Manipulating energy storage characteristics of ultrathin boron carbide monolayer under varied scandium doping†

S. R. Naqvi,^a T. Hussain,^{*c} P. Panigrahi,^d W. Luo^a and R. Ahuja^{ab}

We report, for the first time we believe, a detailed investigation on hydrogen storage efficiency of scandium (Sc) decorated boron carbide (BC₃) sheets using spin-polarized density functional theory (DFT). We analyzed the energetics of Sc adsorption and explored the most favorable adsorption sites of Sc on BC₃ sheets with 3.12%, 6.25%, and 12.5% coverage effects. Our investigations revealed that Sc strongly binds on pristine BC₃ sheet, with a minimum binding energy of ~5 eV, which is robust enough to hinder Sc–Sc metal clustering. Sc, the lightest transition metal, adsorbs a large number of H₂ molecules per atom, resulting in a reasonable storage capacity. With 12.5% Sc-coverage, functionalized BC₃ sheets could attain a H₂ storage capacity of 5.5 wt% with binding energies suitable for a practical H₂ storage medium.

Introduction

Hydrogen (H₂) has emerged as an alternative energy carrier with a strong potential to serve a vibrant economy in the future particularly owing to its application in the transportation sector.^{1–3} However, H₂ economy presents challenges when it comes to the fabrication of a solid-state material for H₂ storage with high gravimetric/volumetric density that performs efficiently under ambient conditions.^{4,5} Previously, several new materials have been explored and studied for practical H₂ storage but the criteria of the U.S. Department of Energy (DOE) for the year of 2017 have yet to be accomplished.⁶ Thus, it is important to design and explore novel solid-state materials with the desired characteristics to serve as economical, efficient and viable solutions for reversible H₂ storage.

Carbon-based nanomaterials, owing to their low cost, light weight, large surface area and novel H₂ adsorption, have emerged as a subject of further research interest.^{7–15} However, in their pristine forms such nanomaterials show very feeble binding affinities as a result of weak van der Waals interactions between H₂ and the host material.^{16,17} For practical purposes the binding energy of H₂ with the respective storage material should be in the

range of –0.2 eV to –0.6 eV.¹⁸ To achieve this criterion, metal decorated carbon-based nanomaterials have been investigated as potential candidates for H₂ storage. The binding affinity could be further tuned by introducing isolated charged sites. However, the bonding mechanism and the binding enthalpy for the interaction of H₂ with metal adatom depend on the type of metallic site, the extent of polarizability and on charge localization. It has been shown theoretically that charge transfer between the alkali metal (AM) centers and the host material leaves the AM adatom in the cationic state. The H₂ adsorption enthalpy is enhanced due to transfer of charge between H₂ and the metallic species.¹⁹ A rapid decrease in adsorption energy due to increasing temperature has also been reported, which limits the room temperature H₂ storage of AM functionalized carbonaceous materials.^{20–23} To enhance the binding aptitude of H₂, both alkaline earth metal (AEM) and transition metal (TM) coated materials have been extensively studied in the recent past.^{26–34} Smaller adsorption energies of H₂ for AEM than TM decorated storage media have been reported.²⁶ Functionalization with TMs leads to strong hybridization between the hydrogen σ - or σ^* -orbitals and low-lying empty d-orbitals in the TM atoms.¹⁹ This kind of interaction is typically observed in the Kubas complexes,^{24,25} and is responsible for enhanced binding affinity towards H₂ molecules. However, heavier TMs lead to lower gravimetric density for H₂ storage. In addition, clustering is also a crucial problem for TM-doped carbon-based materials, leading to lower storage efficiency.^{27,29} Thus, H₂ storage efficiency could be drastically improved by using light TM atoms and further preventing the metal clustering effect.

In this context, Nachimuthu *et al.* have reported a H₂ storage capacity of 6.4 wt% in Ni–Ti–Mg functionalized boron-doped graphene. Their results indicate that the boron content in graphitic materials could successfully hinder the formation of metallic clusters.^{26,33} In contrast, Beheshti *et al.* suggested that

substitutional doping of boron atoms in graphene also efficiently prevents Ca atoms from forming clusters, which is unavoidable in the case of pure graphitic materials.³⁰

Recent investigations on boron carbide (BC₃) nanomaterials in pure,³⁵ titanium-doped,³² calcium-doped⁴² and lithium-doped³⁴ systems have urged the scientific community to unravel the potential of this novel material for the purpose of practical H₂ storage. In the present work, we are interested in exploring the H₂ storage potential of scandium (Sc) functionalized boron carbide (BC₃) nanosheets using spin-polarized density functional theory (DFT) calculations. Our investigations include structure analysis, bonding characteristics, charge transfer mechanisms and hydrogenation of functionalized BC₃ sheets. The novelty of the present study lies in the fact that even in its pristine form BC₃ sheet holds multiple Sc dopants with much higher binding energies than graphene, graphane, h-BN sheet, silicene and many other materials, which make this material superior to these 2D materials.

Methodology

The computational analysis of structure, energetics, and charge transfer mechanisms was carried out within the framework of spin-polarized DFT using the Vienna Ab-initio Simulation Package (VASP).^{36,37} For electrons, exchange and correlation interactions were treated with generalized gradient approximation (GGA) as suggested by Perdew–Brucke–Ernzerhof,³⁸ whereas the description of ion–electron interactions was provided by the projector augmented wave method (PAW), which treats the following electronic states as valence: Sc 3p4s3d, B s2p1 and C s2p2.³⁹ For a geometrical description, GGA serves quite well except that the actual energies are underestimated. In order to give an accurate description of the energetics of our systems, we need to account for van der Waals

interactions. Therefore, we included the semi-empirical corrections of Grimme⁴⁰ as available in VASP. Owing to the sensitiveness of H₂ binding energies with functionalized BC₃@Sc systems, we have also compared the performance of DFT-D2 with that of non-local van der Waals functional. For all the computations, the energy cut-off was set to 500 eV. Our initial designed system was a 2 × 2 × 1 supercell, which consisted of 8 B and 24 C atoms. A vacuum thickness of 20 Å was inserted normal to the surface in order to decouple the periodically recurring images. The structures were allowed to relax until the total energy and force converged to 10⁻⁵ eV per atom and 0.05 eV Å⁻¹ respectively. The Brillouin zone was sampled using a *Γ*-point scheme with 5 × 5 × 1 mesh for structural relaxation. The density of states calculations with a denser 11 × 11 × 1 mesh were performed using the tetrahedron method. The charge transfer mechanism between the metal adatoms and BC₃ sheet was investigated using Bader charge analysis.⁴¹

Results and discussion

To functionalize BC₃ we have carefully selected the lightest transition metal Sc, which could result in a high gravimetric density and adequate binding enthalpy for H₂. Boron content in BC₃ sheets is expected to hinder clustering of Sc atoms over the sheets. The optimized structure of the (2 × 2 × 1) supercell of BC₃ is presented in Fig. 1. The supercell of pristine BC₃ monolayer consists of 8 B and 24 C atoms. The primitive cell of BC₃ sheet (marked with dotted lines) consists of 2 B and 6 C atoms.

Structural analysis

Structural analysis of optimized BC₃ reveals the C–C and B–C bond lengths to be 1.42 Å and 1.56 Å respectively, which agree well with previously reported results.^{42,43}

Fig. 1 (a) Top and side view of BC₃ sheet; the primitive cell is marked with dotted lines. High symmetry sites available for adatom occupation are indicated as T1, T2, H1, H2, B1 and B2. (b) Binding energy for occupied binding sites.

To functionalize pure BC_3 sheet with Sc atoms, we have investigated the adsorption behavior of a single Sc atom on all available high symmetry sites on the single side of the sheet. The six available adsorption sites for the Sc atom are designated (i) top of B atom (T1), (ii) top of C atom (T2), (iii) hollow site in BC ring (H1), (iv) hollow site in C ring (H2), (v) bridge between B and C atoms (B1) and (vi) bridge between two C atoms (B2), as shown in Fig. 1. For each possible site, the Sc atom is initially kept at a vertical distance of 2 Å. However, the Sc atom initially on T2 and B2 sites migrates towards the more favorable H2 site. The Sc atom binds to H2 sites with a binding energy of 7.11 eV at a vertical distance ($d_{\text{Sc-sheet}}$) of 1.45 Å. Initial and final geometries of all the possible configurations of Sc on BC_3 are given in S1 (ESI†). The adsorption energies for all Sc occupied sites are presented in Fig. 1(b). The adsorption energy of the Sc atom is defined as:

$$E_b = [E(\text{BC}_3) + E(\text{Sc})] - E(\text{BC}_3@\text{Sc}) \quad (1)$$

here $E(\text{BC}_3@\text{Sc})$, $E(\text{BC}_3)$ and $E(\text{Sc})$ refer to the total energies of Sc functionalized BC_3 sheet, pristine BC_3 sheet and Sc atom respectively. Binding energies of Sc atoms (equivalent to 3.12% Sc-coverage) on all the available occupation sites show that Sc binds to the sheet with binding energy exceeding the cohesive energy (3.9 eV) of Sc in bulk phase.⁴⁴

The strong binding of single Sc on BC_3 encouraged us to introduce more Sc dopant on the sheet. Thus, in a similar

fashion, we found the most favorable site for the second Sc atom (6.25% Sc-coverage) on the BC_3 sheet, as shown in Fig. 2. The most preferred binding site for the second Sc atom turns out to be the hollow site of the C ring (H2) exactly opposite to the first Sc atom. The binding energy per Sc is found to be 6.02 eV, which is slightly lower than for 3.12% Sc-coverage. However, it is still much higher than Sc–Sc cohesive energy, indicating that BC_3 could be further exposed to Sc adatoms. The distance $d_{\text{Sc-sheet}}$ has now increased by 0.19 Å due to the weakening of the bond as compared to the single Sc case (see Table 1).

In the case of 4 Sc on BC_3 sheet (12.5% Sc-coverage), the most favorable binding configuration is shown in Fig. 2(c). The optimized geometry of this configuration is found to be a little degraded owing to the relatively high Sc doping. Here the binding energy per Sc is found to be 5.45 eV, still almost 40% higher than Sc–Sc cohesive energy. The energetics analysis reveals that even at a significantly high Sc doping concentration, the metal dopants bind strongly enough to nullify cluster formation and make a uniform distribution over the BC_3 monolayer.

The bonding mechanism between Sc and BC_3 monolayer could be explained by studying the charge transfer mechanism. We employed Bader charge analysis for this purpose, which depicts a transfer of $1.251e^-$ of charge from Sc atom to BC_3 sheet due to the lower electronegativity of the former than the latter. The bulk portion of this transferred charge goes to the C atoms of BC_3 that are in close vicinity to Sc dopant. This would

Fig. 2 Top (left) and side (right) views of BC_3 sheet functionalized with (a) 1 Sc [3.12% Sc-coverage], (b) 2 Sc [6.25% Sc-coverage] and (c) 4 Sc [12.5% Sc-coverage]. C1 and C2 indicate the carbon atoms that were chosen for the plotting of density of states.

Table 1 Binding energy (eV) for the most stable configuration, dopant to sheet distance $d_{\text{Sc-sheet}}$, dopant-dopant distance $d_{\text{Sc-Sc}}$ and final charge on the dopant

System	Binding energy per Sc E_b (eV)	Average Sc to BC_3 distance $d_{\text{Sc-sheet}}$ (Å)	Minimum dopant-dopant distance $d_{\text{Sc-Sc}}$ (Å)	Charge per Sc (e^-)
BC_3 -1Sc	7.11	1.45	—	+1.444
BC_3 -2Sc	6.02	1.64	3.28	+1.390
BC_3 -4Sc	5.45	1.95	3.65	+1.251

transform Sc into a partially positive charged state, which proves to be extremely helpful in anchoring the incident H_2 molecules. The accumulation and depletion of charges were described by plotting the isosurface charge densities for 3.12%, 6.25% and 12.5% Sc-coverage, as shown in Fig. 3(a-c). The charge density can be calculated by the following relation:

$$\Delta\rho = \rho(\text{BC}_3@n\text{Sc}) - \rho(\text{BC}_3) - \rho(n\text{Sc}) \quad (2)$$

$$\{n = 1, 2, 4\}$$

The minimum distance between Sc atoms ($d_{\text{Sc-Sc}}$) in the case of 2 Sc (6.25% coverage) and 4 Sc (12.5% coverage) doping is found to be 3.28 Å and 3.65 Å respectively. The binding energy per Sc atom decreases, whereas the optimum distance between the Sc and BC_3 sheet increases with the increase in Sc dopant. Though the bond elongation for increased Sc-coverage ($d_{\text{Sc-sheet}}$) justifies comparatively weaker binding between the sheet and Sc atoms, the binding is still strong enough to prevent the formation of Sc-Sc clusters. Results from structural and charge analysis are presented in Table 1.

Fig. 3 Top (left) and side (right) views of isosurface charge densities of BC_3 with (a) 1 Sc atom [3.12% Sc-coverage], (b) 2 Sc [6.25% Sc-coverage] and (c) 4 Sc [12.5% Sc-coverage]. Cyan and yellow indicate the accumulation and depletion of charge, respectively.

Electronic structure analysis

In order to investigate the electronic structure of the designed Sc decorated BC₃ system, we have plotted and explained the partial electronic density of states (PDOS) of pure and functionalized BC₃ sheets (Fig. 4). PDOS of pure BC₃ (Fig. 4(a)) reveals a small bandgap of ~0.65 eV, which is in reasonable agreement with the previously reported value.⁴³ The PDOS of Sc functionalized BC₃ sheet (3.12% coverage) is shown in Fig. 4(b). C1 indicates the C atom that is closer to the Sc atom, and C2 resides at a greater distance from Sc, as indicated in Fig. 2. The Sc(d) state is found to be strongly hybridized with B(p) and C1(p) states of the BC₃ sheet. With 6.25% coverage, the extent of Sc(d) to B(p) and C1(p) hybridization decreases, which is reflected in a decrease in binding energy, as presented in Table 1. With higher coverage, the Sc to Sc attraction weakens the binding energy of BC₃ sheet to Sc.

Hydrogenation

After establishing the stability, the Sc functionalized BC₃ sheets were exposed to H₂ molecules. We consider placing H₂ molecules in different possible configurations whilst performing a set of structural relaxations. The average adsorption energies of H₂ were calculated using the following formula:

$$E_{\text{ads}} = [E(\text{BC}_3@m\text{Sc} + n\text{H}_2) - E(\text{BC}_3@m\text{Sc}) - nE(\text{H}_2)]/n \quad (3)$$

here $E(\text{BC}_3@m\text{Sc} + n\text{H}_2)$ corresponds to the total energy of the hydrogenated system, $E(\text{BC}_3@m\text{Sc})$ is the energy of the bare system, $E(\text{H}_2)$ is the energy of H₂, and n represents the number of adsorbed H₂.

The H₂ gravimetric density (storage capacity) can be calculated by the following relation:

$$\text{H}_2 \text{ storage capacity} = N_{\text{H}} \times W_{\text{H}} / [(N_{\text{B}} \times W_{\text{B}}) + (N_{\text{C}} \times W_{\text{C}}) + (N_{\text{Sc}} \times W_{\text{Sc}}) + (N_{\text{H}} \times W_{\text{H}})]$$

In the above relation N represents the number of each type of atoms and W represents the molecular weight of each element present in the system.

The number of H₂ molecules around Sc was gradually increased from 1 to the maximum adsorption limit. For the lowest Sc-coverage (3.12%), a maximum of five H₂ molecules per Sc atom could be adsorbed to the functionalized sheet, which resulted in a relatively small H₂ storage capacity of 2.364 wt%. Top and side views of the lowest energy hydrogenated systems are represented in Fig. 5(a) whereas all the other possible configurations are given in S2 (ESI[†]). The average distance

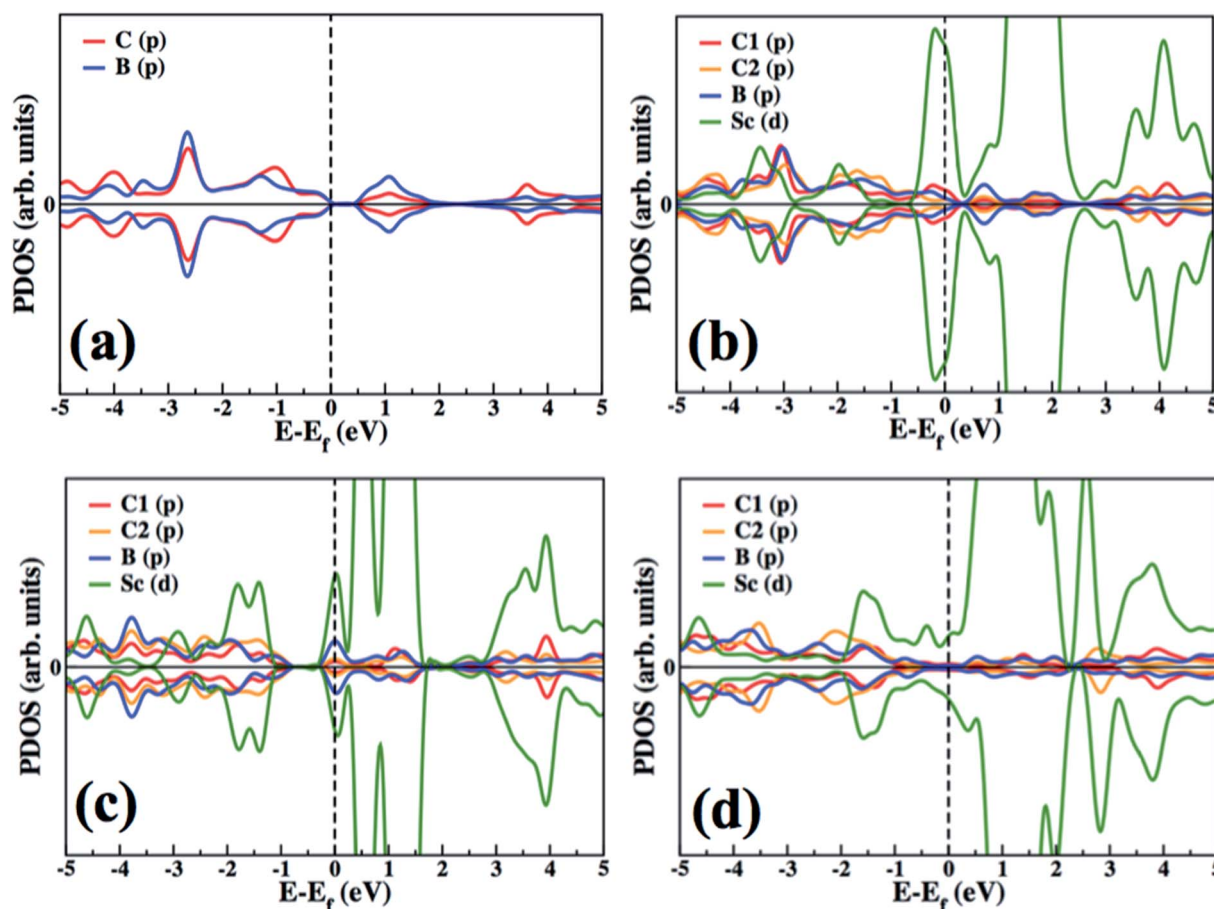

Fig. 4 Partial electronic density of state plots for (a) pure BC₃, (b) BC₃ with 1 Sc atom [3.12% Sc-coverage], (c) BC₃ with 2 Sc [6.25% Sc-coverage] and (d) BC₃ with 4 Sc [12.5% Sc-coverage]. The dashed line indicates the Fermi level.

between adsorbed H₂ and Sc atoms ($d_{\text{H}_2\text{-Sc}}$) and the average binding energy for maximum H₂ uptake are 2.2 Å and -0.34 eV respectively.

It is important to mention here that the H₂ adsorption energies are quite sensitive to van der Waals functionals, so a careful choice of a functional needs to be made in order to achieve unvarying values of adsorption energies. The DFT-D2 method of Grimme used in the present study has been extensively used and it has yielded reliable results consistent with the literature.^{45–48} For a comparison we have calculated the adsorption energies of H₂ and 2 H₂ adsorbed on BC₃@Sc by using the non-local van der Waals functional optPBE-vdW⁴⁹ and found that the adsorption energies of H₂ and 2 H₂ around BC₃@Sc are -0.310 eV and -0.293 eV respectively. These values are roughly 23% lower than those calculated by DFT-D2.

The bond length of H₂ has increased slightly to 0.76 Å. In the case of two Sc atoms, each Sc could bind 5 H₂ (shown in Fig. 5(b)), which yielded a H₂ storage capacity of 4.184 wt%, significantly higher than that of the BC₃@Sc system. The iso-surface charge density of BC₃@Sc-H₂ and BC₃@Sc-5H₂ is shown in S3 (ESI[†]). The adsorption energies of H₂ with the functionalized BC₃ material again show a decreasing trend with an increasing number of H₂. However, the binding energy of H₂

for maximum hydrogen coverage is -0.3 eV, which still lies in the energy window above weak physisorption (Fig. 6). The average distance between each H₂ and Sc atom is 2.39 Å and the average bond length of H₂ is 0.77 Å. We employed a similar procedure to hydrogenate the BC₃ sheet with 12.5% Sc-coverage. In total, 16 H₂ molecules could be incorporated in the functionalized system, giving a gravimetric density of 5.5 wt% (Fig. 5(c)).

Interestingly, the first H₂, introduced in between 2 Sc atoms (on each side of the sheet), experiences dissociative adsorption. The two H atoms locate to an optimal distance apart ($d_{\text{H-H}}$) of 2.2 Å and each H attains an electronic charge of $-0.495e^-$. The bond dissociation leads to adsorption of one H per Sc atom (H/Sc) at an average distance ($d_{\text{H-Sc}}$) of 1.93 Å and average binding energy of -0.9 eV. Further addition of H₂ in the vicinity of Sc atoms leads to associative adsorption of H₂. In the first step, the H₂ introduced in between 2 Sc atoms gets dissociated due to the presence of enough charge to contribute to the σ^* -antibonding orbitals. To support this argument, Bader charge analysis also reveals partially polarized H₂ molecules in the vicinity of Sc atoms. However, for successive adsorption of H₂, there is not enough charge available to destabilize the H₂ molecule. It is evident from Fig. 6 that for each Sc-coverage value, the average

Fig. 6 Adsorption energies of H₂ on functionalized BC₃ sheets for three different values of Sc-coverage.

adsorption energy of H₂ monotonically decreases with increasing number of H₂ molecules.

By gradually increasing the number of H₂ from 1 H₂/Sc to the maximum limit of adsorption, the average binding energy for associative adsorption varies from -0.31 to -0.20 eV for 12.5% Sc-coverage (Fig. 6). The average bond length of adsorbed H₂ molecules increased to 0.78 Å which is slightly larger than for free H₂ (0.75 Å). Bond elongation is typically observed in Kubas interaction where an amount of charge is donated from H₂ to the empty d-orbital of TM followed by back-donation of charge from TM to an anti-bonding orbital of H₂. Such donation and back-donation of charge governed by Kubas interaction has been extensively studied in the literature.^{8,50–52} The greater charge transfer results in a longer bond length of H₂. Successive addition of H₂ molecules to the functionalized BC₃ sheet (with 12.5% Sc-coverage) reveals that a total of 15 H₂ (including 2 dissociated molecules) could be adsorbed in the vicinity of Sc atoms, where one H₂ directly binds to the sheet at a distance ($d_{\text{H}_2\text{-sheet}}$) of 2.7 Å above the B2 site. Top and side views of the functionalized system with maximum H₂ uptake and average adsorption energies with increasing number of H₂ are represented in Fig. 5(c).

The functionalized systems (BC₃@Sc, BC₃@2Sc, BC₃@4Sc) reported in the present work could achieve a maximum H₂ storage capacity of 5.5 wt%, which fulfills the DOE target to be met by the year 2017. However, the H₂ capacity is smaller than given in a paper by Durgun *et al.*,⁷ which reported on the H₂ storage properties of selected transition metals (Ti, Sc, V) decorated on carbon chain, graphene and carbon nanotubes, which attained high H₂ storage capacities. However, to ensure the uniform distribution of metal dopants over the host materials, the binding energies of the former must be higher than their respective cohesive energies. In the paper mentioned above, the binding energies of TM dopants (Ti, Sc, V) fall short of their respective cohesive energies, which could allow the formation of TM clusters which significantly reduces the H₂ storage capacity.

The novelty of our work lies in the fact that, despite lower H₂ storage capacity as compared with the Durgun *et al.* paper, Sc, 2 Sc and 4 Sc bind strongly with BC₃, nullifying the possibility of cluster formation and ensuring the formation of stable doped systems.

Conclusions

We have performed spin-polarized DFT calculations to study the H₂ adsorption aptitude of Sc decorated BC₃ sheet. Our calculations reveal that Sc binds strongly to the BC₃ sheet with a binding energy that is much higher than its bulk cohesive energy. Hydrogen storage investigations performed with 3 different Sc-coverages (3.12%, 6.25%, and 12.5%) show that the binding energy of Sc on pristine BC₃ sheet decreases from 7.11 eV to 5.45 eV as the Sc content increases from 3.12% to the maximum 12.5%. However, even in the case of high Sc doping, the calculated binding energies are still much higher than their corresponding cohesive energies. The density of states analysis shows that Sc adsorption tunes the electronic behavior of BC₃ sheet and metallicity is enhanced with an increased Sc content. Adsorption energies of H₂ on BC₃-Sc_n systems lie within an energy window that is reasonable for practical H₂ storage. Based on these results we expect that Sc decorated BC₃ sheets can be used as a practical H₂ storage medium.
