circles) at 298 K. Curves show the theoretical plots of eqn (1) at $\lambda = 1.2$ eV (grey curve) and 2.7 eV (black curve).

process was monitored by acquiring the decay traces of $[\text{Pt}^{\text{III}}(\text{CAN})]^+$ under various concentrations of TMEDA. Fig. 5a shows the decay traces of the 770 nm absorption band for the deaerated acetonitrile solutions containing 100 μM PtOME and 50 mM CF_3I in the presence and absence of TMEDA. The half-life of the decay trace decreased from 70 μs to 25 μs upon the addition of 50 μM TMEDA. This behavior was ascribed to the reductive regeneration of PtOME by TMEDA. The regeneration rate was calculated from the relationship, $1/\tau(\text{TMEDA}) - 1/\tau$, where $\tau(\text{TMEDA})$ and τ are the half-lives of the 770 nm decay traces in the presence and absence of TMEDA, respectively. The pseudo-first order linear fit of the regeneration rates vs. the concentration of TMEDA yielded the rate constants for regeneration (k_{regen}) in the range of 3.4 to $7.7 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$. As shown in Table 4, these values are comparable to the k_{PeT} values

but are approximately one order of magnitude smaller than k_{BeT} .

The classical Marcus theory for adiabatic outer-sphere electron transfer provided a valuable basis for correlating the kinetic parameters (*i.e.*, k_{PeT} , k_{BeT} , and k_{regen}) to the driving force. The electron transfer steps could be best described using eqn (1) with consideration for the diffusion process:^{92,93}

$$k_{\text{eT}} = \frac{k_{\text{diff}}k_{\text{et}}}{k_{\text{-diff}} + k_{\text{et}}} = \frac{k_{\text{diff}}(k_{\text{B}}T/h)\exp\left[-(\Delta G_{\text{eT}} + \lambda)^2/(4\lambda k_{\text{B}}T)\right]}{k_{\text{-diff}} + (k_{\text{B}}T/h)\exp\left[-(\Delta G_{\text{eT}} + \lambda)^2/(4\lambda k_{\text{B}}T)\right]} \quad (1)$$

In eqn (1), k_{et} , h , ΔG_{eT} , and λ are the rate for adiabatic outer-sphere electron transfer, the Planck constant, the free energy change, and the reorganization energy for electron transfer, respectively.⁹⁴

As shown in Fig. 6, the k_{PeT} values adhere well to the theoretical curve calculated using the Marcus theory of electron transfer, with a λ value of 2.7 eV. The large reorganization energy indicates bond scission in CF_3I after electron transfer. The positive dependence of k_{PeT} on $-\Delta G_{\text{PeT}}$ points to the occurrence of PeT in the Marcus normal region (*i.e.*, $-\Delta G_{\text{PeT}} < \lambda$). The Marcus normal behavior suggests two possible strategies for accelerating PeT: (1) raising E_{ox}^* of the photoredox catalyst by incorporating ligands with wide band gap energies (*i.e.*, high ΔE_{T}) and weak π -backbonding abilities (*i.e.*, cathodically shifting E_{ox}), and (2) using $^*\text{CF}_3$ sources with large (more positive) E_{red} values, such as the Shibata reagent.⁶⁶ The former approach involves a tradeoff because the effect may be offset by a reduction in the visible absorption cross-section.

The analyses using eqn (1) revealed a positive dependence of k_{BeT} on $-\Delta G_{\text{BeT}}$, with a λ value of 2.7 eV. This λ value was identical to that obtained under PeT, as expected for forward and reverse electron transfer. One potential strategy for retarding the hazardous BeT involves raising the E_{ox} of the photoredox catalysts using ligands with weak π -accepting or strong σ -donating properties. Alternatively, the use of $^*\text{CF}_3$ sources with large (more positive) E_{red} values may be advantageous.

The reductive regeneration by TMEDA was found to be essential because the trifluoromethylated products could not be obtained if TMEDA was replaced with a Brønsted base, such as K_3PO_4 , K_2HPO_4 or KO^tBu (ESI, Tables S1 and S2†). As shown in Fig. 6, the regeneration by TMEDA followed a typical Rehm–Weller behavior with a λ value of 1.2 eV. The large positive dependence indicated that the rate of regeneration increased using catalysts with large E_{ox} values; however, predicting the influence of k_{regen} on the overall cycle was not straightforward due to the presence of an additional regeneration path involving radical species generated on the trifluoromethylated substrate (path C in Scheme 2). The above analyses based on the Marcus theory of electron transfer established that the photoredox catalysis performance could be improved by implementing the following molecular controls: (1) E_{ox} of the catalyst should be as small as possible to speed up PeT and to slow down BeT; (2) E_{ox}

Table 5 Quantum yields for trifluoromethylation of 1-dodecene and *N*-methylpyrrole by the Pt(II) complexes and the established photoredox catalysts based on Ir(III) and Ru(II) complexes

	Ptdfppy	Ptppy	PtOMe	<i>fac</i> -Ir(ppy) ₃	[Ir(ppy) ₂ (dtbbpy)]PF ₆	[Ru(bpy) ₃]Cl ₂
QY _{alkene} ^a	18	17	16	12	10	6.5
QY _{hetero} ^b	2.4	3.9	4.8	3.0	2.5	0.67

^a Quantum yields for trifluoromethylation of 1-dodecene. ^b Quantum yields for trifluoromethylation of *N*-methylpyrrole. The quantum yields were determined using standard ferrioxalate actinometry (6.0 mM K₃[Fe(C₂O₄)₃], QY = 1.1 at 420 nm (light intensity = 6.7 × 10⁻¹⁰ Einstein s⁻¹)).

of the catalyst should be more positive than E_{ox} of the sacrificial electron donor to warrant regeneration; (3) the value of ΔE_T for the catalyst may be optimized, since larger values of ΔE_T will accelerate oxidative PeT but very large ΔE_T values eventually initiate competing reductive quenching.

Having established the photoredox catalytic cycle, we sought to understand the influence of the C₄N ligand structures on the overall catalytic performance. The quantum yields of the three Pt(II) complexes for trifluoromethylation (QY) of 1-dodecene and *N*-methylpyrrole were determined using standard ferrioxalate actinometry (6.0 mM K₃[Fe(C₂O₄)₃], quantum yield = 1.1 at 420 nm; see the ESI† for experimental details). As summarized in Table 5, the QY values exceeded 100% in all cases. These results strongly indicated the significant involvement of radical propagation (path D in Scheme 2). This hypothesis was supported by the observation of a dark-state reaction after shutting off photoirradiation (ESI, Fig. S10†). It is noted that the Pt(II) catalyst prepared with an electron-poor C₄N ligand produced a larger value of QY for the alkene, whereas the QY values for the heteroarene exhibited an opposite trend. Because the radical propagation and subsequent steps, including iodination and E2 elimination, were independent of the identity of the photoredox catalyst, variations in QY could be explained in terms of the photoredox cycle. Obviously, the QYs for 1-dodecene followed a trend opposite to those of *f* and k_{BET} for the series of Pt(II) complexes, suggesting that the effects of *f* and k_{BET} would be marginal. One possible explanation for the QY trend is that regeneration is the limiting step in the overall catalytic performance. Of note, in Table 5 are the greater QY values of the Pt(II) complexes over those of the well-established Ir(III) and Ru(II) catalysts. The improved photon economy of the Pt(II) catalysts is likely due to elimination of the hazardous reductive quenching pathway that exists in the Ir(III) and Ru(II) catalyst systems.

Conclusions

We demonstrated the photoredox catalytic properties of a series of cyclometalated Pt(II) complexes for use in the trifluoromethylation of non-prefunctionalized alkenes and heteroarenes under visible light irradiation. The Pt(II) complexes displayed excellent catalytic performances, as demonstrated by high yields and functional group tolerance. The oxidative quenching pathway was exclusively allowed in the photoredox catalysis cycle due to the high excited-state redox potentials (E_{ox}^* and E_{red}^*) of the Pt(II) catalysts. Direct spectroscopic measurements revealed Marcus normal behaviors for the photoinduced electron transfer, back electron transfer, and reductive

regeneration processes. These results suggested several molecular strategies that could be used to enhance the catalyst performances. Forward photoinduced electron transfer to generate $\cdot CF_3$ could be accelerated by incorporating ligands with a high triplet-state energy and weak π -accepting properties, whereas hazardous back electron transfer could be minimized through the use of ligands having weak π -accepting or strong σ -donating properties. Alternatively, $\cdot CF_3$ reagents with low (*i.e.*, more positive) reduction potentials, such as the Shibata reagent, could have identical effects. Correlations between the quantum yields and the rate constants for electron transfer pointed to the notion that regeneration by a sacrificial electron donor or radical species of the trifluoromethylated substrate could be a limiting process in the overall catalysis cycle. Evidence for radical propagation suggests an oxidation potential smaller than -0.91 V vs. SCE for the radical species of the trifluoromethylated substrate. Accordingly, a large driving force exceeding 1.43 eV for catalyst regeneration by the radical species of the trifluoromethylated substrate can be estimated, strongly supporting that regeneration by the sacrificial electron donor may be the limiting process. We hope that the research described in this work will provide useful insights into the future development of photoredox catalysts for a range of organic transformations.
