Microwave-assisted hydrothermal synthesis of chrysanthemum-like Ag/ZnO prismatic nanorods and their photocatalytic properties with multiple modes for dye degradation and hydrogen production

Zichan Xin,^{ab} Li Li,^{ID}*^{ab} Xiuli Zhang^b and Wenzhi Zhang^b

A series of Ag/ZnO composites were prepared by microwave-assisted hydrothermal synthesis. Their composition, structure, and morphology were well characterized by X-ray diffraction (XRD), UV-visible diffuse reflectance spectroscopy (UV-vis/DRS), X-ray photoelectron spectroscopy (XPS), scanning electron microscopy (SEM), and N₂ adsorption–desorption analyses. The results showed that the microwave-assisted synthesis method did not significantly alter the crystal structure of the composites. However, light absorption by the composite was clearly enhanced, its Brunauer–Emmett–Teller surface area values changed, and excellent surface morphology was observed. Moreover, the Ag/ZnO composite formed *via* microwave-assisted hydrothermal synthesis exhibited more regular stacking piled into a chrysanthemum-like structure. Under ultraviolet, visible-light, simulated sunlight, and microwave-assisted irradiation, the composite exhibited better photocatalytic properties for the photocatalytic degradation of rhodamine B compared to that of P25 and ZnO. Moreover, the composite was investigated as a catalyst for the degradation of four dyes with different structures under UV conditions, exhibiting good degradation performance. Furthermore, the degradation efficiency did not change significantly after three cycles, indicating a certain degree of stability. In addition, the photocatalytic hydrogen production experiments showed that the nanocomposite Ag/ZnO had some ability to produce photocatalytic hydrogen.

1. Introduction

Currently, the photocatalytic degradation of organic pollutants *via* semiconductors has been beneficial for the environmental purification.^{1–4} Photocatalytic technology can effectively degrade or completely mineralize common organic compounds without secondary pollution. Moreover, photocatalysts such as TiO₂, a type of environmentally friendly catalyst, has many advantages owing to its simple structure, easily controllable operating conditions, strong oxidizing ability, and economic and environmental benefits.^{5,6}

Simultaneously, the photocatalytic generation of hydrogen is one of the most promising routes to use this abundant energy for environment-friendly and clean technologies. However, the main problems hindering the use of photocatalytic technology are low catalytic efficiency, caused by the low light utilization rate and the high recombination rate of the photogenerated

electron–hole pairs.⁷ The photocatalytic activity of semiconductors can be enhanced by changing the preparation method for different particle size and/or morphology.

In recent years, microwave synthesis has been favored by most researchers because of its rapid and simple procedure.⁸ Microwave synthesis can often optimize the morphology of the products, thus improving the various properties of the material. Because of the different absorptive capacity of the material, in the process of microwave reaction, the degree of heating of the material is different. For highly polar molecules, the friction between them will increase. Microwaves exhibit the characteristics of penetration, low thermal inertia and selective heating. Compared to other methods, microwave synthesis has unique advantages such as selective heating, fast heating speed, high reaction efficiency, and low energy consumption; therefore, it is widely used in the preparation of semiconductor composite materials.^{9–11} For example, Wu *et al.* prepared MWCNTs wrapped with a uniform and small diameter of ZnS nanospheres using microwave irradiation,¹² and Pal *et al.* fabricated Au-decorated ZnO nanorods with excellent photocatalytic activities *via* microwave-assisted synthesis.¹³ Moreover, the light utilization rate can also be improved by

^bCollege of Chemistry and Chemical Engineering, Qiqihar University, Qiqihar 161006, PR China

doping noble metals, transition metals, or nonmetallic elements to inhibit the recombination of the photogenerated electron–hole pairs or change its band structure. Among the above mentioned methods, doping is an effective tool to improve the photocatalytic activity of semiconductors. In particular, transition metals such as platinum, silver, and iron could improve charge transfer by trapping the photoinduced charge carriers, thus enhancing the performance of photochemical degradation.^{14–16}

At present, many types of photocatalysts such as ZnO and TiO₂ are used for photocatalytic oxidation. Zinc oxide is a type II–VI semiconductor with a direct band gap of 3.37 eV at room temperature and a large exciton binding energy of ~60 meV.¹⁷ Because of its chemical stability, abundance of raw materials for its preparation, and cost effectiveness, zinc oxide has been widely used as a catalytic material. However, some issues such as light corrosion in the ultraviolet region, poor light stability, wide band gap, and the exclusive use of ultraviolet excitation are of concern. Therefore, in this study, the noble metal Ag was doped into the semiconductor ZnO material using microwave-assisted hydrothermal synthesis. Due to the surface plasmon resonance (SPR) of noble metal nanoparticles, we hypothesized that Ag can change the electron conducting manner to some extent, reduce the recombination rate of the photogenerated electron–hole pairs and improve the efficiency of the photocatalytic reaction. In contrast, the unique polarization effect of microwaves was expected to improve the morphology and particle distribution of the synthesized products and thus, possibly improve the photocatalytic activity of the Ag/ZnO composite. Moreover, a series of Ag/ZnO composite materials were prepared under different microwave irradiation times to investigate the effect of microwave irradiation time on the physicochemical properties of the product. The photocatalytic conditions of the Ag/ZnO degradation dye rhodamine B and photocatalytic hydrogen production were studied under different photocatalytic conditions to obtain better experimental results.

2. Experimental section

2.1. Reagents and instruments

Zinc acetate dehydrate (Zn(CH₃COO)₂·2H₂O) and silver nitrate (AgNO₃) were purchased from Tianjin Kermel Co. Ltd. Sodium peroxide was purchased from Tianjin Dagu of Plastic Manufacturing Co. Ltd. Dyes were purchased from the Beijing chemical plant. All chemicals were of analytical grade (AR) and used without further purification. Secondary distilled water was employed for all experiments. Microwave synthesis was performed using a MDS-8G microwave reactor (Shanghai SINEO Microwave Chemical Technology Co. Ltd.). Photochemical investigations were performed using a BL-GHX-V photochemical reaction instrument (Xi'an Biological Technology Co. LTD). Absorbance spectra were recorded using a TU-1901 UV-vis double beam spectrophotometer (UV-vis, Beijing Purkinje General Company).

2.2. Synthesis

In a typical process, Zn(CH₃COO)₂·2H₂O, Na₂O₂, and AgNO₃ were dissolved in 40 mL isopropanol solution in a molar ratio of 1 : 1.5 : 0.05 for CTAB : Zn : Ag. The resultant reaction mixture was stirred for 30 min to mix thoroughly and then transferred to a Teflon-lined stainless autoclave heated at 200 °C. The reaction mixture was subjected to microwave irradiation for 3, 4.5, and 6 h at 300 W. The reaction mixtures were removed, washed, filtered, dried at 80 °C, and calcined at 300 °C for 2 h and the products were named Ag/ZnO-3h, Ag/ZnO-4.5h and Ag/ZnO-6h, respectively. The sample for the comparison was labeled ZnO, which was prepared under the same conditions by heating at 200 °C under microwave irradiation for 3 h at 300 W, and calcined at 300 °C for 2 h.

2.3. Characterizations

X-ray diffraction (XRD) patterns were collected on a Bruker-AXS D8 X-ray diffractometer equipped with CuKα radiation. X-ray photoelectron spectra were recorded using a VG-ADES400X spectrometer as the excitation source and the degree of vacuum was 1 × 10⁻⁸ Pa. The microstructure was examined by high-resolution transmission electron microscopy (HR-TEM) (JEM-2100F) operated at 200 kV. The SEM-EDS of the sample was analyzed using a Hitachi S-4700 scanning electron microscope at a working voltage of 5 kV. The optical absorbance spectra of the as-prepared samples were recorded on a UV-vis spectrophotometer (TU-1901) equipped with a diffuse reflectance accessory using BaSO₄ as the reflectance standard. The microstructure and morphology of the products were characterized using an S-4700 scanning electron microscope (Japan) operated at 5 kV. The Brunauer–Emmett–Teller (BET) surface areas, pore volumes (VP) and the distribution of pore size were derived from the nitrogen adsorption at 77 K using a Quantachrome Nova Win II instrument.

2.4. Multi-mode photocatalysis experiment

The photocatalytic device consisted of a cylindrical glass tube and built-in light source surrounding a quartz sleeve. Ultraviolet light was irradiated using a 125 W Hg-lamp with a maximum emission at ~313.2 nm; visible light was obtained using a 400 W Xe lamp with the main emission lines at >410 nm. The simulated sunlight source was irradiated using a 1000 W Xe-lamp with emission from strong UV to near IR consecutive spectra (~300–1050 nm); the distance between the lamp and reaction liquid was 8.5 cm. A microwave discharge electrodeless lamp (MDEL) with H shape model and a power of 15 W with a maximum emission at ~280 nm was used for the microwave-assisted test. The output power of the microwave was ~600 W.¹⁶ In a typical reaction under UV light and simulated sunlight, 90 mL of the aqueous RhB solution (50 mg L⁻¹) and 0.15 g of the photocatalyst powder was mixed in a quartz photoreactor. For the experiments under visible light, 220 mL of the aqueous RhB solution (50 mg L⁻¹) and 0.3 g of the photocatalyst powder were mixed in a quartz photoreactor. For the microwave-assisted irradiation, 500 mL of the aqueous RhB solution (50 mg L⁻¹)

and 0.5 g of the photocatalyst powder were mixed in a quartz photoreactor. During the photocatalytic process under light irradiation, the suspensions were kept at constant temperature (20 ± 5 °C) by placing the lamp with jacket into the interior of the reaction suspensions or by means of circulating the solutions to a cooler using a peristaltic pump.

Photocatalytic reaction. In each test, the catalyst was dispersed in organic pollutants (RhB, $C_0 = 50 \text{ mg L}^{-1}$) by ultrasonic dispersion for ~ 10 min. Prior to irradiation, the suspension was magnetically stirred in the dark for 30 min to achieve absorbance–desorbance equilibrium. The solution was stirred vigorously during the photocatalytic reaction and 3 mL aliquots were collected at selected time intervals and centrifuged to remove the photocatalyst powders. Then, the quantitative dilution was carried out. The concentration of RhB in the photocatalytic reaction was analyzed using a UV-vis spectrophotometer at 554 nm wavelength.

2.5. Photocatalytic hydrogen production experiment

Photocatalytic hydrogen production was carried out in a vacuum reactor connected to a closed circulatory system (lab solar-III AG system). Initially, 100 mg of photocatalyst was dispersed in 50 mL of distilled water and 3.0 g of $\text{Na}_2\text{S} \cdot \text{H}_2\text{O}$ and 2.2 g of Na_2SO_3 were added as sacrificial agents. After the vacuum degassing treatment, the light was tested under the condition of stirring for the photocoagulation of water. A 300 W xenon lamp was used as the light source fixed at 10 cm from the reaction solution. High purity nitrogen was used as the carrier gas at a flow rate of 0.5 mL s^{-1} . The reaction was carried out with an output pressure of 0.4–0.5 MPa, and an operating voltage and an operating current of about 20 mV and 50 mA, respectively. During the reaction, circulating cooling water maintained the temperature of the reactor at about 5 °C. The gas of the hydrogen production process was collected and analyzed by gas chromatography. The hydrogen production was calculated according to the peak area of different reaction time, and the catalytic activity of the catalyst was measured by the total hydrogen production time of 8 h.

3. Results and discussion

3.1. XRD analysis

The crystal structures of the obtained Ag/ZnO products were investigated by XRD; the results are shown in Fig. 1. Pure Ag has a cubic crystal structure, as shown in Fig. 1, and the visible characteristic diffraction peaks appear primarily at the 2θ values of 38.21° , 44.47° , 64.47° , and 77.48° (JCPDS03-0921). Pure ZnO has a wurtzite structure with its characteristic diffraction peaks located primarily at the 2θ diffraction angle values of 31.7° , 34.4° , 36.2° , 47.5° , 56.5° , 62.8° , 66.4° , 68.1° , and 69.2° (JCPDS36-1451). Moreover, the XRD spectra of a series of Ag/ZnO composites retained the characteristic peaks for ZnO and Ag, indicating that Ag and ZnO in the Ag/ZnO composites have the cubic phase and wurtzite structures, respectively. These results indicated that the change in microwave irradiation times had no effect on the crystal type of Ag/ZnO. Moreover, the sharp

Fig. 1 XRD patterns of Ag, ZnO, Ag/ZnO-3h, Ag/ZnO-4.5h, and Ag/ZnO-6h.

peaks of Ag/ZnO samples indicated a better crystallization of the synthesized product.

Furthermore, Fig. 1 shows that the diffraction peak intensity of each substance in the microwave-assisted synthesis of Ag/ZnO-6h was slightly stronger than that of each material in the other composite materials, indicating that the extended microwave radiation time was helpful in improving the crystal structure of the samples.¹⁸ The cubic structure of Ag in Ag/ZnO-6h was found to be superior to those of other composite materials as shown in Fig. 1 and the photocatalytic activity was expected to be better than those of the composites synthesized for different times.

Furthermore, the crystallite sizes of each of the synthesized products were calculated using the Scherrer equation: $D_c = 0.89\lambda / (B \cos \theta)$ (λ is the wavelength of the X-ray; B is the half-width of the diffraction peak; θ is the diffraction angle), as summarized in Table 1, indicating that the crystallite size of each Ag/ZnO composite decreased significantly compared to that of ZnO and the decrease can be attributed to doping with the noble metal Ag.

Table 1 Crystallite sizes (D_c), energy band gaps (E_g), BET surface areas (S_{BET}), average pore diameters (D), and pore volumes (V_{total}) of ZnO and Ag/ZnO composites^a

Sample	D_c/nm	E_g/eV	$S_{\text{BET}}/(\text{m}^2 \text{g}^{-1})$	D/nm	$V_{\text{total}}/(\text{cm}^3 \text{g}^{-1})$
ZnO	47.0	3.21	1.05	4.1	0.004
Ag/ZnO-3h	40.4	3.17	6.71	3.3	0.014
Ag/ZnO-4.5h	43.1	3.14	6.40	3.2	0.030
Ag/ZnO-6h	44.0	3.12	6.74	3.4	0.029

^a D_c is the crystallite sizes.

Moreover, the crystallite size of each Ag/ZnO increased significantly with an increase in microwave irradiation time, indicating that microwave irradiation promotes the growth of grains.¹⁹

3.2. UV-vis diffuse reflectance spectra analysis

The light absorption characteristics of Ag/ZnO composites were characterized by UV-vis diffuse reflectance spectroscopy (Fig. 2). Fig. 2a shows that the synthesized Ag/ZnO composites had strong absorption both in the ultraviolet and visible regions. The broad absorption in the visible region is due to the surface plasmon resonance (SPR) of Ag nanoparticles in the product.²⁰ In contrast, the strong polarization effects of the microwave irradiation resulted in further aggregation of the Ag nanoparticles, thus enhancing the absorption of the synthesized Ag/ZnO composites in the visible region, predicting that the synthesized products Ag/ZnO will have some visible-light activity. Moreover, the intensity of the optical absorption of the composite materials gradually increased on increasing the microwave irradiation time, indicating that the extended microwave radiation time was helpful to the optical absorption of the products. Fig. 2b shows the plot of $(\alpha h\nu)^2$ versus energy ($h\nu$); the relation between the absorption coefficient α and the photon energy $h\nu$ is $(\alpha h\nu)^2 = K(h\nu - E_g)$, where parameter K is associated with the valence band and conduction band and E_g is the optical energy gap between the valence and conduction band.²¹ The calculated E_g values of ZnO, Ag/ZnO-3h, Ag/ZnO-4.5h, and Ag/ZnO-6h are listed in Table 1. The E_g values of each product, as listed in Table 1, show that the band gap energies of the Ag/ZnO-6h composite was slightly lower than those of the other samples, indicating that Ag/ZnO-6h may have better photocatalytic activity.

3.3. XPS analysis

XPS analysis was performed to investigate the surface elemental composition and chemical state for a series of Ag/ZnO samples; the results are shown in Fig. 3. There were primarily four types of elements, which are Ag, Zn, O, and C, on the composite surface as shown in Fig. 3a. The presence of C was ascribed to the adventitious hydrocarbon from the XPS instrument. Fig. 3b

shows that the binding energies of Ag 3d_{5/2} and Ag 3d_{3/2} for Ag/ZnO-3h were 368.2 and 374.2 eV, respectively, at the microwave irradiation time of 3 h. The energy spacing of the two lines was 6.0 eV, which were the characteristic peaks of the Ag metal, indicating that Ag in the product exists in the form of Ag⁰.²² The binding energy of Zn 2p_{3/2} and Zn 2p_{1/2} were 1022.3 and 1045.4 eV, respectively, indicating that the Zn in the composite was in the state of Zn²⁺ (Fig. 3c).²³ The peak at 531.0 eV corresponds to O 1s, indicating that O was the lattice oxygen (Fig. 3d).²⁴ These results were consistent with the reported XPS data of Ag/ZnO composites. The study also found that the peaks of Ag 3d_{5/2} and Ag 3d_{3/2}, Zn 2p_{3/2} and Zn 2p_{1/2}, and O 1s shifted to lower binding energy with increasing microwave irradiation time, and the shift in the binding energy indicated a strong interaction between metallic Ag and ZnO.²³ The binding energy changed with varying microwave irradiation time, indicating that the microwave irradiation time can change the degree of charge transfer between Ag and ZnO in the products to some extent.^{25,26} Moreover, the peaks of Ag in Ag/ZnO-6h were extremely sharp and strong and consistent with the XRD results, further indicating that increasing microwave irradiation time was appropriately conducive to the growth of crystals.

3.4. SEM and TEM analysis

SEM analysis was performed to investigate the surface morphology of the Ag/ZnO composites. Fig. 4 shows the SEM images of ZnO and Ag/ZnO composites, indicating that ZnO has a regular morphology of six prismatic nanorods in a wide range. However, the prepared Ag/ZnO composite materials showed relatively regular nanorods stacked into a chrysanthemum-like structure within a wide range (Fig. 4(e, h and k)). The significantly improved morphology was primarily attributed to the easy formation of Ag and ZnO particles with relatively well-defined structure and dispersion owing to strong polarization and high selectivity under microwave radiation. Thus, Ag/ZnO particles were formed with a more regular geometric shape, which was conducive to enhancing the activity of the composite materials to some extent. The reduction of Ag⁺ can be divided into the following steps: first, the rapid formation of nuclei

Fig. 2 (a) UV-vis/DRS spectra and (b) plot of $(\alpha h\nu)^2$ versus energy ($h\nu$) of Ag, ZnO, Ag/ZnO-3h, Ag/ZnO-4.5h, and Ag/ZnO-6h.

Fig. 3 XPS spectra of Ag/ZnO-6h (a), Ag 3d (b), Zn 2p (c), and O 1s (d).

under microwave irradiation; then, their coalescence or Ostwald ripening into larger particles; subsequently, slow diffusion growth of particles to form the precursor and further coalescence; finally, complete reduction of Ag⁺ and the rapid growth of the particles to their final size.^{11,27} The traditional heating process is slow; however, the microwave heating rate is very fast and the temperature of the reaction mixture reached 200 °C within 10 min; thus, the overall reaction can be completed in a very short time. Because rapid microwave heating quickly reduced the nuclei of Ag particles, the effect of microwave irradiation reduced the Ag particles, generating local temperatures around them and prompting ZnO to reach the desired nuclei temperature to form chrysanthemum-like Ag/ZnO composites by stacking and affecting each other (Fig. 4d–l). Moreover, appropriately extending the microwave radiation time was helpful for the aging of the particles and to achieve dense growth. Compared to Ag/ZnO-3h (Fig. 4d–f), Ag/ZnO-4.5h stacked more closely and the particle size increased slightly (as shown in Fig. 4g–i). This occurred because microwave irradiation not only promoted the ion diffusion of reactants and decreased the reaction activation energy, but also sufficient microwave radiation time was helpful to the ordered growth of crystals.²⁸ Therefore, the morphology of the Ag/ZnO-6h sample was slightly different because of the increased microwave radiation time of 6 h. Fig. 4j–l shows that the arrangement of

the shape was more regular and ordered with decreased volume.

In summary, crystals with different morphology were formed at different irradiation times because the ponderomotive force primarily acted at the interfaces and cavities, resulting in rapid growth of the grains and a systematic elimination of the porosity in the microwave field.²⁹

To further investigate the morphology of the Ag/ZnO composites, HRTEM analysis and element mapping images were carried out; the results are shown in Fig. 5 and 6. According to the HRTEM results, we only found the lattice stripe of the (002) surface of the ZnO in the composite; the lattice stripe of Ag was not found.³⁰ Therefore, we believe that the formation mechanism of Ag/ZnO in this study is consistent with the above situation described in our study. According to the XRD results of the Ag/ZnO composite, the existence of the characteristic diffraction peaks of Ag can be clearly observed. Simultaneously, through the characterization of XPS and UV-vis/DRS, it is also possible to further prove the existence of Ag in the composite. However, we do not find Ag in the HRTEM image (see Fig. 5) of the Ag/ZnO-6h sample. We think the reason is the fact that the size of the composite of our synthetic Ag/ZnO-6h is larger and the SEM detection can be seen in the range of about 2.2–2.6 μm. Because of the limited range in HRTEM detection, there is no choice for observing such a large

Fig. 4 SEM images of ZnO (a–c), Ag/ZnO-3h (d–f), Ag/ZnO-4.5h (g–i), and Ag/ZnO-6h (j–l).

area. Therefore, ZnO nanorods were more observed at HRTEM detection. In addition, the TEM results show that there are no other particles on the surface of ZnO, showing that Ag is clearly nucleated at the center of the composite material. In addition, because the size of the ZnO nanorods is larger, the Ag nucleus under this degree of inclusion cannot be detected in the lattice stripe. Simultaneously, we conducted the elemental mapping tests on Ag/ZnO-6h samples (see Fig. 6). It was found that there is indeed the existence of Ag; however, due to the large size of the ZnO nanorods, the Ag nucleus is not easy to be detected. In addition, in the element mapping results, the upper left image in Fig. 6d shows a region with a large amount of Ag elements. In the corresponding SEM photo (Fig. 6a), the region is a blank area; we postulate that there may be a naked Ag nucleus that is not covered by ZnO as its size is too small to be clearly observed in the SEM.

3.5. N₂ adsorption desorption measurement

To investigate the surface physiochemical properties of the nanocomposites Ag/ZnO prepared by microwave-assisted hydrothermal synthesis, N₂ adsorption–desorption measurements were performed

and compared to those of ZnO. Fig. 7a and b represent the N₂ adsorption–desorption isotherm and pore size distribution plot of ZnO and Ag/ZnO-6h, respectively, considering that the isotherms and pore size distribution plots of Ag/ZnO-3h and Ag/ZnO-4.5h were very similar to that of Ag/ZnO-6h. The N₂ adsorption–desorption isotherms of ZnO and Ag/ZnO-6h exhibit a typical type IV pattern according to the classification of IUPAC;³¹ this type of composite shows a hysteresis loop of type-H3. Moreover, the formation of the hysteresis loop should be related to the capillary condensation phenomenon in the mesoporous materials. We also found that the hysteresis loop of the product significantly shrank after doping with the noble metal Ag under microwave irradiation, indicating that the desorption mechanism of the product was correspondingly altered by changes in the synthesis conditions.³²

Moreover, the BET specific surface area and pore volumes of the products are shown in Table 1, indicating that the BET specific surface area and the pore volume of Ag/ZnO increased to varying degrees as compared to that of ZnO. The average pore diameters decreased slightly, indicating that the surface physiochemical properties of the composites prepared by microwave irradiation were effectively improved. Because

Fig. 5 Results of the TEM image (a) and HRTEM analysis (b–d) of Ag/ZnO-6h.

Fig. 6 Element mapping images of Ag/ZnO. (a) SEM, (b) Zn, (c) O, (d) Ag and (e) EDS spectroscopy of Ag/ZnO composites.

a higher BET surface area can provide a more active component, microwave-assisted synthesis can improve the photocatalytic activity of composite materials to some extent.

3.6. Photocatalytic activity of Ag/ZnO

To investigate the photocatalytic properties of the as-synthesized Ag/ZnO composites, photocatalytic tests were performed with RhB as the model molecule under ultraviolet light. The plots in Fig. 8a show that Ag/ZnO-6h exhibited the highest photocatalytic activity, which was significantly higher than those of other photocatalytic systems. In this study, we generated a reaction kinetic diagram to clearly understand the effects of different conditions on the degradation of RhB (Fig. 8b) using the formula $1/C = kt + b$, where C is the ratio of the concentration after RhB degradation at time t and the initial concentration and k is the rate constant (min^{-1}). Fig. 8b shows a linear relationship between $1/C$ and reaction time t , indicating that the degradation of RhB obeys pseudo-second-order kinetics. The apparent reaction rate constants for direct photolysis, P25, ZnO, Ag/ZnO-3h, Ag/ZnO-4.5h, and Ag/ZnO-6h were 0.00716, 0.00742, 0.03463, 0.05406, 0.07538, and 0.17136 min^{-1} , respectively. Therefore, the order of photocatalytic activity is Ag/ZnO-6h > Ag/ZnO-4.5h > Ag/ZnO-3h > ZnO > P25 > direct photolysis, which is consistent with the activity order of direct photolysis by ultraviolet radiation and the degradation of RhB by different catalysts.

The photocatalytic degradation experiments of dyes of different structures with Ag/ZnO-6h as the catalyst were performed under ultraviolet light to investigate the universality of degradation as shown in Fig. 8c. The concentration of four types of dyes gradually decreased by ultraviolet degradation on increasing the reaction time; the degradation rate of RhB, methyl orange, methylene blue, and crystal violet were 93.44%, 84.26%, 99.47%, and 97.21%, respectively. Simultaneously, the structure of the four types of organic compounds showed distinct differences, belonging to different types, indicating that the Ag/ZnO composite had generality for the degradation of dyes with different structures under ultraviolet light.

Moreover, in this study, we further investigated the other photocatalytic activities of Ag/ZnO, and other modes of photocatalysis were performed in the conditions of simulated sunlight, visible light, and microwave-assisted irradiation as shown in Fig. 8d. As shown in Fig. 8d Ag/ZnO-6h has high degradation activity in ultraviolet and microwave-assisted photocatalysis. This is because the UV light catalysis reaction is more convenient for the delivery of photogenerated carriers and additional photoelectron transfer pathways. In the process of microwave radiation, the emission spectrum of the microwave discharge electrodeless lamp is primarily in the ultraviolet region; although its power is only 15 W, its activity is close to the activity results under the irradiation of the 125 W high pressure mercury lamp.³³

Therefore, the prepared Ag/ZnO-6h showed higher photocatalytic activity for the photocatalytic conditions in different modes, which can be attributed to the following factors: (1) the doped Ag can indirectly affect the interfacial charge transfer

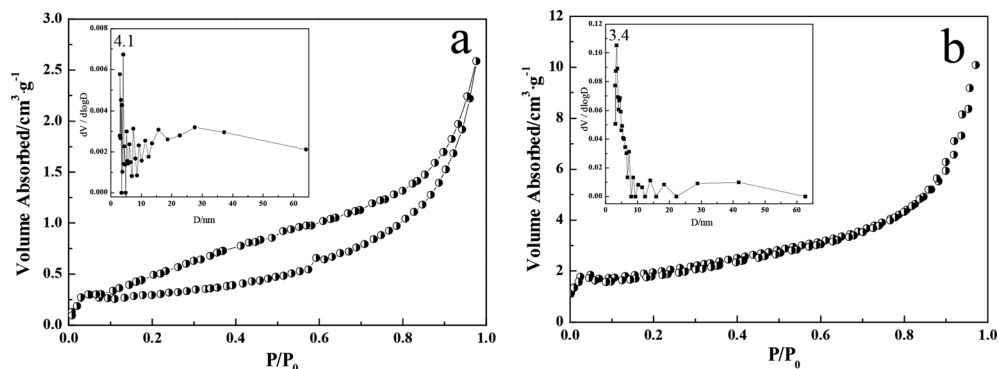

Fig. 7 N_2 adsorption-desorption isotherms and pore size distributions (inset) of ZnO (a) and Ag/ZnO-6h (b).

process, and its electron trap effect can inhibit the recombination of photogenerated electron-hole pairs, thus improving the photocatalytic activity of Ag/ZnO composite. (2) Under microwave irradiation, the local high temperature produced by the doped noble metal Ag accelerated the speed of the particle nuclei, resulting in a greater transformation of the particle size and morphology of the products and thus changing their physical properties. Moreover, increasing the BET specific surface area provides more active sites for the reaction. (3) The polarization of microwaves in the microwave-assisted synthesis process leads to the excellent chrysanthemum-like morphology of Ag/ZnO-6h samples. (4) Doping with noble metal Ag promoted the formation of the product and produced a strong

absorption in the visible region, increasing the response range of the light absorption of the catalyst, thus effectively enhancing the utilization efficiency of light.

In addition, from the data shown in Fig. 1 and 2, we can find the reason why an increase in Ag content would improve the photocatalytic properties. On the one hand, with an increase in microwave-synthesis time, the cubic structure of Ag in Ag/ZnO-6h was found to be superior to those of other composite materials (Fig. 1). On the other hand, the increase in cubic structure of Ag shows that the amount of single silver in the composite is significantly greater. The SPR effect of silver increases with an increase in the amount of silver, which improves the absorptive capacity of the visible light of the

Fig. 8 (a) UV photocatalytic degradation profiles for RhB with different photocatalysts; (b) UV photocatalytic degradation RhB kinetics with different photocatalysts; (c) results of Ag/ZnO-6h UV photocatalytic degradation for different dyes; (d) photocatalytic degradation of RhB profiles with different photocatalysts under different modes.

composite; therefore, the photocatalytic activity was better than those of the composites synthesized for less time in this study and other reports (see Table 2).

3.7. Circulation experiment

The ultraviolet photocatalytic cycle experiments of Ag/ZnO-6h were performed to examine the stability of the photocatalyst. The Ag/ZnO-6h sample was washed several times with ethanol and deionized water, dried, and calcined. The results of the experiments for three cycles of the recycled catalyst are shown in Fig. 9, indicating no significant change in the degradation efficiency of Ag/ZnO-6h after the third run. Therefore, Ag/ZnO-6h had a certain stability under ultraviolet light.

3.8. Photocatalytic hydrogen production

To compare the photocatalytic hydrogen production capacity of Ag/ZnO samples with different microwave irradiation time, photocatalytic hydrogen production with Ag/ZnO-6h, Ag/ZnO-4.5h and Ag/ZnO-3h were carried out; the results are shown in Fig. 10. As shown in Fig. 10, the abilities of photocatalytic hydrogen production of samples prepared under different synthesis times are slightly different and the hydrogen production of Ag/ZnO-6h is the highest, indicating the effect of the excellent morphology of the catalyst on photocatalytic hydrogen production. The above results show that the hydrogen production performance of the as-prepared Ag/ZnO-6h nanocomposites is vastly superior, which suggests promising application prospects.

3.9. Possible photocatalytic mechanism

Reactive species trapping experiments were performed to investigate the possible reactive oxygen species in the photocatalytic process.^{37–39} In this study, three different chemicals, *p*-benzoquinone (BZQ, a $\cdot\text{O}_2^-$ radical scavenger), disodium ethylenediaminetetraacetate ($\text{Na}_2\text{-EDTA}$, a hole scavenger), and methanol (MeOH, a $\cdot\text{OH}$ radical scavenger) were employed and the results are shown in Fig. 9.

Fig. 11 shows that the photocatalytic activity of RhB clearly decreased after adding MeOH, and the degradation rate decreased from 93.44% to 13.03%, indicating that $\cdot\text{OH}$ was the active species in the photocatalytic process. Moreover, the degradation rate of RhB decreased to 72.13% and 57.66% after adding $\text{Na}_2\text{-EDTA}$ and BZQ, respectively, indicating that h^+ and $\cdot\text{O}_2^-$ also had an important role in the photodegradation of RhB.

Table 2 Comparison of the degradation rate of dyes with different Ag/ZnO catalysts

Sample	Dye	Degradation rate	Ref.
Ag/ZnO-6h	RhB	94%	This work
Ag/ZnO-1FAZ	RhB	90.2%	34
PC-Ag _{10%} /ZnO _{90%}	RhB	About 79%	35
ZnO@Ag	MB	About 65%	36

Fig. 9 The recycling use results of Ag/ZnO-6h under UV photocatalytic degradation.

Based on the above conclusions, we postulate a possible photocatalytic mechanism of Ag/ZnO under different light sources. As shown in Fig. 12a, when the catalyst is irradiated with ultraviolet light, the electrons in the valence band (VB) are excited to the conduction band (CB) as the photon energy is larger than or equal to the band gap energy of ZnO. Moreover, the same number of holes (h^+) is generated in the valence band. As shown in Fig. 12a, the electrons in the conduction band move from the semiconductor ZnO to Ag because of the lower Fermi level of Ag. In addition, Ag nanoparticles as electron traps not only reduce the recombination of photogenerated electron-hole pairs, but also prolong the retention time of the photogenerated electrons, thus improving the photocatalytic activity of the composites. Subsequently, an electron acceptor such as O_2 can easily trap photogenerated electrons to form superoxide radical anions ($\cdot\text{O}_2^-$); also, photogenerated holes react with the surface $\cdot\text{OH}$

Fig. 11 Reactive species trapping experiments of the Ag/ZnO-6h composite.

to produce hydroxyl radicals ($\cdot\text{OH}$), which have a powerful oxidation ability to degrade organic molecules.^{40,41} Simultaneously, the conduction band position of Ag/ZnO-6h, calculated as -0.83 eV by the formula $E_{\text{CB}} = X - E_{\text{C}} - 0.5E_{\text{g}}$, is more negative than the hydrogen electrode reaction potential (0.0 eV vs. NHE), such that the conduction band electrons can reduce water to produce hydrogen. The VB of ZnO is 2.89 eV, which is more positive than those of $\cdot\text{OH}/\text{H}_2\text{O}$ (2.27 eV) and $\text{OH}^-/\cdot\text{OH}$ (1.99 eV); hence, OH^- can be oxidized to $\cdot\text{OH}$ by holes. Together with the electrons transferred from Ag, this results in more electrons reacting with O_2 , generating a large amount of superoxide radicals ($\cdot\text{O}_2^-$). In addition, O_2 is reduced to $\cdot\text{O}_2^-$ under the action of the electrons from the CB of ZnO.⁴²

Fig. 12b exhibits the speculated photocatalytic mechanism for Ag/ZnO illumination with visible light. ZnO barely absorbs visible light because of its wide band gap (3.21 eV) and it almost does not produce holes and electrons. Ag/ZnO displays a drastically reinforced photocatalytic performance in contrast to pure samples under visible light. SPR effect of Ag nanoparticles is the main reason. Because of the SPR effect of the metallic Ag, Ag/ZnO can respond to visible light (550 nm) to produce hot plasmonic electrons, which can transfer to the CB of ZnO. In order to recover to the primal state, Ag needs to accept electrons from the VB of ZnO. The above factors can increase charge carrier lifetimes and depress the recombination of holes and electrons. In addition, the near-field resonant energy transfer of Ag could accelerate the production and separation of hole–electron pairs in ZnO.

Furthermore, as shown in Fig. 12c, under the irradiation of UV + vis light, the hot plasmonic electrons of Ag can be transformed to the CB of ZnO, thus improving the H_2 production rate. Ag nanoparticles play two roles in this photocatalytic system. The first is to transfer electrons to the surface of ZnO and then react with H^+ in water to produce hydrogen. The other is that the Ag surface plasmon photogenerated electrons can be injected into the CB of ZnO to improve the separation of electrons and holes. Therefore, this can not only improve the absorption of visible light, but also reduce the recombination probability of the photogenerated electron–hole pair, thus improving the photocatalytic activity of hydrogen production.⁴³

4. Conclusions

A series of chrysanthemum-like composites Ag/ZnO were prepared *via* microwave-assisted hydrothermal synthesis. Due

to the strong polarization of microwave irradiation, the intensity of optical absorption of the composites increased and the morphology improved, thus improving the surface physicochemical properties of the composites. Simultaneously, the crystallite size of the composites significantly increased, the band gap energies of the composites slightly reduced, and the arrangement of the shapes of the composites became more regular and ordered on increasing the microwave irradiation time, indicating that increasing microwave irradiation time was conducive to the growth of crystals. Moreover, in the experimental study of multi-mode photocatalytic degradation of RhB and photocatalytic hydrogen production, Ag/ZnO-6h composites show good photocatalytic performance, which is due to the following factors: the doping of noble metal Ag increases the light absorption response range of the catalyst, while its role in the electron trap inhibited the recombination of photo-generated electrons and holes. In contrast, sufficient microwave radiation time promoted the ordered growth of crystals and improved the physicochemical properties.
