Highly efficient hydrogenation of carbon dioxide to formate catalyzed by iridium(III) complexes of imine–diphosphine ligands†

Chong Liu, Jian-Hua Xie, Gui-Long Tian, Wei Li and Qi-Lin Zhou*

A new iridium catalyst containing an imine–diphosphine ligand has been developed, which showed high efficiency for the hydrogenation of CO₂ to formate (yield up to 99%, TON up to 450 000). A possible catalytic mechanism is proposed, in which the imine group of the catalyst plays a key role in the cleavage of H₂ and the activation of CO₂.

Carbon dioxide (CO₂), an economical, safe, environmentally friendly, and renewable carbon source, is an ideal one-carbon building block for organic chemicals, including carbohydrates and fuels.¹ However, its thermodynamic and kinetic stability presents a fundamental obstacle to the use of CO₂ in both academia and industry.² High-energy reagents, harsh reaction conditions, and special activation mechanisms are typically required for transforming CO₂ into other chemicals. Hydrogen is a green high-energy material that can be used to convert CO₂ to valuable secondary energy carriers, such as methane, methanol, and formic acid. Formic acid is widely used in agriculture and in the leather and dye industries, as well as in fuel cells and synthetic chemistry.³

Homogeneous catalytic hydrogenation of CO₂ into formic acid catalyzed by transition-metal complexes based on rhodium,⁴ ruthenium,⁵ iridium,⁶ iron,⁷ and cobalt⁸ has been extensively investigated since it was first reported in 1976 by Inoue *et al.*,^{4a} who used Wilkinson's catalyst, RhCl(PPh₃)₃, to accomplish the reaction. In the early 1990s, Graf and Leitner^{4b} achieved turnover numbers (TONs) as high as 3400 for CO₂ hydrogenation reactions catalyzed by rhodium phosphine complexes. Noyori *et al.*^{5a,b} found that with RuH₂(PMe₃)₄ as a catalyst, the reaction was more efficient in supercritical CO₂ than in traditional organic media. Half-sandwich iridium(III) complexes containing a strong electron donor ligand such as 4,4'-dihydroxy-2,2'-bipyridine or 4,7-dihydroxy-1,10-phenanthroline were used for the hydrogenation of CO₂ by Himeda *et al.*,^{6b} who reported a TON of 2.2 × 10⁵. Subsequently, a significant breakthrough was made by Nozaki *et al.*,^{6c} who discovered that an iridium(III) trihydride complex with a

pyridine-based PNP-pincer ligand has extraordinary catalytic activity (TON 3.5 × 10⁶). However, from the practical point of view, the reported catalysts exhibited high activity only at harsh conditions such as high temperature and high pressure. Hence the research focus in the field of hydrogenation of CO₂ is still the search for efficient catalysts, especially those with new activation models.

Late-transition-metal-amine complexes, which have a nitrogen atom with strong nucleophilicity, basicity, and donor ability, have been used as metal–ligand cooperative catalysts.⁹ A noteworthy example is the iridium hydride catalyst containing an amine–diphosphine ligand developed by Hazari *et al.*,^{6c} which shows high activity for the hydrogenation of CO₂. As part of our exploration of stable and efficient metal–ligand cooperative catalysts,¹⁰ we designed a new type of iridium(III) catalysts containing imine–diphosphine ligands, which exhibit high activity for the hydrogenation of CO₂. Herein, we report the preparation and characterization of iridium(III)/imine–diphosphine catalysts **1** and their application for the hydrogenation of CO₂ to formate.

Catalysts **1** were synthesized in high yields by the complexation of tridentate amine–diphosphine ligands **2** (ref. 11) with [Ir(COE)₂Cl]₂ under hydrogen and subsequent treatment with base (Scheme 1). Complexation in THF at 100 °C produced complexes **3** (85–90% yield), which were stable solids that could be kept for several months under a nitrogen atmosphere. Catalysts **1** were obtained in 75–80% yield from the reaction of **3** with KO^tBu in THF. Interestingly, when we monitored the reaction of **3b** by NMR at –45 °C, we observed a new species characterized by a singlet at δ = 54.84 ppm in the ³¹P NMR spectrum and a double-doublet at δ = –16.87 ppm (*J* = 21.8, 13.1 Hz) in the ¹H NMR spectrum, neither of which belonged to **3b** [³¹P NMR: δ = 40.74 ppm (t, *J* = 10.4 Hz); ¹H NMR: δ = –21.87 ppm (td, *J* = 15.8, 7.4 Hz, 1H), –26.04 ppm (td, *J* = 16.9, 7.8 Hz, 1H)] or to **1b** [³¹P NMR: δ = 52.98 ppm (dd, *J* = 13.0, 346.8 Hz), 59.83 ppm (dd, *J* = 7.3, 346.8 Hz); ¹H NMR: δ =

† Electronic supplementary information (ESI) available: Experimental procedures; spectral data for all new compounds. See DOI: 10.1039/c5sc00248f

–10.77 ppm (t, $J = 17.4$ Hz, 2H), –19.39 ppm (t, $J = 15.2$ Hz, 1H)] (ESI). We speculated that this species was a 16-electron iridium dihydride complex, $\text{IrH}_2[(^t\text{Bu}_2\text{PC}_6\text{H}_4\text{CH}_2)_2\text{N}]$ (**A**),¹² generated by the elimination of HCl from **3b** upon treatment with KO^tBu . Complex **A** was unstable and rapidly converted to an 18-electron iridium trihydride complex of imine–diphosphine complex **1b** by means of a shift of a hydride from CH_2 to iridium.¹³

Attempts to grow crystals of **3** and **1** were unsuccessful. Fortunately, **3a** slowly underwent an exchange of hydride to chloride in 1,1,2,2-tetrachloroethane, affording dichloride complex **B** as a crystal (Scheme 1).¹⁴ X-ray crystallographic analysis of **B** confirmed the structure of **3a** as having one nitrogen atom and two phosphorus atoms coordinated to iridium, as well as two six-membered heterometallic rings. In the crystal of **B**, two phosphines were coordinated to iridium in a *trans* arrangement (P1a–Ir–P1 174.90(9)°), and two chlorides were in a *cis* arrangement (Cl1–Ir–Cl2 100.24(8)°). One chloride (Cl2) was *cis* to the nitrogen (Cl2–Ir–N 82.5(2)°), and the other chloride (Cl1) was *trans* to the nitrogen (Cl1–Ir–N 177.3(2)°). The bite angles of the ligands in the complexes **3** and **1** are larger than those in the conventional PNP ligands.^{6c,e} The flexibility of the ligands in the complexes **3** and **1** is important because a proton is released from the ligand during the catalytic process, which changes the conformation of the ligand.

The activity of the iridium catalysts **1** for the hydrogenation of CO_2 to formate was evaluated. The initial experiments were carried out under 60 atm of 1 : 1 CO_2/H_2 in aqueous KOH in the presence of 0.1 mol% iridium catalyst at 140 °C for 20 h. Catalysts **1a** and **1b** gave 93% and 99% yields of formate, respectively (Table 1, entries 1 and 2). When the catalyst loading was reduced to 0.001 mol%, **1b**, with four *tert*-butyl groups on

^a General reaction conditions: 5 mL aqueous 1 M KOH solution, 0.1 mol% or 0.001 mol% iridium catalyst relative to KOH in 100 μL THF, 60 atm of $\text{H}_2 : \text{CO}_2$ (1 : 1, initial), 140 °C, 20 h. ^b Yield, which represents conversion of the added KOH, based on ^1H NMR analysis with sodium 3-(trimethylsilyl)-1-propanesulfonate as an internal standard. ^c TON = turnover number; number of moles of product formed per mole of catalyst.

the phosphorus atoms, it still afforded an 81% yield (entry 4); however, **1a**, which has four phenyl groups on the phosphorus atoms, gave only a 23% yield (entry 3). Increasing the reaction temperature and extending the reaction time have a negligible improvement on the yield of the reaction. The use of K_3PO_4 and other weaker bases resulted in a lower yield. We were delighted to find that **1b** could be generated *in situ* from **3b** under the

Scheme 2 Proposed mechanism for the hydrogenation of CO₂ catalyzed by **1b**.

reaction conditions, and the yield (78%) with the *in situ*-generated catalyst was similar to that obtained from the isolated catalyst (entries 4 and 6). The use of the stable catalyst precursor **3b**, instead of the active catalyst **1b** itself, offered an additional advantage for the reaction performance.

Using the most active catalyst (**1b**), we optimized the conditions for the hydrogenation of CO₂ to formate (Table 2). First, we investigated the influence of the initial pressures of H₂ and CO₂ and found that when the total initial pressure of a 1 : 1 mixture of H₂ and CO₂ was lowered from 60 to 40 atm, the yield of formate decreased from 81% to 35% (entries 1 and 2). Raising the H₂/CO₂ ratio from 1 : 1 to 2 : 1 or to 5 : 1, at the same total initial pressure, markedly increased the yield (to 99%, entries 3 and 4). Increasing the initial concentration of KOH from 1 M to 2 M or 5 M at the catalyst loading of 0.0001 mol% (relative to KOH) dramatically increased the yield and TON of the reaction (entries 6 and 7 vs. 5).

Under the optimal reaction conditions ($P(\text{H}_2)/P(\text{CO}_2)$ 40/20 atm, 5 M KOH, 140 °C, 0.0001 mol% **1b**), formate was obtained in 45% yield (TON = 450 000, turnover frequency = 22 500 h⁻¹, entry 7). This result showed that **1b** was a very efficient catalyst

for the conversion of CO₂ to formate under relatively mild reaction conditions.

For a comparison, the iridium complexes with tridentate PNP, PNN,¹⁵ and PNO¹⁶ ligands (**4–7**, Fig. 1) were also synthesized (for details, ESI†), and their catalytic activities for the hydrogenation of CO₂ to formate were studied. The very low activity of complex **4** containing *N*-methyl (entry 7, Table 1) indicates that the NH moiety in catalyst **3** was essential for the formation of iridium(III)/imine–diphosphine catalysts **1**. The iridium complexes with PNN ligands (**5** and **6**) and PNO ligands (**7**), which can also form iridium(III)/imine–diphosphine catalysts, showed extremely low activity for the hydrogenation of CO₂ (Table 1, entries 8–14).

On the basis of the above-described experimental results for the hydrogenation of CO₂ catalyzed by iridium(III)/imine–diphosphine, we proposed a mechanism involving metal–imine cooperative catalysis (Scheme 2).¹⁷ First, a molecule of H₂ adds to the C=N double bond of **1b** to generate iridium–trihydride complex **C**, which was isolated in 75% yield and was identified (ESI†). Base-mediated addition of the N–H proton and the Ir–H hydride of **C** to the carbonyl group of CO₂ via a six-membered-ring transition state (**TS**) generates formic acid and complex **A**, which was detected by NMR (*vide ante*). A rapid shift of hydride from α -CH₂ to iridium regenerated the catalyst **1b** and finished a catalytic cycle. An experiment with **C** and CO₂ showed the formation of intermediate **A**, which was quickly converted to complex **1b** in 69% yield. This metal–imine bi-functional catalysis provides a highly efficient hydrogenation of CO₂.

In summary, we developed a new type of iridium catalyst containing an imine–diphosphine ligand, which showed high activity for the hydrogenation of CO₂ to formate (yields up to 99%, TONs up to 450 000). The Ir–imine–diphosphine-catalyzed hydrogenation of CO₂ proceeded through a metal–imine bi-functional mechanism. This activation model should be applicable for other transformations.
