Aconitic acid derived carbon dots as recyclable “on–off–on” fluorescent nanoprobe for sensitive detection of mercury(II) ions, cysteine and cellular imaging†

Fengjiao Zhao,^a Jiali Qian,^a Feifei Quan,^a Chengxin Wu,^a Yian Zheng^b ^{id} and Lei Zhou ^{id} ^{*a}

In this study, aconitic acid (AA) was applied as a new carbon precursor for the fabrication of fluorescent carbon dots (CDs) using a facile one-step microwave-assisted synthesis approach with ethylenediamine as the co-doping reagent. The AA derived CDs (AA-CDs) were water-soluble and the aqueous solution of AA-CDs exhibited excitation-independent, bright blue fluorescence with an absolute quantum yield of 45.1%. Without further surface modification, the intrinsic fluorescence can be gradually quenched by the incremental addition of Hg²⁺ ions through an effective electron or energy transfer process due to the high affinity of Hg²⁺ to AA-CDs. By introducing cysteine (Cys) into the AA-CDs-Hg²⁺ system, the quenched fluorescence will be recovered *via* the formation of Hg-S bonds, which can be utilized to further enhance the selectivity for sensing Hg²⁺ ions. Based on the “on–off–on” system, we established a sensitive and selective fluorescence sensor for turn-off detection of Hg²⁺ ions and turn-on detection of Cys in aqueous solution, with detection limits of 5.5 and 30 nM, respectively. The fluorescence of AA-CDs could be repeatedly turned off and on for over 10 cycles by alternately adding Hg²⁺ ions and Cys, suggesting excellent reversibility. Furthermore, the prepared AA-CDs were successfully applied for the determination of Hg²⁺ in environmental water samples, and also as fluorescent nanoprobe for imaging Hg²⁺ ions and Cys in living cells.

1. Introduction

Nanoscale materials, benefiting from their versatile structures and functions, have received intense attention and offer promising applications in both research and practice for analytical science.^{1–4} As an emerging fluorescent carbon nanomaterial, carbon dots (CDs) possess some distinct features such as excellent optical properties, chemical stability, biocompatibility, and low toxicity,^{5–8} which enable them to be widely used in different fields including bioimaging, medical diagnosis, catalysis, photovoltaic devices, and so on.^{6–15} Generally, CDs can interact with analytes to facilitate the non-radiative electron/hole recombination and annihilation *via* electron or energy transfer processes, resulting in either enhancement or quenching in the intrinsic fluorescence of CDs for subsequent qualitative or quantitative analysis. Depending on different

carbon source and synthesis methods, CDs usually contain some functional groups such as carboxyl, amino, and/or mercapto groups, *etc.*, and accordingly their inherent fluorescence could be easily quenched by some electron acceptors in solution. Consequently, CDs were usually applied as fluorescent nanoprobe for the detection of metal ions.^{16–18}

As one of the most toxic chemicals, Hg²⁺ ions have severe adverse effects on human health and environment safety. Given their persistence, easy mobility and bioaccumulation, Hg²⁺ ions have become one of the most important heavy metal pollutants throughout the world.¹⁹ Therefore, developing new methods and strategies for the detection of Hg²⁺ ions in environment and biological samples are of continuous interests in analytical chemistry.^{20–22} As strong electron acceptor, Hg²⁺ ions are easily bound onto the surface of CDs through the electrostatic and/or coordination interactions, resulting in significant fluorescence quenching. Based on this, several CDs have been utilized as fluorescent probes for the detection of Hg²⁺ ions in different samples.^{23–39} Among these studies, quenching mode has been employed for the quantitative analysis of Hg²⁺ ions. However, the quenching mode is usually subjected to poor selectivity from uncertain factors affecting fluorescence quenching. It is well known that Hg²⁺ ions could exhibit strong interaction with

mercapto groups to form Hg–S bonds, and as a consequence, the mercapto compounds were commonly used in some sensing systems to recover the quenched fluorescence by Hg²⁺ ions. The so-called “on–off–on” sensing strategy greatly improves the selectivity for the detection of Hg²⁺ ions, and meanwhile, this principle could be applied to establish new analytical methods for the determination of some important mercapto-containing biomolecules. Recently, some studies have been reported using Hg²⁺-quenched CDs as probes for the detection of mercapto biomolecules such as cysteine (Cys).^{40–47} Nevertheless, there are still considerable problems to be investigated in these studies. For instance, Hg²⁺ ions served only as an intermediate to quench the fluorescence of CDs whereas their analysis was ignored; the quantum yield of CDs was too low to improve the detection sensitivity; and the selectivity of the developed method had yet to be further improved.

In previous studies, the researchers had obtained fluorescent CDs with high quantum yield using citric acid as carbon precursor.^{48–51} Aconitic acid (AA) has a similar structure with citric acid, and its molecular skeleton contains one ethylenic bond, so we speculate it to be a more ideal precursor for the preparation of CDs. In this study, AA as a new carbon precursor was used for the preparation of CDs by a facile, one-step microwave-assisted method. The resulting AA–CDs were water-soluble, and emitted excitation-independent, bright blue fluorescence with high absolute quantum yield of 45.1%. Without further surface modification, Hg²⁺ ions could effectively quench the fluorescence of AA–CDs with excellent selectivity. By introducing Cys into this AA–CDs–Hg²⁺ system, the previously quenched fluorescence would be recovered, which could be utilized to further enhance the selectivity of Hg²⁺ ions sensor. Subsequently, we established a sensitive analytical method to detect Hg²⁺ ions and Cys in aqueous solution. Moreover, the as-prepared AA–CDs and AA–CDs–Hg²⁺ system were applied as fluorescent nanoprobes to facilitate label-free intracellular imaging of Hg²⁺ ions and Cys in living cells.

2. Experimental

2.1. Chemicals

Aconitic acid (AA) was of analytical reagent grade and purchased from Alfa Aesar Chemistry (Tianjin, China). 1,2-Ethylenediamine (EDA, analytical reagent grade) was obtained from Baishi Chemical Reagent (Tianjin, China). 4-(2-Hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES) was received from Sigma-Aldrich. Twenty amino acids including alanine (Ala), arginine (Arg), asparagine (Asn), aspartic acid (Asp), cysteine (Cys), glutamine (Gln), glutamic acid (Glu), glycine (Gly), histidine (His), isoleucine (Ile), leucine (Leu), lysine (Lys), methionine (Met), proline (Pro), phenylalanine (Phe), serine (Ser), threonine (Thr), tryptophane (Trp), tyrosine (Tyr), valine (Val), were all of analytical reagent grade and purchased from Xi'an Zhoudingguo Biotech (China). All metal salts were of analytical grade and dissolved in ultrapure water. All chemicals were used as received without further purification.

2.2. Apparatus and characterization

All fluorescence spectra were surveyed on an F97Pro fluorospectrophotometer (Lengguang Technology, Shanghai, China) using 10.0 nm slit width for both excitation and emission, and equipped with a 10 mm × 10 mm quartz cuvette. The ultraviolet-visible (UV-vis) absorption spectra were recorded using a UV 2800SPC spectrophotometer (Sunny Hengping Scientific Instrument, Shanghai, China) with a 10 mm path length quartz cell. The fluorescence quantum yield (QY) of AA–CDs was determined by absolute method (called absolute QY) using an FLS920 spectrometer (Edinburgh Instruments, U.K.) and the integrating sphere accessory. For the determination of absolute QY, only dilute solutions and the corresponding solvent at the excitation wavelength ($\lambda_{\text{ex}} = 360$ nm) were used. Time-resolved fluorescence spectra were carried out in a time-correlated single photon counting (TCSPC) system from FLS920 spectrometer with $\lambda_{\text{ex}} = 360$ nm and $\lambda_{\text{em}} = 450$ nm (the details are given in ESI†). The morphologies of AA–CDs were observed by transmission electron microscopy (TEM, Tecnai F30, FEI, Netherlands), with an accelerating voltage of 200 kV. The sample for TEM observation was made by dropping AA–CDs solution onto 300-mesh copper grids coated with a lacy carbon film. The particle size distribution was measured on a BI-200SM dynamic light scattering (DLS) instrument (Brookhaven, USA). The elemental analyses (C, H and N) were performed on a Vario EL elemental analyzer (Elementar, Germany). The surface functional groups of AA–CDs were investigated by X-ray photoelectron spectroscopy (XPS, PHI 5702, PerkinElmer) equipped with an Al K α exciting source and Fourier transform infrared spectra (FT-IR, NEXUS 670 spectrometer, Nicolet) from 4000 to 400 cm⁻¹ using KBr pellets, respectively. The zeta potential of AA–CDs in HEPES buffer was measured using Malvern Zetasizer 3000HSa (He–Ne laser, $\lambda = 632.8$ nm).

2.3. Microwave-assisted synthesis of AA–CDs

Typically, 0.0871 g AA and 100.4 μL of EDA were dissolved in 5 mL ultrapure water to form a homogeneous solution. Then, the solution was put into a domestic microwave oven (Midea, China) and radiated for 6 min at 700 W, with the change of the solution from original colorless liquid to golden-yellow solid, indicating the formation of AA–CDs. The golden-yellow solid was then dried at 50 °C for 2 h in vacuum oven. After completely dried, the solid was ground into uniform powder and stored for further use. The AA–CDs powder can be easily dispersed in water to reconstruct stable solution.

2.4. On–off–on sensor for Hg²⁺ ions and Cys

For the fluorescence on–off–on sensing experiments, an appropriate amount (20 $\mu\text{g mL}^{-1}$) of AA–CDs was dissolved in 3 mL HEPES buffer (10 mM). For the turn-off sensor, various concentrations of Hg²⁺ ions up to 20 μM were gradually added into the AA–CDs solution to quench their fluorescence. For the turn-on sensor, different amounts of Cys were added into the non-fluorescence AA–CDs–Hg²⁺ system (adding 20 μM Hg²⁺ ions into AA–CDs solution in advance) to recover their

fluorescence. The selectivity measurements were investigated for Hg^{2+} ions and Cys using common metal ions and other 19 amino acids, respectively. Subsequently, the reversibility of the “on-off-on” fluorescence sensor was tested by adding Hg^{2+} ions and Cys alternately. All of the experiments were carried out at room temperature, and the excitation and emission wavelengths were fixed at 360 and 450 nm, respectively.

Further, three water samples were collected to assess the applicability of AA-CDs for Hg^{2+} detection in real environmental samples, including tap water (from our lab), lake water (from the lake in the campus of Lanzhou University), and river water (from the Yellow River in Lanzhou section). All water samples were naturally settled for 24 h, and then centrifuged for 10 min at 10 000 rpm. Subsequently, the supernatant was filtered through a 0.45 μm pore size cellulose acetate membrane filter before analysis.

2.5. Fluorescence imaging in living cells

The SMMC-7721 hepatoma cells, obtained from the Institute of Cell Biology (Shanghai, China), were seeded in 12-well plates (1 mL per well) and cultured using Roswell Park Memorial Institute-1640 (RPMI-1640) supplemented with 5% fetal bovine serum (FBS), 1% streptomycin at 37 °C in a humidified atmosphere of 5% CO_2 overnight. After adding proper concentrations of AA-CDs (200 $\mu\text{g mL}^{-1}$), AA-CDs- Hg^{2+} (100 μM for Hg^{2+}), and Cys (150 μM), the 12-well plates were put back to incubator for 1 h at 37 °C. After that, remove the incubation media and rinse with new culture media. And then, the cells incubated by AA-CDs was further incubated for another 30 min at 37 °C using Hg^{2+} ions (100 μM) and the cells incubated with AA-CDs- Hg^{2+} was further incubated for another 1 h using Cys (150 μM). Prior to fixation of the cells on the slide for inspection, the excess culture media were removed by washing three times with phosphate buffer solution (PBS, 10 mM, pH 7.4). Afterwards, the fluorescence images were taken on an Olympus FV-1000 laser confocal microscope (Japan) with 405 nm laser.

3. Results and discussion

3.1. Characterization of AA-CDs

Aconitic acid is speculated to be an ideal precursor to produce CDs due to its unsaturated bond that may give more possibilities to generate excellent optical properties. As expected, the obtained AA-CDs exhibited strong blue fluorescence under UV light (365 nm, inset in Fig. 1). Further, the optical properties of the prepared AA-CDs were confirmed by UV-vis absorption and fluorescence spectra in aqueous solution. As shown in Fig. 1, the AA-CDs solution exhibited an absorption at about 340 nm in UV-vis spectrum, which was ascribed to the $n-\pi^*$ transition of the AA-CDs.⁵² The fluorescence spectra showed that the optimum emission of AA-CDs was peaked at 450 nm when excited at 360 nm. By consecutively altering the excitation wavelengths from 300 to 380 nm, no obvious wavelength shift was observed in the fluorescence emission spectra of AA-CDs, demonstrating an excitation-independent fluorescence behavior. The absolute QY of AA-CDs was measured to be

Fig. 1 UV-vis absorption (black line) and fluorescent emission spectra of AA-CDs under various excitation wavelengths from 300 to 380 nm. Inset: photographs of AA-CDs under daylight (left) and UV lamp (right, 365 nm).

45.1%, which was competent for acting as a highly sensitive sensor.

The morphology of the prepared AA-CDs was characterized by TEM and the results showed that the AA-CDs were well mono-dispersed and uniform in size (Fig. S1a†). Dynamic light scattering analysis revealed that the size of AA-CDs was distributed in the range of 1.8 to 4.0 nm with an average size of 2.9 nm (Fig. S1b†). Further elemental analysis indicated that the prepared AA-CDs were mainly composed of carbon (45.36%), hydrogen (6.34%), nitrogen (19.19%), and oxygen (29.11%, calculated value).

The FTIR spectrum was acquired to identify the surface functional groups of the prepared AA-CDs (Fig. S2†). The absorption band at 3429.7 cm^{-1} is ascribed to the stretching vibration of N-H, and the bands at 3250 and 1146.1 cm^{-1} are attributed to the characteristic absorption of O-H and C-O, respectively. The band at 2928.8 cm^{-1} can be assigned to the C-H stretching vibration and the characteristic absorption band of C=O and/or C=C stretching vibration at around 1668.6 cm^{-1} is also observed. The bands at 1581.3 and 1358.5 cm^{-1} indicate the existence of -COOH.^{43,53} The surface composition for AA-CDs was further characterized by XPS, and the survey spectra presented three peaks for AA-CDs at around 285 eV, 399.5 eV and 531 eV, corresponding to C 1s, N 1s and O 1s, respectively (Fig. S3a†). The high resolution XPS spectrum of C 1s (Fig. S3b†) can be resolved into three peaks with C-C/C=C at 284.8 eV, C-N/C-O at 285.9 eV and C=O at 287.7 eV, respectively. The fitting of the N 1s peak (Fig. S3c†) gives four components at 399.3 eV, 399.7 eV, 400.1 eV and 401.5 eV, corresponding to C-N/C=N, pyrrole N, pyrrolic N and N-H bonds, respectively. Deconvolution of the O 1s spectrum in Fig. S3d† shows three peaks at 530.5 eV, 531.0 eV and 532.3 eV for C=O, C-O-C and C-OH groups, respectively.^{33,43} These findings suggest that the surface of AA-CDs is functionalized with amino, hydroxyl and carboxylic/carbonyl moieties originated from AA and EDA, which agrees well with the above FTIR results. In addition, the zeta potential of AA-CDs in HEPES

buffer was measured to be -6.23 mV, indicating its negative-charged surface.

In order to evaluate the feasibility for practical sensing applications, the prepared AA-CDs were investigated on its response towards ambient environments. Above all, the AA-CDs were inherently water-soluble because of the hydrophilic groups on the surface, and emitted stronger fluorescence in water compared to other common solvents (Fig. S4a†). Also, the fluorescence intensity had no obvious decrease even after light illumination ($\lambda_{\text{ex}} = 360$ nm) for 7 h, suggesting good photostability of the AA-CDs (Fig. S4b†). When the solid powder and solution of AA-CDs were stored for three months, no appreciable changes in the fluorescence intensity were observed, indicating excellent storage stability of the AA-CDs. External pH and ionic strengths are important factors affecting the fluorescence property of CDs. Fig. S4c† revealed that the fluorescence intensity showed a monotonic increase with increasing pH from 1.0 to 5.0, followed by a strong and stable signal from pH 5.0 to 10.0, and then a monotonic decrease after pH 10.0, which is closely correlated to the pH-dependent nature of hydroxyl and carboxylic/carbonyl moieties attached onto the AA-CDs. Ionic strength had almost no influence on the fluorescence intensity of AA-CDs, even under the extreme condition of 3 mol L^{-1} NaCl solution (Fig. S4d†). Based on above discussions, the prepared AA-CDs are particularly suitable as fluorescent nanoprobes for sensing applications under physiological conditions.

3.2. Turn-off sensor for Hg^{2+} ions

Initially, we investigated the response of common metal ions on the fluorescence of AA-CDs, and the results indicated that the AA-CDs' fluorescence could be effectively quenched by mercury(II) ions, demonstrating that the prepared AA-CDs could serve as fluorescent nanoprobes for Hg^{2+} ions *via* turn-off mode. Fig. 2a showed the fluorescence spectra of the AA-CDs after

adding various concentrations of Hg^{2+} ions (0 – $20 \mu\text{M}$), and a gradual decrease in PL intensity at 450 nm ($\lambda_{\text{ex}} = 360$ nm) with increasing Hg^{2+} ions concentration was observed, revealing that the fluorescence intensity of AA-CDs was sensitive to Hg^{2+} ions concentration. The quenching efficiency (F_0/F) displayed a parabolic increase *versus* the concentration of Hg^{2+} ions, where F_0 and F are fluorescence intensities at 450 nm in the absence and presence of Hg^{2+} , respectively. And in the lower concentration range of 0 – 50 nM, a good linear relationship was obtained with the correlation coefficient (R) of 0.99 (Fig. S5†). The detection limit was estimated to be 5.5 nM according to a signal-to-noise ratio of 3 , which was superior or comparable to other CDs sensing systems (Table S1†) and lower than the maximum level (10 nM, 2 ppb) for Hg^{2+} ions in drinking water mandated by the United States Environmental Protection Agency (EPA).⁵⁴ Generally for a sensor, there are not only in the aspect of sensitivity but more importantly in the aspect of selectivity. Consequently, the selectivity and competition experiments were conducted, and it is clearly observed from Fig. 2b that except for Hg^{2+} , the fluorescence intensity of AA-CDs showed no significant decrease by introducing other counter ions with the concentration of $60 \mu\text{M}$, even in the mixed solution containing other 18 metal ions. The outstanding sensitivity and selectivity demonstrated the feasibility of AA-CDs as fluorescent nanoprobe for sensing Hg^{2+} ions in aqueous solution.

Then, the prepared AA-CDs were attempted to analyze Hg^{2+} ions in environmental water samples, including tap water, lake water, and river water. However, no detectable amount of Hg^{2+} ions was found in these water samples. Thus, the standard addition methodology with three spiked levels (10 nM, 100 nM, 1000 nM) and three replicates at each level were considered for spiked water samples. As listed in Table 1, the average recoveries were in the range of 98.6 – 106.4% , and the RSD values were

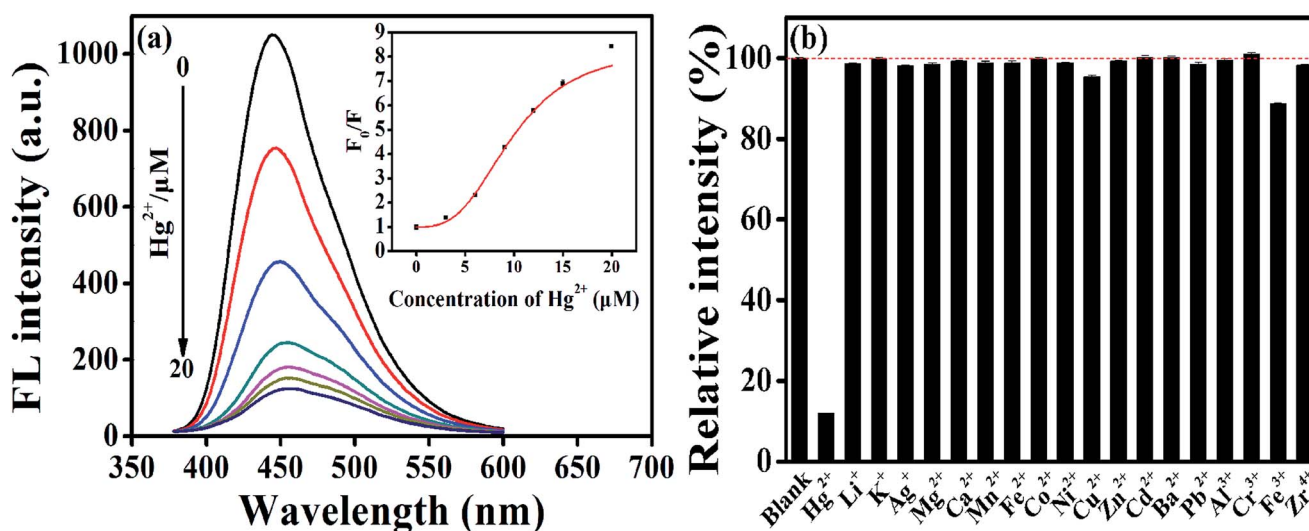

Fig. 2 (a) Fluorescent emission spectra at 450 nm of AA-CDs upon gradual addition of Hg^{2+} ions from 0 to $20 \mu\text{M}$. Inset: the dependence of F_0/F on the concentration of Hg^{2+} ions (F_0 and F correspond to the fluorescence intensities of AA-CDs in the absence and presence of Hg^{2+} ions, respectively). (b) Selectivity of AA-CDs to different metal ions (the concentration for all other metal ions is $60 \mu\text{M}$). Excitation wavelength is 360 nm and the excitation and emission slit width was 5.0 nm. Blank corresponds to the fluorescence intensities of AA-CDs.

Table 1 Determination of Hg^{2+} ions in environmental water samples using AA-CDs

Samples	Added (nM)	Found (nM)	Recovery (%)	RSD (% , $n = 3$)
Tap water	10	10.3	103.0	1.5
	100	103.5	103.5	2.3
	1000	1064.0	106.4	3.5
Lake water	10	10.3	103.0	2.1
	100	104.3	104.3	1.7
	1000	985.8	98.6	2.0
River water	10	10.1	101.0	2.5
	100	104.2	104.2	1.9
	1000	1020.2	102.0	2.1

less than 3.5%, testifying that the prepared AA-CDs could be used for the determination of Hg^{2+} ions in real waters.

3.3. Turn-on sensor for Cys

Turn-off mode for sensor has a potential risk in selectivity, namely some uncertain factors can cause fluorescence quenching. Typically, Hg^{2+} ions could interact with mercapto groups to form Hg-S bonds, and accordingly, some mercapto compounds were commonly used in this study as a recovery agent, and it was found that with the addition of Cys into AA-CDs- Hg^{2+} system, the fluorescence quenched by Hg^{2+} could be dramatically recovered. The turn-on strategy greatly improves the selectivity for the detection of Hg^{2+} ions, by excluding the fluorescence quenching arisen from other uncertain factors.

And meanwhile, this principle could be applied to construct a fluorescence turn-on sensor for Cys detection. As illustrated in Fig. 3a, there is an increase in the fluorescence intensity at 450 nm by varying the Cys concentration from 0 to 10 μM , beyond which a sharp increase in the PL intensity is visible. A good linear

relationship is found in the Cys concentration range of 0–700 nM, with the correlation coefficient R of 0.99 and the detection limit of 30 nM ($S/N = 3$), which is comparable to those reported by other CDs sensing systems (Fig. S6 and Table S2[†]). To verify the selectivity of AA-CDs- Hg^{2+} system to Cys, the fluorescence responses of AA-CDs- Hg^{2+} to different amino acids were monitored and the results were presented in Fig. 3b and S7.[†] It is clear to find that except for Cys, there are almost no significant changes in fluorescence intensity after adding other 19 kinds of amino acids or mixed amino acids solution, demonstrating that the AA-CDs- Hg^{2+} system has an excellent selectivity to Cys. It is worth noting that in some literatures,^{41,55} the addition of histidine (His) could also recover the quenched fluorescence by Hg^{2+} ions, *i.e.* those reported sensors could not distinguish Cys and His. However, the developed AA-CDs- Hg^{2+} sensing system could clearly discriminate Cys and His in this study (Fig. 3b).

3.4. Mechanism discussion for the “on-off-on” process

It is well known that fluorescence emission of most CDs derives from the radiative recombination of excitons, which can be quenched by electron acceptors such as metal ions.⁴⁹ Generally, the surface state has a significant impact on the band gap and excited states of CDs. With addition of Hg^{2+} ions, the oxygen-containing groups on the surface of AA-CDs could coordinate with Hg^{2+} ions to form complexes. Upon photo-excitation, the excited state of AA-CDs could relax its energy in the non-electron transfer manner, leading to a substantial decrease of the fluorescence of AA-CDs, as supported by Fig. 4. The AA-CDs solution exhibits strong blue fluorescence, while an almost complete fluorescence quenching is observed by introducing Hg^{2+} ions to this solution. Upon addition of Cys to the solution of AA-CDs- Hg^{2+} , the quenched fluorescence of AA-CDs is recovered immediately. The fluorescence enhancement of AA-CDs- Hg^{2+} solution may be attributable to the formation of

Fig. 3 (a) Fluorescent emission spectra at 450 nm of AA-CDs- Hg^{2+} upon gradual addition of Cys from 0 to 63 μM . Inset: the dependence of F/F_0 on the concentration of Cys. (b) Selectivity of AA-CDs- Hg^{2+} system to different amino acids (the concentration for all amino acids is 63 μM). F and F_0 correspond to the fluorescence intensities of AA-CDs- Hg^{2+} in the presence and absence of Cys, respectively). Other conditions are same as in Fig. 2.

Fig. 4 UV-vis absorption (solid lines) and fluorescent emission spectra (dash lines) for AA-CDs, AA-CDs-Hg²⁺, AA-CDs-Hg²⁺-Cys systems. Inset: photographs of AA-CDs, AA-CDs-Hg²⁺, AA-CDs-Hg²⁺-Cys systems (from left to right) under UV lamp (365 nm).

Hg-S bonds, which enables the removal of Hg²⁺ ions from the surface of AA-CDs. The UV-vis spectra were used to prove the aforesaid principle. Compared to AA-CDs (black solid in Fig. 4) absorption at 340 nm, a slight red-shift occurs for AA-CDs-Hg²⁺ (red solid in Fig. 4) at 345 nm, while the peak position of AA-CDs-Hg²⁺-Cys system (blue solid in Fig. 4) was almost the same as AA-CDs. During the experiment, no obvious absorbance was observed for Hg²⁺ ions, Cys and Hg²⁺-Cys in the wavelength range from 300 to 400 nm, and accordingly, this slight red-shift should be attributed to the interactions between Hg²⁺ ions and functional groups of AA-CDs surface.⁴⁰ Further verification was followed by the TCSPC technology, which was used to study the exciton behaviors of the AA-CDs, AA-CDs-Hg²⁺ and AA-CDs-Hg²⁺-Cys system, respectively. Under the excitation wavelength of 360 nm and emission wavelength of 450 nm, an average lifetime can be achieved using eqn (3) in ESI.† The time-resolved fluorescence spectra were shown in Fig. S8† and all detailed curve fittings were presented in Table S3.† The decay time of AA-CDs (Fig. S8a†) is 14.92 ns ($\chi^2 = 0.976$) with two components: 5.21 ns (ca. 6.87%) and 15.64 ns (ca. 93.13%). The decay time of AA-CDs-Hg²⁺ (Fig. S8b†) is 9.93 ns ($\chi^2 = 1.106$) with two components: 4.13 ns (ca. 34.13%) and 12.94 ns (ca. 65.87%). The decay time of AA-CDs-Hg²⁺-Cys system (Fig. S8c†) is 14.03 ns ($\chi^2 = 1.014$) with two components: 3.82 ns (ca. 5.47%) and 14.66 ns (ca. 94.26%). The significant change in lifetime indicates an ultrafast AA-CDs/Hg²⁺ electron-transfer process and dynamic quenching process.⁵⁶ Fluorescence quenching may attribute to non-radiative electron/hole recombination and annihilation through an effective electron or energy transfer process resulting from the strong electrostatic interaction and metal-ligand coordination between the AA-CDs and Hg²⁺ ions.⁵⁷

The reversibility is considered to be significant for recycling of the indicator, especially for understanding the sensor mechanism.²⁰ However, previous studies illustrated that most sensor systems responded to Hg²⁺ ions irreversibly or the reversibility of the reported sensors had not been proved. In this

study, the sequential addition of constant amounts of Hg²⁺ ions (20 μ M) and Cys (63 μ M) to the aqueous solution of AA-CDs gives rise to an alternative change in fluorescence intensity for the developed system. As exhibited in Fig. 5, the fluorescence recovery and quenching efficiency could reach as high as 90% after 10 cycles according to the original fluorescence value of AA-CDs, demonstrating excellent “on-off-on” reversibility. Here, it should be mentioned that the adding concentrations of Hg²⁺ and Cys were respective 20 μ M and 63 μ M in the first cycle. After ten cycles, the cumulative concentrations of Hg²⁺ and Cys were about 0.8 mM and 2.6 mM.

3.5. Imaging Hg²⁺ ions and Cys in living cells

From above results, the prepared AA-CDs could be applied as fluorescent nanoprobe for sensing Hg²⁺ ions and Cys in aqueous solution with high sensitivity and selectivity. Benefited by their small size (generally several nanometers), CDs are easily internalized into the cells through caveolae-mediated endocytosis.⁵ Herein, we further investigate the feasibility for imaging Hg²⁺ ions and Cys in living biological systems using SMMC-7721 cells as a model. The cytotoxicity of the prepared AA-CDs to SMMC-7721 cells was firstly evaluated by a standard MTT assay (in ESI†), and the results revealed that no significant changes in cell viability and morphology were observed, implying excellent biocompatibility and low cytotoxicity (Fig. S9†). Subsequent experiments were carried out using AA-CDs as fluorescent nanoprobe for imaging intracellular Hg²⁺ ions and Cys in SMMC-7721 cells. As shown in Fig. 6a-c, by incubating the cells with AA-CDs (200 μ g mL⁻¹) at 37 °C (1 h), a significant blue fluorescence from the intracellular region could be observed clearly (Fig. 6a). While, it is hard to find fluorescence signal from the cells incubated with exogenous Hg²⁺ ions (100 μ M) for another 1 h after incubating by AA-CDs (Fig. 6d). Furthermore, exogenous Cys (150 μ M) was used to incubate the living cells and no fluorescence could be observed (Fig. 6g). One can find in Fig. 6j that the cells incubated with AA-CDs-Hg²⁺ were further incubated for another 1 h at 37 °C

Fig. 5 The reversibility of AA-CDs by alternately adding Hg²⁺ ions and Cys in HEPES buffer.

Fig. 6 Confocal laser scanning fluorescence microscopy images (a, d, g and j, $\lambda_{\text{ex}} = 405 \text{ nm}$), corresponding bright-field images (b, e, h and k), and the overlay of bright field and fluorescence images (c, f, i and l) for SMMC-7721 cells. (a–c) Cells were incubated with AA-CDs for 1 h at 37°C . (d–f) Cells were incubated with AA-CDs for 1 h at 37°C and then incubated with Hg^{2+} ions for 30 min at 37°C . (g–i) Cells were incubated with Cys for 1 h at 37°C . (j–l) Cells were incubated with AA-CDs- Hg^{2+} for 1 h at 37°C and then incubated with Cys for 1 h at 37°C .

using Cys, the intracellular fluorescence was observed again from the confocal laser scanning microscopy z-stack images, indicating that the AA-CDs- Hg^{2+} system could be applied for imaging intracellular Cys.

4. Conclusion

In summary, using aconitic acid as a new carbon precursor, we prepared a kind of excellent fluorescent CDs by facile one-step microwave-assisted synthesis. The AA-CDs were completely water-soluble and the solution emitted excitation-independent, strong blue fluorescence with an absolute quantum yield of 45.1%. The obtained AA-CDs were remarkably stable against light illumination, extreme pH, and ionic strengths, and could serve as a promising fluorescence sensor. Without further surface chemical modification, Hg^{2+} ions could effectively quench the fluorescence of AA-CDs, meanwhile, introducing Cys into this AA-CDs- Hg^{2+} system could recover the quenched fluorescence. The developed on-off-on system has been proved to have good reversibility and consequently, and the fluorescence sensor system was designed for the detection of Hg^{2+} ions and Cys with excellent sensitivity and selectivity. Furthermore, the prepared AA-CDs have been demonstrated the reliability and feasibility for determining Hg^{2+} in environmental water samples and label-free imaging of Hg^{2+} ions and Cys in living cells. Benefited from above-mentioned advantages, it is believed that the aconitic acid derived CDs and the designed on-off-on sensor strategy will find their potential applications in environmental and biological fields.
