# Electron transportation path build for superior photoelectrochemical performance of  $Aq_3PO_4/$ TiO<sub>2</sub>†

Lianqing Yu[,](http://orcid.org/0000-0002-1915-9420) <sup>D\*</sup> Jiandong He, <sup>D</sup> Chengxing Huang, Ming Li, Yaping Zhang, Xiaoyan Zhou and Haifeng Zhu

TiO<sub>2</sub> is an attractive photoanode material with its large band gap, whilst its performance largely suffers from low efficiency on both charge separation and solar conversion. Herein, a self-organized TiO<sub>2</sub> nanotube arrays (TNT) is prepared by anodized Ti foil in ethylene glycol electrolyte to ameliorate charge transmission ability. Ag<sub>3</sub>PO<sub>4</sub> is further synthesized on TNT substrate by dipping method. HRTEM images results indicate Ag<sub>3</sub>PO<sub>4</sub> nanoparticles are successfully deposited on the surfaces of TNT. Photoelectrochemical tests show the  $Ag_3PO_4/TiO_2$  heterojunction has a higher photocurrent density of 2.34 mA cm<sup>-2</sup> at 0 V than that of pure TNT (0.38 mA cm<sup>-2</sup>). This is attributed to an Ag "pump" reduced on the interface of Ag<sub>3</sub>PO<sub>4</sub>/TiO<sub>2</sub>, therefore electron transportation path is built between Ag<sub>3</sub>PO<sub>4</sub> and TiO<sub>2</sub> leading to photogenerated electrons and holes effective separation. This high photocurrent density array films facilitates it a desirable photoelectrochemical material for water splitting. **PAPER**<br> **Electron transportation path build for superior<br>

# 1 Introduction

Photoelectrochemica (PEC) water splitting is recognized as one of the most promising strategies in solar energy conversion. Titanium dioxide  $(TiO<sub>2</sub>)$  has been specifically selected out among various PEC materials since Honda-Fujishima first found the ability of  $TiO<sub>2</sub>$  for photo-splitting water under ultraviolet light in 1972.<sup>1</sup> In 1976, Carey found that PCBs in  $TiO<sub>2</sub>$ suspension solution successfully dechlorinated under UV irradiation.2 In 1991, Graztel successfully developed a dyesensitized solar cell by using  $TiO<sub>2</sub>$  nanoparticles.<sup>3</sup> But  $TiO<sub>2</sub>$ suffers from its poor charge separation and high charge transmission resistance.4,5 One dimensional (1-D) nanostructure allows a short diffusion length for holes in radial direction, whereas the long axial direction of the structure becomes the preferred electron channel that provides enough length of light attenuation as well.<sup>6,7</sup> Besides these above, 1-D nanostructures also provide excellent photovoltaic, photocatalytic, and PEC properties relative to random-shaped particles.<sup>8-12</sup> Therefore, the 1-D self-organized  $TiO<sub>2</sub>$  nanotube array (TNT) is expected to design. In 2001, Grimes and co-workers successfully prepared TNT by anodization in hydrofluoric acid electrolyte.<sup>13</sup> Further, Macak synthesized TNT by anodizing in glycerol electrolyte containing 0.5% NH4F, the morphology more smooth than that obtained in aqueous electrolyte, and the length of nanotube

reached above 10  $\mu$ m.<sup>14</sup> Also, TNT exhibits more attractive PEC performance and larger specific surface area than  $TiO<sub>2</sub>$  nanoparticles or nanosheets.<sup>15,16</sup> However, band gap of TiO<sub>2</sub> at 3.0– 3.2 eV can only absorb ultraviolet light corresponding for 5% of sunlight, which means the solar utilization efficiency is less than satisfactory.

 $Ag_3PO_4$  a n-type semiconductor can absorb visible light wavelengths less than 520 nm (indirect band gap of 2.4 eV), and the quantum yield reaches more than 90%, which aroused attention of many researchers; $17-19}$  but its conduction band (CB) is at 0.45 V vs. NHE, so  $Ag<sup>+</sup>$  of  $Ag<sub>3</sub>PO<sub>4</sub>$  will be easily reduced to elemental Ag under visible light irradiation.<sup>10,20-26</sup> Wang et al. studied Ag<sub>3</sub>PO<sub>4</sub>/AgBr/Ag degradation of organic matter, due to better stability of AgBr and plasma effect of Ag nanoparticles, which improved  $Ag_3PO_4$  stability and photocatalytic capacity.<sup>27</sup> Teng found that  $Ag/Ag_3PO_4/TiO_2$  can photodegrade chlorophenol efficiently, and Ag nanoparticles can effectively prevent the occurrence of  $Ag_3PO_4$  light corrosion, and photocurrent density at 0.28 mA cm<sup>-2</sup>.<sup>28</sup> Xu *et al.* reported Ag<sub>3</sub>PO<sub>4</sub>/TiO<sub>2</sub>/Fe<sub>3</sub>O<sub>4</sub> photodegraded benzene sulfonate and had a great bactericidal effect.<sup>29</sup> Photodegradation properties on  $Ag_3PO_4$  or its composites can be found in many research, but seldom on PEC properties, which is closely relative to photo-water-splitting. Moreover, all of works is not enough to achieve high performance because electrons randomly flow after the electron-hole separation resulting in fast electron–hole recombination.

In this study,  $Ag_3PO_4$  nanoparticles were chemically deposited on 1-D TNT. A heterojunction of  $Ag_3PO_4/TiO_2$  was formed and linear sweep voltammetry test showed photocurrent was about 6 times bigger than pure TNT and the band flat potentials

of Ag<sub>3</sub>PO<sub>4</sub>/TiO<sub>2</sub> positively shifted, which meant solar absorption range of  $TiO<sub>2</sub>$  was significantly broadened. Ag was also synthesized on the interface between  $Ag_3PO_4$  and TiO<sub>2</sub> due to light illumination, which formed an efficient system for separation of photo-generated charges and improvement of PEC properties.

## 2 Experimental

Ti foil of 1 cm<sup>2</sup> was provided with anodization in ethylene glycol electrolyte containing 4 wt%  $H_2O$  and 0.25 wt% NH<sub>4</sub>F for 1 h under constant potential (50 V) at room temperature.<sup>14,30</sup> The samples were washed with distilled water and dried at 60 $^{\circ}$ C. The as-prepared TiO<sub>2</sub> was thermally treated at 450 °C for 2 h under atmospheric conditions.

 $Ag<sub>3</sub>PO<sub>4</sub>$  nanoparticles were deposited into the crystallized TiO2 nanotubes by sequential chemical bath deposition method. Typically, the sample was successively immersed in four different beakers for 3 minutes in each beaker. One beaker contained 5 mM AgNO<sub>3</sub> aqueous solution, another contained 5 mM  $\text{NaH}_2\text{PO}_4$ , and the other two contained distilled water to rinse the samples from the excess of each precursor solution. Such an immersion cycle was repeated several times, typically between 2 and 8 cycles.

The surface morphology was observed through a field-emission scanning electron microscope (Hitachi S-4800, Japan). Transmission electron microscopy (TEM) images were taken with JEOL JEM-2100 transmission electron microscope at 200 kV. The absorbance was measured with UV-vis spectrophotometer (Hitachi U-3900, Japan). The elemental chemical status was measured by X-ray photoelectron spectroscopy (Thermo ESCA-LAB 250Xi), equipped with Al K $\alpha$  radiation. All energies were calibrated to spurious carbon at 284.8 eV.

The PEC properties of samples were investigated by a threeelectrode configuration electrochemical workstation (CHI 760E), employing the samples, Ag/AgCl and Pt mesh as working, reference and counter electrode, respectively (Fig. S4†). The supporting electrolyte used was 1 M KOH ( $pH = 14$ ) aqueous solution. Mott–Schottky plots were measured at 1000 Hz. Electrochemical impedance spectroscopic (EIS) measurements were performed between  $10^5$  Hz and  $10^{-2}$  Hz dark. The working electrode was illuminated with a 300 W xenon lamp. The photocurrent was recorded concurrently with the light switching on and off without applied voltage. FSC Advances<br>

## 3 Results and discussion

### 3.1 Electron transportation analysis

After deposited Ag<sub>3</sub>PO<sub>4</sub>, a heterojunction of Ag<sub>3</sub>PO<sub>4</sub>/TiO<sub>2</sub> first formed and promoted separation of the photogenerated carriers.<sup>25,31,32</sup> Additionally, Ag<sup>+</sup> of Ag<sub>3</sub>PO<sub>4</sub> was proved photoreduced and decomposed to weakly active Ag under photoillumination,<sup>31-35</sup> which could obviously enhance visible light absorbance above 700 nm (Fig. 1c) and accelerate photogenerated carrier separation due to its surface plasma resonance (SPR).28,36 As reported by many researchers, SPR in Ag can

Fig. 1 Schematic diagram of bidirectional photo-induced electron transportation (a), photogenerated electron–hole pairs separation process (b) and UV-vis spectra (c).

Fig. 2 High resolution XPS spectra of (a) Ti 2p and (b) Ag 3d of  $Ag_3PO_4/TiO_2$ .

be directly excited under visible light illumination to generate and inject hot carriers into the CB of semiconductors.37,38 This role is just like a "pump" (Fig. 1a and b), electrons in  $Ag_3PO_4$  are absorbed by Ag and then "pumped" into higher energy level, the CB of TiO<sub>2</sub>, due to lower conductivity of  $Ag_3PO_4$  and SPR of Ag which assisted electrons to get over the barrier of  $\text{Ag}_3\text{PO}_4/\text{TiO}_2$ junction. Then electrons transported from the CB of TiO<sub>2</sub> to Ti base along 1-D electron channel of TNT. Equally, holes were injected from the valence band (VB) of  $TiO<sub>2</sub>$  into the VB of  $Ag_3PO_4$ , and then participated in oxidation reaction. The transfer route of electron can be  $E_{CB}(Ag_3PO_4) \rightarrow E_f(Ag) \rightarrow$  $E_{CB}$ (TiO<sub>2</sub>). If without the SPR of Ag, charges transportation route are shown in Fig. S4,† the light induced electrons transported from higher conductor band  $(-0.612 \text{ V} \nu s$ . NHE) of TiO<sub>2</sub> to lower conductor band (+0.45 V vs. NHE) of  $Ag_3PO_4$ , and the holes were accumulated in the valence band of  $TiO<sub>2</sub>$ , which is inconsistent with experimental results of electron transportation from  $TiO<sub>2</sub>$ to Ti foil.

# $3<sup>2</sup>$

 $Ag_3PO_4/TiO_2$  sample was examined by X-ray photoelectron spectroscopy (XPS), and the results are shown in Fig. 2. The binding energies of the XPS spectra were calibrated by C 1s (284.8 eV). The carbon peak is due to the adventitious hydrocarbon from the XPS instrument itself (Fig. S2†). In Fig. 2a, the characteristic peak at 458.5 eV and 464.2 eV assigned to  $Ti^{4+}$  in

 $TiO<sub>2</sub>$  are depicted.<sup>39</sup> Two binds at 367.7 and 373.7 eV, are ascribed to Ag  $3d_{5/2}$  and Ag  $3d_{3/2}$  bonding energies in Fig. 2b. These bands could be further deconvoluted into two peaks, respectively, at 366.4, 367.3 eV and 372.8, 373.7 eV, where the bands at 366.4 and 372.8 eV are ascribed to the  $Ag^+$  of  $Ag_3PO_4$ , and those at 367.3 and 373.7 eV are attributed to the metallic Ag<sup>0</sup>. As some papers have reported,<sup>40,41</sup> these results verify the existence of metallic  $Ag^0$  on  $Ag_3PO_4/TiO_2$  photocatalysts after the reaction.

# $\overline{1}$  ov

Diameter of the self-organized pure TNT prepared by anodizing method is about 60 to 90 nm (Fig. 3a and b). Fig. 3b showed SEM images of the sample for 4 cycles deposited  $Ag_3PO_4$  on TNT, and the nanoparticles of  $Ag_3PO_4$  covered the surface with a diameter of about 10 nm. Also, some particles with a diameter of 40 to 50 nm were formed because of severe agglomeration for 8 cycles, shown in Fig. S3.† Illustration of EDS indicated that the atomic proportion of Ag and P is 2.44 to 1, close to stoichiometric ratio of 3 to 1 (Fig. 3c).

TEM images of the sample for 4 cycles deposited  $Ag_3PO_4$  on TNT were shown in Fig. 4a and b.  $Ag_3PO_4$  nanoparticles located at both surface TNT and inside of nanotubes at a diameter of 10–20 nm. To further confirm the existence of  $Ag_3PO_4$ , HRTEM (Fig. 4c) showed the lattice fringe of 0.35 nm was consistent with

# $\mathbf{1}$ .4 Photoelectrochemical properties pr

Under scanning potential between  $-0.9$  V to 0.3 V vs. Ag/AgCl, the current density of TNT deposited  $Ag_3PO_4$  were bigger than that of the pure TNT (Fig. 5a), only 0.387 mA  $cm^{-2}$  at 0 V vs. Ag/ AgCl, whereas the current density of 4 cycles deposition was almost 5 times higher, reached to 2.340 mA  $\rm cm^{-2}.$  It reported that maximum photocurrent of  $Ag_3PO_4/TiO_2$  nanowire array heterostructure photoelectrodes was about 0.7 mA  $cm^{-2}$  at an applied bias  $0.23$  V vs. Ag/AgCl.<sup>42</sup> The improvement of photocurrent could be ascribed to Ag "pump", preferred electron transportation direction along TNT and large absorption spectrum of Ag<sub>3</sub>PO<sub>4</sub>.<sup>29,43</sup> UV-vis spectra (Fig. 1c) proved the band gap of pure TNT and  $Ag_3PO_4$  at 3.1 eV and 2.38 eV, respectively. And the recombination of photogenerated charge carriers was significantly reduced in the heterojunction (Fig. S1b†). Under intermittent light irradiation, time-dependent photocurrent generation is presented in Fig. 5b. The photocurrents respond exactly to the presence of solar light was interrupted every 50 s (light on/off) under 0 V vs. Ag/AgCl, and the steady state behavior of each photoanode follows the same trend as that of the I–V curves (Fig. 5a). Furthermore, the loading amounts of  $Ag_3PO_4$  on TNT increase with the increasing of cycle time (Fig. 3c and S3c†). Whatever  $I-V$  curves or  $I-t$  curves showed photocurrent increased initially and then decreased with increase loading amount of Ag<sub>3</sub>PO<sub>4</sub>. Therefore appropriate loading amounts of  $Ag_3PO_4$  is fatal to enhance PEC **ESC Advances**<br>

performance of TNT. In addition, there are no appreciable dark currents, demonstrating the photochemical stability of all of photoanodes in the alkaline solution. The steady-state photocurrents do not show any signicant degradation with time.<sup>44</sup>

Fig. 6a represented Nyquist diagrams from electrochemical impedance spectroscopy (EIS) for samples tested in dark. The equivalent circuit for this cell system was depicted in inset of Fig. 6a.  $R<sub>b</sub>$  was the bulk resistance of the electrolyte.  $C<sub>sc</sub>$  and  $R<sub>sc</sub>$ were the capacitance and the resistance of the solid-state interfacial layer which was formed at the highly charged state due to the passivation reaction between the electrolyte and the surface of the electrode.  $C_{d1}$  and  $R_{ct}$  were the double layer capacitance and the charge transfer resistance. W was the Warburg resistance result from the diffusion resistance of redox couple.

The Mott-Schottky plots of  $Ag_3PO_4/TiO_2$  are used to analyze the flat band potential and carrier concentrations of semiconductor (Fig. 6b). Under the applied voltage, the Fermi level can be changed and bended the energy band, and flat band potential  $V_{\text{fb}}$  refers the applied potential which makes the inner electric field intensity of semiconductor approach zero. The carrier concentrations of semiconductor  $N_D$  and the slope of linear part of Mott–Schottky plots have the relation as follow:

$$
N_{\rm D} = \frac{2}{e\epsilon\epsilon_0 m} \tag{1}
$$

where, *e* is the elementary charge  $(1.602 \times 10^{-19} \text{ C})$ , *ε* is the dielectric constant of sample and the dielectric constant of anatase is 48,  $\varepsilon_0$  is the vacuum dielectric constant (8.854  $\times$ 

Fig. 5  $Ag_3PO_4/TiO_2$  composites linear sweeps voltammetry (a),  $i$  –t curve (b), UV-vis spectra.

 $10^{-14}$  F cm<sup>-1</sup>), *m* is the slope of the linear part of Mott-Schottky plots. The flat band potential  $V_{\text{fb}}$ ,  $C_{\text{SC}}$  and carrier concentrations  $N_D$  have a relationship, below:

$$
C_{\rm SC}^{-2} = \left(\frac{2}{\varepsilon_0 \varepsilon e N_{\rm D}}\right) \left(V - V_{\rm fb} - \frac{k_{\rm B}T}{e}\right) \tag{2}
$$

where,  $C_{SC}$  is the space charge capacitance,  $\varepsilon_0$ ,  $\varepsilon$  and e are constant,  $N_D$  is carrier concentrations, V and  $V_{fb}$  is respectively the applied potential and the flat band potential (vs. the potential of the reference electrode),  $(k_BT)/e$  is 25.8 mV at room temperature.

The parameters obtained from EIS and Mott–Schottky plots are shown in Table 1. The charge transfer resistances  $R_{\rm ct}$ of 4 cycles deposition  $Ag_3PO_4$  minimal only 404.7 ohm cm<sup>-2</sup> , since the carrier concentration  $N_D$  of it was 2.6 times higher than that of the pure TiO<sub>2</sub> about  $4.85 \times 10^{22}$  cm<sup>-3</sup>. Moreover, the carrier concentration of  $Ag_3PO_4/TiO_2$  samples was obviously higher than that of the pure  $TiO<sub>2</sub>$ . And valence bands of two semiconductors were very close,<sup>29,33,43,45,46</sup> which inferred the heterojunction formed by depositing  $Ag_3PO_4$  nanoparticles on TNT (Fig. 1b). Potentials of both conduction band  $(-0.612 \text{ V} \text{ vs. NHE})$  and valence band  $(+2.588 \text{ V} \text{ vs. NHE})$  of  $TiO<sub>2</sub>$  are more negative than those of Ag<sub>3</sub>PO<sub>4</sub> (conduction band potential: +0.45 V vs. NHE, valence band potential: +2.9 V  $\nu$ s. NHE).<sup>33</sup> It benefits for transfer of photogenerated carriers and separation of photogenerated electron–hole pairs, also increases the carrier concentrations. The flat band potential  $(V_{\text{fb}})$  is close to the conduction band which makes the curving band of space charge layer straight. The  $V_{\text{fb}}$  of TNT was  $-0.612$  V, after deposition Ag<sub>3</sub>PO<sub>4</sub> of 4 cycles  $V_{\text{fb}}$  lowed to  $-0.410$  V. The reason for lower  $V_{\text{fb}}$  was the photogenerated electrons were "pumped" into CB of  $TiO<sub>2</sub>$  by SPR of Ag. It

meant the range of absorption spectrum broaden and photocatalytic properties enhancement. As shown in Fig. 1c, the absorbance of  $Ag_3PO_4/TiO_2$  was significantly increased than pure TiO<sub>2</sub>, implying  $Ag_3PO_4$  is a very promising material for building fast electron transportation path to improve PEC performance of  $TiO<sub>2</sub>$ .

# 4 Conclusion

A preferred electron transportation path was designed to improve the photoelectrocatalytic activity through deposition  $Ag_3PO_4$  nanoparticles to the self-organized TiO<sub>2</sub> nanotube arrays. Ag<sub>3</sub>PO<sub>4</sub>/TiO<sub>2</sub> effectively reduced the recombination of photogenerated electron–hole pairs due to unique 1-D nanostructure, as well as SPR of photoreduced Ag from  $Ag_3PO_4$ . The charge carrier concentration of  $Ag_3PO_4/TiO_2$  increased 2.6 times than that of pure TNT. The photocurrents of  $Ag_3PO_4/TiO_2$  were significantly improved by 5 times. Therefore, fabrication of  $Ag_3PO_4/TiO_2$  nanotube arrays is a highly efficient method to build a noteworthy photoelectrode for PEC water splitting.
