Morphology- and pH-dependent peroxidase mimetic activity of nanoceria†

Xiaoshu Wei, Xiaofeng Li, Yuqian Feng and Sen Yang *

The peroxidase mimetic properties of nanoceria have attracted extensive attention in recent years. In this work, the peroxidase mimetic properties of CeO₂ nanocrystals with different morphologies, namely, nanocubes and nanorods, were investigated. Two types of oxidative species, HO• radicals and peroxide-like intermediates, were identified in the CeO₂/H₂O₂ systems. The formation of these oxidative species is strongly dependent on the pH value and the morphology of the CeO₂ nanocrystals. The origin of the peroxidase mimetic activity of nanoceria was mainly ascribed to the presence of HO• under acidic conditions, whereas the peroxide-like species also played a major role under neutral and basic conditions. CeO₂ nanorods with excellent redox properties and higher concentration of Ce³⁺ and oxygen vacancies were more favorable for the generation of both HO• and peroxide-like intermediates than that of CeO₂ nanocubes, exhibiting excellent peroxidase mimetic activity toward 2,2'-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS), methylene blue (MB), and congo red (CR) in the presence of H₂O₂.

1 Introduction

Nanoceria has been extensively used in the field of catalysis because of the facile redox cycles between Ce³⁺ and Ce⁴⁺.^{1–3} Among various catalytic applications of nanoceria, one interesting phenomenon is the peroxidase mimetic behavior, that is, some active oxidative species can be generated and some substrates can be oxidized concurrently during the catalytic decomposition of H₂O₂.^{4–6} For example, it has been reported that CeO₂ nanoparticles exhibited excellent catalytic oxidation activity towards the classical peroxidase substrate 3,3',5,5'-tetramethylbiphenyl dihydrochloride in the presence of H₂O₂.⁷ Because of their peroxidase mimetic properties, nanoceria and cerium-containing materials have been widely used in medical diagnosis, biosensing, and Fenton-like processes for the degradation of organic pollutants.^{8–11}

Several oxidative species have been detected or proposed during the catalytic decomposition of H₂O₂ by nanoceria.^{5,12,13} Liu *et al.*⁸ attributed the peroxidase mimetic activity of H₂TCPP-CeO₂ nanocomposites to the formation of HO•, which was confirmed with a fluorescent probe technique. Lousada *et al.*¹⁴ confirmed the formation of HO• and studied the dynamics of formation of HO•. Besides HO•, the generation of other oxygen-derived free radicals such as HO₂•, O₂•, and O₂[–] have also been suggested.^{15,16} However, several researchers have attributed the

oxidation ability of nanoceria to some brown peroxide-like intermediates,^{17–20} which oxidize organic substances through intermolecular rearrangement.^{17,21,22} Although the exact structure of the active oxidative species responsible for the peroxidase mimetic activity of nanoceria have not been fully elucidated, it is believed that the pH value of the reaction medium has a significant influence on the peroxidase mimetic properties of nanoceria.⁸ Most studies have shown that nanoceria could be used as a peroxidase mimic in the pH range of 2.0–6.0,^{7,23} whereas a few studies have shown that the peroxidase mimetic activity of nanoceria could be observed at even higher pH values.^{13,21} Therefore, further study is still needed to understand the relationship between the pH of the solution and the nature of the oxidative species and their oxidation abilities.

The peroxidase mimetic property of nanoceria originates from the redox cycles between Ce³⁺ and Ce⁴⁺.^{15,24} Generally, the easier the redox cycles between Ce³⁺ and Ce⁴⁺, the better the peroxidase mimetic activity of nanoceria.¹² Up to now, several strategies including doping ceria with heteroatom ions such as Zr⁴⁺ and decreasing the particle size of the ceria particles has been used to enhance the peroxidase mimetic activity of ceria.^{12,17,23} Zhou *et al.* reported that the redox performance of nanoceria could also be optimized by tuning the crystal planes exposed on the surfaces.²⁵ Since then, a series of studies have been carried out to optimize the catalytic performance of nanoceria for various reactions by tuning the morphology of CeO₂ nanocrystals.^{26–29} However, to the best of our knowledge, the influence of the exposed crystal facet on the peroxidase mimetic activity of nanoceria has only been reported in a recent paper, which found that the Fenton-like reactivity of CeO₂

Beijing Key Laboratory of Farmland Soil Pollution Prevention and Remediation, College of Resources and Environmental Sciences, China Agricultural University, Beijing 100193, PR China. E-mail: syang@cau.edu.cn; Tel: +86 1062733470

† Electronic supplementary information (ESI) available. See DOI: 10.1039/c8ra00622a

nanocrystal was related to their exposed facets.³⁰ Therefore, it is worth applying nanoceria with different morphologies as peroxidase mimetics to optimize the catalytic activity and understand the underlying mechanisms of the nanoceria mimic enzyme.

In this work, CeO₂ nanocubes and nanorods were prepared by a hydrothermal method and their peroxidase mimetic properties were investigated under both acidic and basic conditions. Our studies revealed a strong morphology-dependent peroxidase mimetic activity of nanoceria. The nature of the active oxidative species at different pH values and their oxidation abilities were investigated to gain a deep understanding of the mechanism of the peroxidase-mimetic activity of nanoceria.

2 Experiments

2.1 Materials

Ce(NO₃)₃·6H₂O, NaOH, HCl, H₂O₂ (30%, w/w), *n*-butyl alcohol, methylene blue (MB) and congo red (CR) were purchased from Sinopharm Chemical Reagent Co. Ltd (Shanghai, China). Catalase, 2,2'-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS) and 5,5-dimethyl-1-pyrroline *N*-oxide (DMPO) were obtained from Sigma-Aldrich Co. LLC. (Saint Louis, USA). All reagents were of analytical reagent grade and were used without further purification.

2.2 Synthesis of CeO₂ nanocubes and CeO₂ nanorods

CeO₂ nanocatalysts were synthesized through a hydrothermal process.^{25,31} Typically, Ce(NO₃)₃·6H₂O (1.5 g) was dissolved in distilled water, and an appropriate amount of 10% NaOH solution was rapidly added to give a final NaOH concentration of approximately 2.0 M. After stirring for approximately 15 min, the slurry (approximately 40 mL) was placed into a 50 mL Teflon-sealed autoclave and heated. The morphology of the as-prepared nanoceria depended on the hydrothermal temperature and reaction time, that is, nanocubes were formed by heating at 180 °C for 24 h and nanorods were formed by heating at 120 °C for 12 h. After cooling, the final product was collected by filtration, washed with deionized water, and then dried at 60 °C.

2.3 Catalyst characterization

The size and morphology of the nanoceria was characterized with a JEM-2100F high-resolution transmission electron microscope (HRTEM, JEOL, Japan). The powder X-ray diffraction (XRD) patterns were obtained on an D8 Advance X-ray diffractometer (Bruker, Germany) with Ni-filtered Cu K α radiation (λ = 0.1541 nm). The Brunauer–Emmett–Teller (BET) surface area was evaluated from nitrogen adsorption–desorption data recorded at 77 K using a model NOVA 3200e automated gas sorption system (Quantachrome, USA). X-ray photoelectron spectra (XPS) measurements were performed on an ESCALAB 250Xi high-performance electron spectrometer (Thermo Fisher, USA) using monochromatized Al K α ($h\nu$ = 1486.6 eV) as the excitation source. Raman spectra were

collected by a Raman spectrometer (Renishaw inVia, UK) with a laser wavelength of 514.5 nm. Hydrogen temperature-programmed reduction (H₂-TPR) was conducted with a Chemi-Sorb 2750 apparatus (Micromeritics, USA) equipped with a TCD detector. TPR was performed by heating the nanoceria samples (50 mg) at 10 °C min^{−1} from 50–700 °C in a 5 vol% H₂–N₂ mixture with a flow rate of 25 mL min^{−1}.

2.4 Electron paramagnetic resonance (EPR) measurements

To monitor the potential radicals formed in the nanoceria/H₂O₂ system, DMPO was used as the spin trap and EPR spectra were recorded using a JES-FA200 EPR spectrometer (X-band) with dual cavities (JEOL, Japan). Typical parameters were as follows: modulation frequency, 100 kHz; microwave frequency, 9.05 GHz; sweep width, 50 G; EPR microwave power, 3 mW; modulation amplitude, 1 G; time constant, 0.03 s; and sweep time, 2 min.

2.5 Peroxidase mimetics activity of nanoceria

The catalytic reaction was performed at 25 °C using 1 g L^{−1} CeO₂ with 2 mM ABTS, 15 mg L^{−1} MB or 70 mg L^{−1} CR as substrate and 20 mM H₂O₂, unless otherwise stated. Generally, catalyst powder was added into a conical flask containing an aqueous solution of the substrate. Then, a H₂O₂ solution was added to initiate the oxidation reaction. To avoid the influence of ions on the nanoceria activity, ultrapure water was used in the test, and the initial pH of the reaction system was adjusted using 0.1 M HCl and 0.1 M NaOH solution. The concentration of organics and H₂O₂ in supernatant was analyzed by using a UV–vis spectrophotometer (Beijing Purkinje General, China). The maximum wavelengths (λ_{max}) of H₂O₂, ABTS^{•+}, MB and CR are 240, 734, 664 and 497 nm, respectively.

3 Results and discussion

3.1 Characterization of CeO₂ nanocubes and nanorods

The morphologies of the as-prepared samples were examined by transmission electron microscopy (TEM). The CeO₂ nanocubes had uniform cubic shapes with a size of 20–30 nm (Fig. 1a). The HRTEM image in Fig. 1b shows an interplanar spacing of 0.27 nm, corresponding to the (200) lattice fringe of CeO₂, which indicates that the nanocubes were mainly enclosed by the (100) facets.³¹ As shown in Fig. 1c, CeO₂ nanorods had diameters of approximately 15–20 nm and lengths of 100–200 nm. The HRTEM analysis (Fig. 1d) revealed that the nanorods were single-crystalline and their growth direction was (110). This was consistent with the previously reported results that nanorods expose their (110) and (100) facets.²⁵

The XRD patterns of the CeO₂ nanocubes and nanorods are shown in Fig. 2a. All the diffraction peaks of both samples can be indexed to the pure fluorite structure of CeO₂ (JCPDS 34-0394).²⁸ The sharper peaks of the nanocubes indicated their higher crystallinity and bigger crystallite size than those of the nanorods,²⁶ which was consistent with the TEM and HRTEM analysis. The specific surface areas of the nanocerias were measured by a nitrogen gas adsorption–desorption isotherm

Fig. 1 TEM images of (a) CeO₂ nanocubes and (c) nanorods, and HRTEM images of (b) CeO₂ nanocubes and (d) nanorods.

Fig. 2 XRD patterns (a) and Ce3d XPS spectra (b) of CeO₂ nanocubes and nanorods.

and calculated by the BET method. The nanorods exhibited a larger specific surface area ($89.9 \text{ m}^2 \text{ g}^{-1}$) than that of the nanocubes ($39.7 \text{ m}^2 \text{ g}^{-1}$).

The valence state of the Ce ions in the nanocerias was determined by XPS and the results are shown in Fig. 2b. The Ce3d XPS spectra revealed that a mixed valence state (Ce^{3+} and Ce^{4+}) was present and most of the Ce ions were Ce^{4+} in both nanoceria samples.³² However, the peaks attributed to Ce^{3+} in the nanorods, were clearly stronger than those for the nanocubes, as marked in Fig. 2b, indicating that more Ce^{3+} was on the surface of the nanorods.^{33,34} The Ce3d spectra were fitted using PeakFit software to calculate the Ce^{3+} concentration on the surface of both samples. The relative concentration of Ce^{3+} on the surface of the nanorods was 34.7%, which was much larger than that of the nanocubes (23.3%). The presence of more Ce^{3+} indicated that there were more oxygen vacancies in the CeO₂ nanorods, which was further verified by Raman analysis.

Fig. 3a displays the Raman spectra of the samples; two bands were observed for both samples. The presence of the prominent F_{2g} vibrational mode band at approximately 460 cm^{-1} was ascribed to the symmetric mode of the oxygen atoms around the cerium ions.²⁸ Compared with that of CeO₂ nanorods, the Raman band of the nanocubes displayed a clear increase in

Fig. 3 (a) Raman spectra and (b) H₂-TPR profiles of CeO₂ nanocubes and nanorods.

symmetry and a decrease in the full width at half maximum, along with an evident shift towards higher wave numbers. This was attributed to the higher degree of crystallinity and larger crystallite size of the nanocubes.^{35,36} The weak band at approximately 590 cm^{-1} was associated to the defect-induced mode (D).³⁵ The degree of defect sites on CeO₂ was estimated using the relative intensity of D/F_{2g} .^{28,36} The D/F_{2g} ratio of the CeO₂ nanorods was 0.056, which was higher than that of the nanocubes (0.023). This implied that CeO₂ nanorods had more defect sites such as oxygen vacancies, which was consistent with the XPS results.

The presence of more Ce^{3+} and defects in CeO₂ nanorods suggested that the nanorods could be more reducible than the nanocubes. Subsequently, the redox properties of the nanoceria samples were examined by H₂-TPR. The TPR profiles (Fig. 3b) of both samples showed two reduction bands, one located below 580°C and one above 600°C . The low-temperature reduction band is related to the surface oxygen reduction and is of particular interest in catalytic reactions.³² The low-temperature peak position of the CeO₂ nanorods was at 450°C , which was much lower than that of the nanocubes (510°C), indicating that the CeO₂ nanorods were much more reducible than the nanocubes.²⁸ The facile redox performance of the CeO₂ nanorods indicated that the CeO₂ nanorods should perform well as peroxidase mimetics.

3.2 H₂O₂ decomposition and probing the possible oxidative species

The decomposition of H₂O₂ over CeO₂ nanocubes and nanorods was first investigated from pH 3.0 to 9.0. This set of data is for 20 mM H₂O₂ in the presence of 1 g L^{-1} CeO₂ at 25°C . Fig. 4a shows the H₂O₂ concentration changes as a function of time. The decomposition of H₂O₂ in the presence of CeO₂ follows first-order kinetics as previously reported (Fig. S1†).^{14,37} The rate coefficients are given in Table S1†. It is clear that the effect of the pH on the decomposition of H₂O₂ over nanoceria is not obvious and only a slight increase in conversion can be observed with increasing pH from 3.0 to 9.0.³⁸ However, CeO₂ nanorods display higher activity over all reactivity towards H₂O₂. When the amount of eliminated H₂O₂ was normalized to the surface area of nanocubes and nanorods, CeO₂ nanorods still possessed higher level of activity (Fig. 4b).

It has been reported that nanoceria could facilitate the decomposition of H₂O₂ to produce HO[•] through a series of reactions analogous to Fenton/Haber Weiss reactions:^{15,39,40}

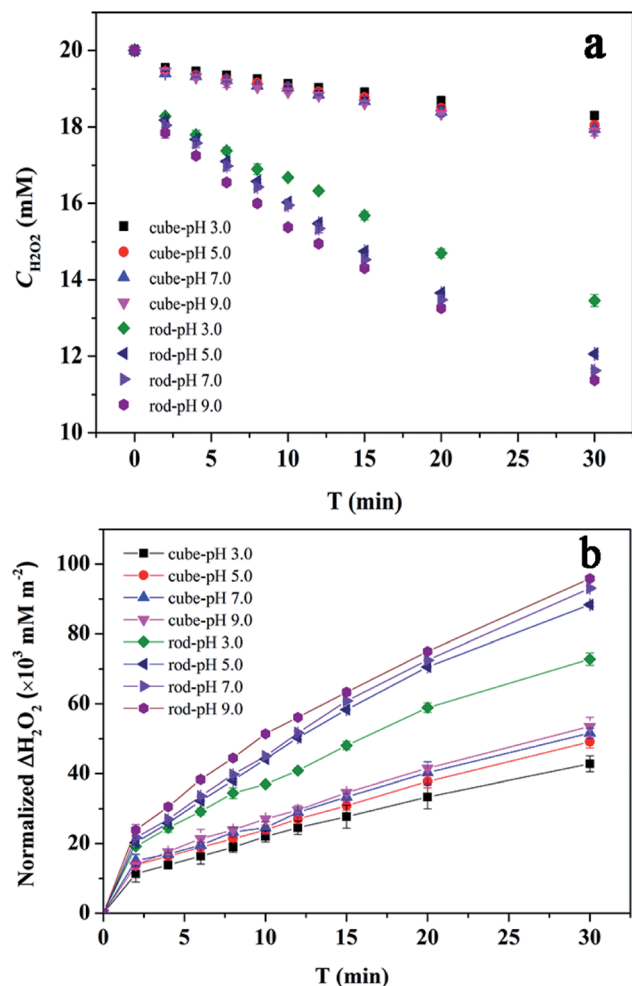

Fig. 4 Catalytic activity of CeO_2 : (a) concentration changes of H_2O_2 as a function of reaction time and (b) the eliminated H_2O_2 was normalized to CeO_2 surface area (20 mM H_2O_2 , 1 g L^{-1} CeO_2 , 25 °C).

To probe the possible generation of HO^\bullet during the catalytic decomposition of H_2O_2 over nanoceria, EPR was performed using the DMPO as a spin trap. As shown in Fig. 5, a 4-line EPR spectrum characteristic of DMPO-OH adducts was detected for a suspension of nanorods upon the addition of H_2O_2 , but the intensity of the DMPO-OH signal decreased from pH 3.0 to pH 9.0. Similar results were obtained for a suspension of nanocubes, except the intensity of the DMPO-OH peaks was significantly lower than those of the nanorods under the same conditions. These results clearly show that HO^\bullet can be generated in the catalytic decomposition of H_2O_2 and the yield of HO^\bullet is decreased with increasing pH from 3.0 to 9.0.^{22,41} And CeO_2 nanorods with better redox properties were more favorable for the generation of HO^\bullet than their nanocube counterparts. Then the ability of the nanoceria to generate HO^\bullet strongly depends on its redox properties.⁴⁰

Fig. 5 DMPO spin trapping EPR spectra of CeO_2/H_2O_2 system. Nanocubes/ H_2O_2 at pH 3.0 (a) and 9.0 (b); nanorods/ H_2O_2 at pH 3.0 (c) and 9.0 (d). The incubation time is 2 min, and $[CeO_2] = 1 \text{ g } L^{-1}$, $[H_2O_2] = 20 \text{ mM}$.

It should be noted that a rapid color change was observed upon the addition of H_2O_2 into the nanoceria suspensions: the nanocubes suspension became light yellow and the nanorods suspension became deep yellow (Fig. 6). The color change was attributed to the formation of another type of oxidative species (the peroxide-like intermediates) from the reaction between H_2O_2 and CeO_2 .^{12,19,38} The small variations in the color change of nanoceria from pH 3.0 to 9.0 were almost completely imperceptible to the eye, indicating that the formation of peroxide-like intermediates was independent of the pH value. Compared with the suspension of the nanocubes/ H_2O_2 , the deeper color of the nanorods/ H_2O_2 system indicated more

Fig. 6 Photographs of nanoceria suspensions after the addition of H_2O_2 at various pH (50 mM H_2O_2 , 0.5 g L^{-1} CeO_2).

peroxide-like species were generated owing to the presence of more Ce^{3+} and oxygen vacancies, as proved by XPS and Raman analysis. A generally accepted view is that the ease of $\text{Ce}^{3+}/\text{Ce}^{4+}$ redox cycles plays a significant role in the decomposition of H_2O_2 and the generation of peroxide-like intermediates.²¹ In this process, the rate of Ce^{3+} oxidation is much faster than that of Ce^{4+} reduction, and high concentration of Ce^{3+} would enhance the reducibility of ceria.^{32,38,42} Therefore, high peroxidase mimetic activity of ceria nanorods can be attributed to the high concentration of Ce^{3+} and the better reducibility.

The above results show that there were two types of oxidative species, namely HO^\cdot and peroxide-like intermediates, which can be generated in the nanoceria/ H_2O_2 systems. The formation of these oxidative species was strongly dependent on the pH value and the morphology of the CeO_2 nanocrystals, which determined the peroxidase mimetic performance of nanoceria.

3.3 Peroxidase mimetic activity of CeO_2 nanocubes and nanorods

The peroxidase mimetic activity of the CeO_2 samples was evaluated semiquantitatively by the oxidation of ABTS in the presence of H_2O_2 from pH 3.0 to 9.0. ABTS is typically used as a horseradish peroxidase substrate, which develops a green color ($\text{ABTS}^{+\cdot}$) upon oxidation in aqueous solution. Control experiments showed that the color change of the systems was negligible without the presence of nanoceria or H_2O_2 (Fig. S2†). As shown in Fig. 7, a distinct and rapid change of the nanoceria/ H_2O_2 suspension to a green color was observed upon the addition of ABTS, indicating that nanoceria did exhibit high peroxidase-mimetic activity, as reported previously.^{7,10} Compared with the nanocubes, the nanorods exhibited a higher activity under the current conditions, which could be explained by the generation of more HO^\cdot and peroxide-like intermediates owing to their better redox property and high concentration of Ce^{3+} and oxygen vacancies. Moreover, it is evident that the color

of the suspensions changes from dark green to lighter with pH value from 3.0 to 9.0, showing a strong pH-dependent peroxidase mimetic activity of nanoceria. Nanoceria display higher peroxidase mimetic activity at acidic conditions and the time-dependent UV-vis spectra of the oxidized product of ABTS ($\text{ABTS}^{+\cdot}$) at room temperature are shown in Fig. 8. To further understand the peroxidase mimetic behaviors of the ceria nanocubes and nanorods, decolorization of MB and CR were carried out.

3.4 Decolorization of MB and CR in nanoceria/ H_2O_2 system

First, decolorization of 15 mg L^{-1} MB with 1.0 g L^{-1} nanoceria and $20 \text{ mM H}_2\text{O}_2$ at pH 3.0 was investigated. It turned out that the decolorization of MB over nanorods was 11.6% after 30 min, while only 4.8% was achieved over nanocubes. To investigate the role of HO^\cdot and peroxide-like intermediates in the decolorization process, we performed this experiment by adding $200 \text{ mM } n$ -butanol as a radical scavenger before the reaction was initiated. Excess n -butanol in solution can scavenge all the HO^\cdot produced in the H_2O_2 decomposition process and inhibit the degradation of MB.⁴⁰ As expected, the decolorization of MB was completely inhibited in the presence of n -butanol. This result verified that the peroxidase mimetic activity of nanoceria was mainly owing to the formation of HO^\cdot under acidic conditions.^{13,14} It is well known that HO^\cdot exhibits high reactivity and can non-selectively oxidize most organic compounds at near diffusion-controlled rates under acidic condition.⁴³ Although the peroxide-like intermediates were also present, it seemed they did not work. In fact, Chen *et al.*⁴⁴ and Hamoud *et al.*¹² reported that the peroxide-like intermediates were prone to decompose in to HO^\cdot under acidic conditions. This can be used to explain the complete inhibition decolorization of MB in the presence of n -butanol.

Subsequently, the decolorization of MB at pH 9.0 was carried out. Because of the strong adsorption on ceria arising under these conditions (pH 9.0), both adsorption and oxidative degradation contributed to the total decolorization. After

Fig. 7 The pH effect on the production of colored product owing to ABTS oxidation in the nanoceria/ H_2O_2 system ($0.2 \text{ g L}^{-1} \text{ CeO}_2$, $10 \text{ mM H}_2\text{O}_2$, 5 mM ABTS , t : 2 min).

Fig. 8 Time-dependent absorbance changes at 734 nm of ABTS in different systems ($0.1 \text{ g L}^{-1} \text{ CeO}_2$, $5 \text{ mM H}_2\text{O}_2$ and 2 mM ABTS).

eliminating the interference arising from adsorption, the degradation of MB was obtained (more information is provided in the ESI†). After 0.5 h, the degradation of MB in the presence of CeO₂ nanorods and nanocubes was only 5.3% and 3.4%, respectively. These results suggested that nanoceria/H₂O₂ system could degrade MB at pH 9.0 but the peroxidase mimetic reactivity of nanoceria was much lower than that at pH 3.0. To further understand the peroxidase-mimetic activity of nanoceria under basic conditions, the degradation of CR, a typical anionic azodye, was investigated at pH 9.0. The CR (70 mg L⁻¹) could be completely degraded after 1 h in the presence of nanorods, whereas the degradation was only 8.2% in the presence of nanocubes. Interestingly, this time, the addition of *n*-butanol could not completely inhibit the degradation of both MB and CR under basic conditions, although the degradation rates of dye were decreased with a certain extent. For example, the complete degradation time of CR in nanorods/H₂O system was delayed from 1 h to 2.5 h upon addition of *n*-butanol. These results suggested that both HO· and the peroxide-like intermediates were acting as the oxidative species in the nanoceria/H₂O₂ system under basic conditions.²⁹ According to previous reports, under neutral and basic conditions, the peroxide-like intermediates can directly function as peroxidase-like active sites^{23,45} or induce an intermolecular rearrangement to achieve the oxidation of organics.^{21,22} Because oxidation ability of HO· was much weaker under basic conditions than acidic conditions,^{12,46} the importance of the peroxide-like intermediates was raised.

4 Conclusions

Nanoceria possesses strong morphology- and pH-dependent peroxidase-like activity for the degradation of ABTS, MB and CR. Two types of oxidative species were generated in the nanoceria/H₂O₂ systems, namely, HO· and peroxide-like intermediates. Under acidic conditions, HO· are primarily responsible for the peroxidase mimetic activity of nanoceria; under neutral and basic conditions, HO· and peroxide-like intermediates are responsible for activity. Compared with CeO₂ nanocubes, ceria nanorods exhibited a higher peroxidase activity owing to their excellent redox property and more Ce³⁺ and oxygen vacancies.
