Electrochemical and chemical routes to hydride loss from an iridium dihydride[†]

A. G. Walden,^a A. Kumar,^{b,c} N. Lease,^b A. S. Goldman^b and A. J. M. Miller*^a

With a view towards replacing sacrificial hydrogen acceptors in alkane dehydrogenation catalysis, electrochemical methods for oxidative activation of a pincer-ligated iridium hydride intermediate were explored. A $1H^+/2e^-$ oxidation process was observed in THF solvent, with net hydride loss leading to a reactive cationic intermediate that can be trapped by chloride. Analogous reactivity was observed with the concerted hydride transfer reagent Ph_3C^+ , connecting chemical and electrochemical hydride loss pathways.

Iridium complexes supported by tridentate ^{R4}PCP (^{R4}PCP = κ^3 -C₆H₃-2,6-(CH₂PR₂)₂) pincer ligands are prolific dehydrogenation catalysts, enabling landmark transformations such as the dehydrogenation,^{1,2} metathesis,³ coupling^{4,5} and dehydroaromatization⁶ of alkanes.⁷ Efficient dehydrogenation reactions require a sacrificial hydrogen acceptor, typically an olefin. The hydrogen acceptor alters the overall reaction thermodynamics and activates the iridium dihydride species.^{7–9} In transfer dehydrogenation, catalyst activation occurs by insertion of the sacrificial olefin into one Ir–H bond, followed by C–H bond-forming reductive elimination with the other Ir–H bond, generating a highly reactive 14e[–] intermediate capable of alkane C–H bond activation (Scheme 1).

The requirement of an added stoichiometric reagent represents a significant limitation in dehydrogenation reactions.^{8,10} In considering new strategies to promote dehydrogenation reactions, we were drawn to electrochemical methods that could *decouple* the catalyst activating and hydrogen accepting steps.^{11,12} We envisioned electrochemical oxidation of (^{R₄}PCP)Ir(H)₂ at an anode, generating a catalytic intermediate while releasing $2H^+/2e^-$ (Scheme 1) that could be used to drive any range of reactions at the cathode.

Electrochemical dehydrogenation relies on (sometimes coupled) electron transfer and proton transfer steps,^{13,14} while chemical dehydrogenation often involves concerted hydride transfer.^{7,15,16} Recent reports have started to draw connections between chemical and electrochemical processes, however. For example, inspired by a report of (^{R4}PCP)Ir-catalyzed hydrogenation of CO₂ to formate,¹⁷ Brookhart and Meyer developed an analogous electrochemical reduction of CO₂ to formate catalyzed by (^{*t*Bu₄}POCOP)Ir complexes (^{*t*Bu₄}POCOP = κ^3 -C₆H₃-2,6-(OP^{*t*}Bu₂)₂).¹⁸⁻²⁰ A striking oxidative example involves two different catalysts for the same alcohol oxidation reaction that operate by two different mechanisms, either a concerted H₂ loss mechanism or an outer-sphere electron transfer mechanism in which a chemical oxidant (not an electrode) and a base facilitate 2H⁺/2e⁻ loss.²¹

Studies of electrochemical reactions that parallel wellknown organometallic oxidations can help bridge the divide between chemical and electrochemical methods. This report focuses on the oxidation of a pincer-ligated iridium dihydride. Net loss of hydride $(H^+/2e^-)$ is promoted by *either* electrochemical or chemical methods to produce an iridium monohydride species.

The dihydride complex was prepared according to previously reported procedures by dehydrohalogenation of $({}^{^{tBu_4}PCP})Ir(H)(Cl)$ (1) under an H₂ atmosphere.^{1,22} This procedure affords a mixture of the five-coordinate dihydride $({}^{^{tBu_4}PCP})Ir(H)_2$ (2) and $({}^{^{tBu_4}PCP})Ir(H)_4$ (3).²³ Samples could be stirred in pentane, filtered, and dried under vacuum to remove the dihydrogen ligand and provide pure 2.[‡]

The oxidation of dihydride 2 was initially explored using cyclic voltammetry (CV). When a solution of 2 in argon-saturated THF containing $[Bu_4N][PF_6]$ supporting electrolyte was assessed by a CV sweep to oxidative potentials, a single irreversible feature was observed at $-0.08 \text{ V} \nu s$. Cp₂Fe^{+/0} (Fig. 1). No return reduction process was apparent, even as the scan rate was increased to 1 V s⁻¹.

An irreversible electrochemical oxidation is consistent with a rapid chemical reaction following electron transfer from 2 to the electrode. The dihydride 2 is more easily oxidized than the hydridochloride complex 1, which exhibited a quasi-reversible oxidation around 0.5 V *vs.* $Cp_2Fe^{+/0}$ in CH_2Cl_2 at fast scan rates in a prior study.²⁴

To identify the product formed at positive potentials under argon, a controlled potential electrolysis experiment was carried out. A high-surface-area reticulated vitreous carbon working electrode was submersed in a THF solution of dihydride 2 and polarized to 0.2 V vs. $Cp_2Fe^{+/0}$. The flow of current diminished as a gradual color change from pale orange to pale yellow was observed. The oxidation passed 239 mC of charge, corresponding to 1.9 e⁻ per Ir, but an aliquot analyzed by ³¹P{¹H} NMR spectroscopy revealed a mixture of species.

Considering the possibility that oxidation of 2 would produce a reactive cationic species,²⁵ the oxidative electrochemistry was also carried out in the presence of a chloride ion source as a trapping agent. In the presence of LiCl (and

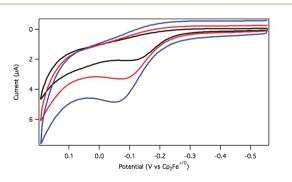

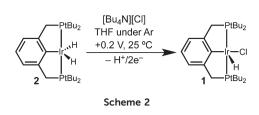

Fig. 1 Cyclic voltammetry of 2 at 25 mV s⁻¹ (black), 100 mV s⁻¹ (red), and 250 mV s⁻¹ (blue) in THF solution with 0.1 M [Bu₄N][PF₆] electrolyte. Glassy carbon working electrode, platinum counter electrode, Ag wire pseudo-reference electrode, 298 K.

with conditions otherwise similar to those described above), the CV response of **2** was essentially unchanged relative to chloride-free conditions, suggesting that chloride does not influence the initial oxidation process.

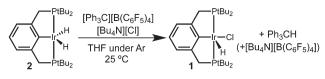

Controlled potential electrolysis of a THF solution containing 2 and excess LiCl or $[Bu_4N][Cl]$ was conducted at 0.2 V ν s. Cp₂Fe^{+/0} (Scheme 2). In the presence of chloride, the solution color changed from pale orange to a much brighter orange, and the 283 mC of charge passed corresponds to a 2e⁻ oxidation (2.3 e⁻ per Ir). Analysis by ³¹P{¹H} NMR spectroscopy now revealed a single phosphorous-containing species (δ 69). The product was isolated from the electrolyte by removal of the THF under vacuum and extraction with pentane. Full NMR spectroscopic analysis in THF-*d*₈ showed a triplet hydride resonance far upfield (δ –42.9) in the ¹H NMR spectrum that is diagnostic of (^{*t*Bu₄}PCP)Ir(H)(Cl) (1). All of the ³¹P and ¹H NMR signals closely matched the previously reported values.²²

The electrochemical conversion of dihydride 2 to hydridochloride 1 represents a net hydride abstraction *via* the loss of $2e^-$ to the anode and loss of H⁺ (to solution or perhaps to a surface site on the electrode), followed by chloride binding. This two-step electrochemical-chemical (EC) transformation is consistent with the irreversible CV response (prior studies of (pincer)Ir(H)(Cl) also implicated an EC mechanism, but did not identify a product).²⁴ The stability of the product, hydridochloride 1, towards further oxidation at the potentials applied during electrolysis is critical to the success of the reaction.²⁴

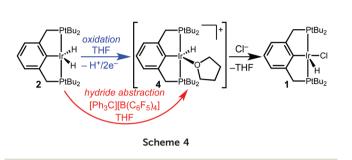

Analogous electrochemical hydride loss *via* a two-electron/ one-proton oxidative process has been reported for a series of Group 6 complexes of the type $CpM(CO)_3H$ (M = Cr, M, W),²⁶ which may involve a concerted proton-coupled electron transfer event in the tungsten case.²⁷ In contrast, the Rh analogue (^{HBu}₄PCP)Rh(H₂), which is best described as a Rh(I) dihydrogen complex,²⁸ does not undergo oxidative hydride loss: reversible 1e⁻ oxidation is observed in CH₂Cl₂, and H₂ loss is observed in coordinating solvents.²⁹

To further probe the hydride transfer reactivity, chemical methods that could effect an analogous hydride loss were explored. When dihydride **2** is allowed to react with the hydride abstractor $[Ph_3C][B(C_6F_5)_4]$ in THF- d_8 , the solution changes color from pale orange to pale yellow. NMR spectroscopic monitoring revealed a mixture of products analogous to those observed in the initial electrolysis.

Hydride abstraction was next attempted in the presence of a chloride source. Treatment of dihydride 2 with 1 equiv. $[Ph_3C][B(C_6F_5)_4]$ and 5 equiv. $[Bu_4N][Cl]$ led to a color change from pale orange to a much brighter orange, coinciding with

Scheme 3

the appearance of the characteristic signals of hydridochloride complex 1 by ${}^{31}P{}^{1}H$ and ${}^{1}H$ NMR spectroscopy (Scheme 3). Triphenylmethane is also observed by ${}^{1}H$ NMR spectroscopy, clearly identifying the fate of the hydride.

We suggest that the electrochemical and chemical hydride abstractions proceed *via* a shared intermediate, given the similar product distributions under various reaction conditions. As shown in Scheme 4, we hypothesize that oxidation of dihydride 2 occurs as a net $1\text{H}^+/2\text{e}^-$ process (*via* one of the pathways described above) to generate a reactive monohydride cation, $[(^{tBu_4}\text{PCP})\text{Ir}(\text{H})]^+$ (4). Chemical hydride transfer from 2 to $[\text{Ph}_3\text{C}][\text{B}(\text{C}_6\text{F}_5)_4]$ would also afford 4. We are not aware of any prior reported isolation of cation 4. An analogous $[(^{tBu_4}\text{POCOP})\text{Ir}(\text{H})]^+$ species, isolated as an acetone or dichloromethane adduct, is an active hydrosilylation catalyst.^{30,31}

From this shared intermediate cation 4, trapping with chloride ion can generate the hydridochloride 1. In the absence of chloride, we suspect that cation 4 decomposes through reactions with itself and/or the solvent, the details of which are currently under investigation. The observation of identical products under electrochemical and chemical reaction conditions suggests that future electrochemical oxidations (even in non-polar solvents)³²⁻³⁴ can be modeled after existing hydride abstraction reactions.

By implicating a key monohydride cation intermediate and building an analogy between well-defined organometallic hydride abstraction reactions and electrochemical oxidation processes, these joint chemical/electrochemical studies provide a foundation for future development of electrochemical dehydrogenation processes.
