## Effects of precursor pre-treatment on the vapor deposition of WS<sub>2</sub> monolayers†

Mei Er Pam,<sup>ab</sup> Yumeng Shi,<sup>\*acd</sup> Junping Hu,<sup>a</sup> Xiaoxu Zhao,<sup>id e</sup> Jiadong Dan,<sup>e</sup>  
Xue Gong,<sup>ac</sup> Shaozhan Huang,<sup>a</sup> Dechao Geng,<sup>a</sup> Stephen Pennycook,<sup>fg</sup>  
Lay Kee Ang<sup>ab</sup> and Hui Ying Yang<sup>id \*a</sup>

Transition metal oxide powders have been widely used as the growth precursors for monolayer transition metal dichalcogenides (TMDCs) in chemical vapor deposition (CVD). It has been proposed that metal oxide precursors in the gas phase undergo a two-step reaction during CVD growth, where transition metal sub-oxides are likely formed first and then the sulfurization of these sub-oxides leads to the formation of TMDCs. However, the effects of stoichiometry of transition metal oxide precursors on the growth of TMDC monolayers have not been studied yet. In this contribution, we report the critical role of the WO<sub>3</sub> precursor pre-annealing process on the growth of WS<sub>2</sub> monolayers. Besides, several WO<sub>3</sub> precursors with different types of oxygen vacancies have also been prepared and investigated by X-ray powder diffraction (XRD), X-ray photoelectron spectroscopy (XPS) and density functional theory calculation. Among all the non-stoichiometric WO<sub>3</sub> precursors, thermally annealed WO<sub>3</sub> powder exhibits the highest oxygen vacancy concentration and produces WS<sub>2</sub> monolayers with significantly improved quality in terms of lateral size, density, and crystallinity. Our comprehensive study suggests that the chemical composition of transition metal oxide precursors would be

fundamentally critical for the growth of large-area and high-quality WS<sub>2</sub> monolayers, which further pave the way for revealing their intrinsic properties and unique applications.

### Introduction

The extraordinary electrical, optical, thermal and mechanical properties, which exist in monolayer transition metal dichalcogenides (TMDC) materials, offer various promising applications in future ultrathin logic devices, nanogenerators, flexible electronics and optoelectronic devices.<sup>1–4</sup> Specifically, the tunable properties of band offset, carrier density,<sup>5</sup> and band gap<sup>6–8</sup> make TMDCs one of the most extensively researched subjects for practical and fundamental studies. Monolayer tungsten disulfide (WS<sub>2</sub>) has been intensively studied as a next generation nanoelectronic and optoelectronic material due to its indirect to direct band gap tunability,<sup>9,10</sup> high on/off current ratio,<sup>11,12</sup> high thermal stability,<sup>13</sup> excellent electrostatic integrity<sup>14</sup> and strong photoluminescence.<sup>15,16</sup> Additionally, WS<sub>2</sub> monolayers have shown an interesting spin orbit coupling effect resulting from the breaking of inversion symmetry of their crystal lattices, and the strong magnetic field interaction in WS<sub>2</sub> monolayers favors their applications in optoelectronic and spintronic devices.<sup>17,18</sup>

Various approaches have been employed to prepare WS<sub>2</sub> monolayers. The layered structure of WS<sub>2</sub> allows the mechanical or chemical exfoliation of monolayer crystals from their bulk counterparts. However, the exfoliated flakes show random thickness, size and shape that create great difficulties in large scale industrial applications.<sup>16</sup> Chemical vapor deposition (CVD) has been widely adapted as one of the most effective strategies to grow wafer-scale two-dimensional (2D) materials including graphene, boron nitride, and TMDCs.<sup>19–23</sup> In the pioneering studies of monolayer WS<sub>2</sub> synthesis, tungsten trioxide (WO<sub>3</sub>) powder was chosen as the growth precursor and a low concentration of hydrogen (H<sub>2</sub>) gas was usually introduced to reduce WO<sub>3</sub> to tungsten suboxide.<sup>22,24,25</sup> Nevertheless, excessive hydrogen supply could also have an etching effect and

induce various structural defects in monolayer WS<sub>2</sub>.<sup>16,25,26</sup> Traditionally, tungsten oxides have been intensively studied previously for photocatalysis,<sup>27,28</sup> electrochemistry,<sup>29</sup> electrochromic application,<sup>30,31</sup> etc. According to the literature, WO<sub>3</sub> powder is usually found in a non-stoichiometric composition and the W element may show various chemical states due to the spontaneous reduction of WO<sub>3</sub> under ambient conditions.<sup>30</sup> It has been demonstrated that the sulfurization process of transition-metal suboxides in the CVD process plays a critical role in the nucleation and crystallization of TMDC monolayers.<sup>22,32</sup>

In the CVD process, the generation and evolution of transition metal sub-oxide species can significantly affect the morphology and edge structure of TMDCs, which lead to dramatically different optical, electrical and magnetic properties.<sup>20</sup> However, the study of the effects of chemical composition of WO<sub>3</sub> on the CVD growth of WS<sub>2</sub>, in terms of quality, morphology and optical properties, is still lacking. Herein, we prepared various tungsten oxide precursors with different oxygen vacancy concentrations, that is, commercially available fresh WO<sub>3</sub> (FWO<sub>3</sub>), thermally annealed WO<sub>3</sub> (AWO<sub>3</sub>), air plasma treated WO<sub>3</sub> (PTWO<sub>3</sub>) and thermally annealed PTWO<sub>3</sub> powder (PTAWO<sub>3</sub>) to provide tungsten suboxide sources. The results reveal that AWO<sub>3</sub> powder with the highest oxygen vacancy content produces WS<sub>2</sub> monolayers with significantly improved domain size, higher coverage density, and higher crystallinity. Besides, we further demonstrate that the use of AWO<sub>3</sub> powder instead of the introduction of hydrogen gas during the growth of monolayer WS<sub>2</sub> to provide a tungsten suboxide source will enhance the growth of monolayer WS<sub>2</sub> and produce monolayer WS<sub>2</sub> with suppressed atomic defects. The control synthesis of WS<sub>2</sub> monolayers by precursor pretreatment provides further insights into the growth mechanism and enables the production of WS<sub>2</sub> monolayers with high quality for the development of a broad range of optoelectronic and electronic applications.

## Experimental methods

### Preparation of tungsten trioxide (WO<sub>3</sub>) precursors

The WO<sub>3</sub> precursors were pretreated with heat, air plasma or both. Four WO<sub>3</sub> precursors prepared with different methods were studied for comparison, including commercially available WO<sub>3</sub> (FWO<sub>3</sub>) (Sigma-Aldrich), thermally annealed WO<sub>3</sub> (AWO<sub>3</sub>), air plasma treated WO<sub>3</sub> (PTWO<sub>3</sub>) and plasma treated annealed WO<sub>3</sub> (PTAWO<sub>3</sub>) powder.

For AWO<sub>3</sub> powder, 500 mg of WO<sub>3</sub> powder was loaded in an alumina boat, placed at the center of a furnace, and heated up to 500 °C in air for 30 minutes.

For PTWO<sub>3</sub> powder, 500 mg of WO<sub>3</sub> powder was loaded in an alumina boat, placed at the center of a plasma reactor center (Plasma Cleaner PDC-32G-2). The sample was directly exposed to a direct inductively coupled plasma. During the plasma treatment process, the chamber was evacuated to 1.5 mTorr with a mechanical pump and the radio frequency power was turned to ~18 W, and at the same time air was introduced into the chamber and the process was continued for 5 minutes.

For PTAWO<sub>3</sub> powder, 500 mg of WO<sub>3</sub> powder was first treated using air plasma with the same preparation steps as the plasma

treated WO<sub>3</sub> powder, and the powder was then annealed using the same procedure that we employed to prepare the annealed WO<sub>3</sub> powder sample.

### Growth process of monolayer WS<sub>2</sub>

The employed CVD process for monolayer WS<sub>2</sub> is based on our previous report.<sup>33,34</sup> Prior to the growth process, single-side polished sapphire substrates were washed with the solution mixture of H<sub>2</sub>SO<sub>4</sub> and H<sub>2</sub>O<sub>2</sub> and blow-dried with nitrogen gas. An alumina boat filled with 500 mg pre-prepared WO<sub>3</sub> powder (Sigma-Aldrich, 99.9%) was located at the center of a furnace, and the cleaned sapphire substrates were placed facing down on the boat with WO<sub>3</sub> powder as illustrated in Fig. S1.† A separate boat with sulfur powder (Sigma-Aldrich, 99.5%) was located at the upstream of the furnace, which was heated up to the sulfur evaporation temperature at 120 °C with a heating belt during the growth of monolayer WS<sub>2</sub>. The CVD chamber was initially pumped down to a base pressure of ~1 mTorr for 5 minutes and maintained at 15 torr with a 100 sccm flow of argon gas during the synthesis process. The furnace was then heated from room temperature to 200 °C and the temperature was kept constant for 10 minutes to evaporate the water vapor in the quartz tube. The temperature was then further heated up to 950 °C at a ramp rate of 25 °C per min and kept constant for 10 minutes. Finally, the growth chamber was cooled down to room temperature naturally. For the hydrogenated environmentally synthesized WS<sub>2</sub> (HWS<sub>2</sub>) sample, the growth process was the same as that described above with commercially available WO<sub>3</sub> powder except that 5% hydrogen gas is introduced into the tube furnace during the growth process.

### DFT calculation of the WO<sub>3</sub> crystal structure

DFT calculations were performed on the crystal structure of WO<sub>3</sub> with and without oxygen vacancies. Our calculations were based on density functional theory (DFT) using plane-wave pseudopotentials with the exchange-correlation of Perdew–Burke–Ernzerhof (PBE)<sup>35,36</sup> form as implemented in the Vienna *Ab initio* Simulation Package (VASP).<sup>37</sup> A cutoff energy of 500 eV was employed for the plane wave expansion of the wave functions. The Brillouin zone was sampled with a 9 × 5 × 5 Monkhorst–Pack *k*-point mesh<sup>38</sup> for the structural optimization. The convergence criteria for the total energy and ionic forces were set to 10<sup>-5</sup> eV and 0.005 eV Å<sup>-1</sup> respectively. Spin polarization was carefully tested and no spin-polarization effect was observed in our calculations.

### Characterization

Photoluminescence (PL) and Raman measurements were obtained with a Witec Alpha300 Confocal Raman system with a laser excitation wavelength of 532 nm and grating density of 600 and 1800 mm<sup>-1</sup> respectively. X-ray photoelectron spectroscopy (XPS, PHI Quantera II) with a monochromatic Al K $\alpha$  source (1486.69 eV), operated at a base pressure of 10<sup>-7</sup> Pa, was employed to obtain the chemical configuration spectra. X-ray diffraction (XRD, Bruker D8) with a Cu K $\alpha$  source was employed to identify the crystalline phases and structures of the prepared

WO<sub>3</sub> powders. The annular dark field scanning transmission electron microscope (ADF-STEM) image was captured on an aberration-corrected JEOL ARM-200F equipped with a cold field emission gun, operating at 80 kV. The convergence semi-angle of the probe is  $\sim 30$  mrd. STEM-ADF images were captured for a half angle range from  $\sim 85$  to 280 mrd. A dwell time of 19  $\mu$ s per pixel was set for a single-scan image.

### Transfer

The as-grown monolayer WS<sub>2</sub> on sapphire was first spin coated with a thin layer of poly(methyl methacrylate) (PMMA) for one minute at a spin speed of 2000 rpm. Then, the edges of the sapphire substrate were removed and the substrate was immersed slowly in a hot solution of 3 mol L<sup>-1</sup> NaOH (160 °C) to detach the PMMA layer from the sapphire substrate. The resulting sample was then delaminated in deionized water and washed a few times in deionized (DI) water. Finally, the sample was transferred onto a target substrate and carefully blow-dried with nitrogen gas. The PMMA coating was finally removed by using hot acetone vapor at 120 °C for 15 minutes. The samples for STEM study were prepared onto 200 mesh Quantifoil R2/1 micromachined copper grids from SPI Supplies, Structure Probe, Inc. using the same transfer method.

## Results and discussion

Generally, the synthesis of 2D TMDCs with the chemical vapor deposition method is based on the direct competition and multiple elementary processes in two reaction pathways between the transition metal suboxide and sulfur. The reaction pathways consist of: (1) transition metal suboxide diffuses and adsorbs on the substrate, and then reacts with S to form monolayer TMDC; (2) transition metal suboxide directly reacts with S in the gas phase to form a TMDC and the resulting WS<sub>2</sub> clusters adsorb, nucleate and form on the substrate.<sup>22,32</sup> Both of the two reaction routes strongly rely on the evaporation and stable delivery of the tungsten source. The metastable state tungsten suboxide can provide a much easier control over the

supply of the tungsten source, and thus facilitate the growth process and enhance the growth of WS<sub>2</sub> monolayers. Therefore, the formation of tungsten suboxide plays a critical role in the nucleation and crystallization of TMDC monolayers. In a previous report, in order to promote the growth of monolayer WS<sub>2</sub>, hydrogen gas was introduced during the synthesis, which assists the reduction of tungsten trioxide.<sup>16,24,25</sup> Fig. 1a illustrates the synthesis process of monolayer WS<sub>2</sub> in an Ar/H<sub>2</sub> atmosphere in which hydrogen gas acts as a tungsten trioxide reductant to reduce tungsten oxide to form volatile tungsten suboxides ( $\text{WO}_3 + x\text{H}_2 \rightarrow \text{WO}_{3-x} + x\text{H}_2\text{O}$ ).<sup>16,25,39</sup> The resulting WO<sub>3-x</sub> are readily volatile, easily evaporate and release the tungsten source.<sup>40-42</sup> The rapid evaporation of the tungsten source will eventually lead to an increase of nucleation sites and hence promote the growth of WS<sub>2</sub>.<sup>24,25</sup> Unfortunately, the excessive supply of hydrogen has etching effects on WS<sub>2</sub> ( $\text{WS}_2 + 2\text{H}_2 \rightarrow \text{W} + 2\text{H}_2\text{S}$ ).<sup>16,25</sup> The excess hydrogen in the growth atmosphere will react with the as-grown WS<sub>2</sub> flakes and remove the sulfur elements, resulting in sulfur vacancies. Precursor pre-treatments such as thermal annealing and plasma treatment create oxygen vacancies in WO<sub>3</sub>, resulting in WO<sub>3-x</sub> (see Fig. 1b). The formation of volatile WO<sub>3-x</sub> suggests great potential in promoting the growth of monolayer WS<sub>2</sub>. Herein, to reveal the effects of oxygen vacancies in WO<sub>3</sub> on the growth of WS<sub>2</sub> monolayers, various tungsten trioxide powders with different oxygen vacancies were prepared, including thermally annealed WO<sub>3</sub> (AWO<sub>3</sub>) powder, air plasma treated WO<sub>3</sub> (PTWO<sub>3</sub>) powder, air plasma treated and annealed WO<sub>3</sub> (PTAWO<sub>3</sub>) powder, and commercially available WO<sub>3</sub> powder (FWO<sub>3</sub>). We first employed AWO<sub>3</sub> powder to obtain the optimized WS<sub>2</sub> growth temperature under the same pressure of 15 torr (see Fig. S1†). As illustrated in Fig. S1,† an optimized growth temperature of 950 °C was determined for WS<sub>2</sub> monolayer synthesis.

We further compared the as-grown WS<sub>2</sub> monolayers produced from the four WO<sub>3</sub> sources with different pre-treatment methods. The growth of monolayer WS<sub>2</sub> strongly depends on the growth conditions, and in order to exclusively probe the effects of WO<sub>3</sub> precursors on the CVD synthesis, regardless of

Fig. 1 Reaction mechanism for CVD growth of (a) the commercial precursor in an Ar/H<sub>2</sub> atmosphere; (b) pretreated precursors in an Ar only atmosphere.

the precursor pre-treatment methods used, all the growth processes were carried out under the same growth conditions with a growth temperature of 950 °C and a growth time of 10 minutes. AFM analysis and Raman characterization (see Fig. S2 and S3†) were carried out to confirm the monolayer nature of the WS<sub>2</sub>. The AFM line profiles at the edge of all the samples demonstrate that the thicknesses are in the 0.6 nm to 0.9 nm range, which fall in the thickness range of monolayer WS<sub>2</sub>. The thickness value differences in such a small range are commonly observed due to the sample's surface conditions. We further compare their Raman peaks, and the samples show two characteristic peaks of monolayer WS<sub>2</sub>: a sharp one at 355 cm<sup>-1</sup> assigned to E<sub>2g</sub> mode and a broad one at 355 cm<sup>-1</sup> assigned to A<sub>1g</sub> mode, matched well with previously reported Raman characterization of monolayer WS<sub>2</sub>.<sup>15,16,43</sup> Therefore, all the samples studied in our work are monolayer WS<sub>2</sub>, and changing the precursor treatment conditions has no effects on the sample's thickness. According to the statistical analysis over an area of 1000 μm × 750 μm on the growth substrate (see Fig. S4†), the growth size of the monolayer WS<sub>2</sub> is greatly influenced by the type of precursor. An average size of less than 10 μm for WS<sub>2</sub> monolayers was obtained with the FWO<sub>3</sub> precursor, while WS<sub>2</sub> monolayers with a maximum size of ~70 μm and an average size of ~40 μm could be achieved with the AWO<sub>3</sub> precursor. WS<sub>2</sub> monolayers with reduced density and an average lateral size of ~10 μm were obtained when the precursor was changed from FWO<sub>3</sub> to PTWO<sub>3</sub>. Interestingly, a simple annealing process on the PTWO<sub>3</sub> precursor resulted in WS<sub>2</sub> monolayers with an average lateral size of ~20 μm and improved surface coverage on the growth substrate. Besides, as shown in the optical

images in Fig. 2a–d, truncated triangular shaped monolayer WS<sub>2</sub> crystals were obtained with FWO<sub>3</sub> and PTWO<sub>3</sub> precursors, while WS<sub>2</sub> monolayers in a regular triangular shape could be achieved with AWO<sub>3</sub> and PTAWO<sub>3</sub> precursors, revealing the morphology modification caused by the various precursor pre-treatment processes. The photoluminescence (PL) properties of WS<sub>2</sub> monolayers in terms of the peak intensity and position can be dramatically changed due to the presence of various excitonic states such as trions, biexcitons and other charge bounded excitons, which strongly depend on the crystal quality and surface charge states of TMDC monolayers.<sup>26,44–47</sup> As illustrated in Fig. 2e–l, the PL peak intensity mapping (Fig. 2e–h) and position mapping results (Fig. 2i–l) show that WS<sub>2</sub> monolayers synthesized from the AWO<sub>3</sub> precursor exhibit a more uniform PL peak intensity across the surface and have dominant PL peak with higher photon energy (~2.0 eV), which is closer to the band gap of WS<sub>2</sub> (2.1 eV),<sup>48</sup> as compared with the other three synthesized samples.

To evaluate the oxygen vacancies in the precursors, we characterized the precursors with X-ray powder diffraction (XRD) as shown in Fig. 3, S5 and S6.† XRD patterns of all the four precursors consist of the monoclinic phase of WO<sub>3</sub> diffraction peaks (see Fig. 3a), showing that the precursor treatment process did not change the crystal phase. However, the enlarged view of the peak ranging from 22 to 26° shows that all the precursors exhibit a peak position shift to a higher diffraction angle as compared to the standard XRD patterns for the monoclinic phase of WO<sub>3</sub> (Fig. 3b). The XRD diffraction peaks from AWO<sub>3</sub> powder exhibit the most significant peak shift (0.1°) to a higher diffraction angle with peak intensity reduction

(a–d) Optical images of the monolayer WS<sub>2</sub> crystals that were grown from FWO<sub>3</sub>, PTWO<sub>3</sub>, AWO<sub>3</sub>, and PTAWO<sub>3</sub> powders, respectively. (e–h) PL intensity mapping images of the monolayer WS<sub>2</sub> crystals that were synthesized from FWO<sub>3</sub>, PTWO<sub>3</sub>, AWO<sub>3</sub> and PTAWO<sub>3</sub> powders, respectively. (i–l) PL position mapping images of the monolayer WS<sub>2</sub> crystals that were synthesized from FWO<sub>3</sub>, PTWO<sub>3</sub>, AWO<sub>3</sub> and PTAWO<sub>3</sub> powders, respectively.

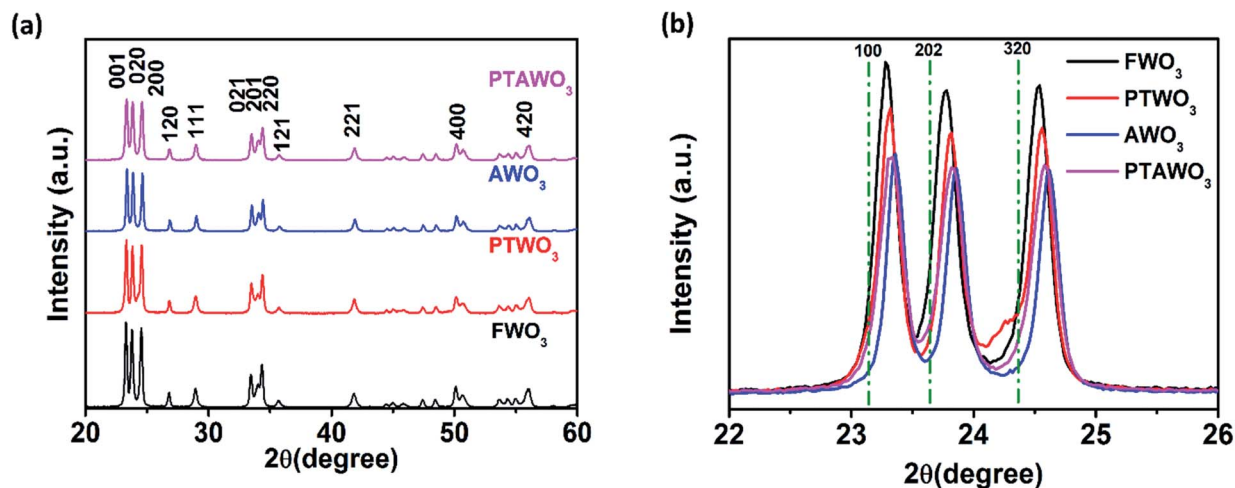

Fig. 3 (a) XRD patterns of FWO<sub>3</sub>, PTWO<sub>3</sub>, AWO<sub>3</sub> and PTAWO<sub>3</sub> powders. (b) Enlarged view of XRD patterns at 001, 020 and 200 planes for FWO<sub>3</sub>, PTWO<sub>3</sub>, AWO<sub>3</sub> and PTAWO<sub>3</sub> powders.

as compared to FWO<sub>3</sub>, followed by PTAWO<sub>3</sub> (0.07°) and finally PTWO<sub>3</sub> (0.03°). The peak position shifts to a higher diffraction angle are related to the contraction of lattice parameters, which results from the formation of more oxygen vacancies and the degradation of the crystallinity of the WO<sub>3</sub> powder due to the thermal annealing process. As shown in Fig. S7,<sup>†</sup> WO<sub>3</sub> powders prepared by different methods also show different colors from a greenish color to deep blue and these color changes have been attributed to the different oxygen vacancy contents in WO<sub>3</sub> powders, which is in good consistency with the XRD results.<sup>30,49–51</sup> To eliminate the effects of water content in the precursors on the growth of monolayer WS<sub>2</sub>, thermal gravimetric analysis (TGA) (see Fig. S8<sup>†</sup>) has been done and the results reveal that surface-absorbed water in the WO<sub>3</sub> powders is less than 1%, implying negligible effects on the growth of monolayer WS<sub>2</sub>.

To further confirm the oxygen vacancy induced peak position and intensity change in XRD spectra, we further examined the optimized crystal structure of WO<sub>3</sub> with and without oxygen vacancies by theoretical calculations (see Table 1). The lattice structures of WO<sub>3</sub> have been studied using density functional theory (DFT) calculations with plane-wave pseudopotentials.<sup>52</sup> The initial space group of stoichiometric WO<sub>3</sub> is P<sub>21/a</sub>(#14), belonging to the monoclinic space group. After structural optimization (Fig. 4), the system's space group converts to Pbcm (#57). The optimized lattice parameters are  $a = 3.904 \text{ \AA}$ ,  $b = 7.778 \text{ \AA}$ , and  $c = 7.558 \text{ \AA}$ . The unit cell volume is  $229.54 \text{ \AA}^3$ , and

these four octahedrons in the system are equivalent. For the samples with oxygen vacancies, we remove one oxygen atom from the octahedron from three different directions, namely,  $a$ -,  $b$ -, and  $c$ -axis directions. For oxygen vacancies in the  $a$ -axis direction, the lattice parameter and volume decrease significantly. For oxygen vacancies in the  $b$ -axis direction, the bravais lattice shape changes, but the volume is substantially unchanged. For oxygen vacancies in the  $c$ -axis direction, the lattice constants of  $a$  and  $b$  decrease significantly, and the volume also decreases. In practice, oxygen vacancies may exist in any direction, and hence, from the above discussion, we can conclude that the presence of oxygen vacancies will cause the lattice constant of WO<sub>3</sub> to shrink, which explains the peak position shift in XRD spectra for WO<sub>3</sub> with different oxygen vacancy contents.

Moreover, X-ray photoelectron spectroscopy (XPS) analysis exhibits noticeable differences in the binding energy of tungsten and oxygen core levels as illustrated in Fig. 5, S9 and Table S1.<sup>†</sup> The XPS peak fitting results from all WO<sub>3</sub> powders show that besides the dominating W4f<sup>(VI)</sup> valence state, a portion of the W4f<sup>(V)</sup> valence state also exists, confirming the presence of oxygen vacancies in all the WO<sub>3</sub> powders. Yet, the XPS spectral fitting of W4f in AWO<sub>3</sub> and PTWO<sub>3</sub> powders suggests a higher contribution from the W4f<sup>(V)</sup> state as compared with that of FWO<sub>3</sub> powder, indicating the higher oxygen vacancy concentration in both AWO<sub>3</sub> and PTWO<sub>3</sub> powders.

Table 1 Calculated optimized structural parameters of WO<sub>3</sub> with and without oxygen vacancies by theoretical calculations

Crystal structure of WO <sub>3</sub>	Lattice parameters (Å)				Angle (Å)		
	$a$	$b$	$c$	Volume	$\alpha$	$\beta$	$\gamma$
Without Oxygen vacancies	3.904	7.778	7.558	229.54	90.00	90.00	90.00
Oxygen vacancies in the $a$ -axis direction	3.796	7.799	7.598	224.95	90.00	90.00	90.02
Oxygen vacancies in the $b$ -axis direction	3.808	7.795	7.573	229.48	90.00	90.00	90.03
Oxygen vacancies in the $c$ -axis direction	3.824	7.651	7.721	225.85	90.84	90.00	90.00

Fig. 4 The view of the optimized structure of  $\text{WO}_3$  from the (a)  $a$ -axis direction, (b)  $b$ -axis direction, and (c)  $c$ -axis direction and (d) the octahedron in the  $\text{WO}_3$  system. There are 4 W atoms and 12 O atoms in this system.

Fig. 5 XPS spectra fitting of W4f and W5p peaks for  $\text{WO}_3$  powders. (a–d) XPS spectra of W4f for  $\text{FWO}_3$ ,  $\text{PTWO}_3$ ,  $\text{AWO}_3$  and  $\text{PTAWO}_3$  powders, respectively.

Remarkably, compared with the other three control samples, a continuous dark oxide layer was formed after the plasma treatment of  $\text{WO}_3$  powder (Fig. S7b†). As reported by Wang *et al.*, Raman spectroscopy is an effective way to characterize the crystallinity of  $\text{WO}_3$  powder.<sup>27</sup> As illustrated in Fig. S10,† all the  $\text{WO}_3$  powders exhibit the two typical dominating Raman peaks of crystalline  $\text{WO}_3$  centered at  $808\text{ cm}^{-1}$  and  $715\text{ cm}^{-1}$ , except the  $\text{PTWO}_3$  powder which shows a lower peak intensity and broader stretching mode peak at around  $808\text{ cm}^{-1}$ . The significant difference in Raman spectra suggests a strong plasma treatment effect on the surface crystallinity of  $\text{WO}_3$ .

In fact, XPS analysis shows that the  $\text{W}4\text{f}^{(\text{V})}$  surface state is slightly reduced by thermal annealing for the  $\text{PTWO}_3$  samples, which could be due to the increased surface oxidation rate

towards linear kinetics after plasma treatment.<sup>53</sup> Therefore, the  $\text{PTAWO}_3$  powder possesses more  $\text{W}4\text{f}^{(\text{V})}$  surface state compared with  $\text{PTWO}_3$ . It is also noticed that XPS analysis and Raman characterization mainly reflect the surface information of chemical composition; meanwhile XRD presents the crystallinity of bulk sample powders. As shown in Fig. 3b, the XRD diffraction peaks from  $\text{PTAWO}_3$  powder exhibit a peak shift to a higher diffraction angle and peak intensity reduction, suggesting more oxygen vacancies formed by the annealing process. Combining the XRD, theoretical calculation and XPS analysis, we reach a conclusion that both thermal annealing and plasma treatment lead to the oxygen vacancy formation, while plasma treatment mainly affects the surface chemical states and the thermal annealing process can significantly change the metal oxide crystallinity and result in a smaller lattice spacing. Obviously, combining the precursor characterization and growth results, large-size triangular  $\text{WS}_2$  monolayer flakes could be produced with a higher oxygen vacancy concentration in the  $\text{WO}_3$  precursor source, while small-size truncated  $\text{WS}_2$  monolayers were generally obtained when the number of oxygen vacancies in the  $\text{WO}_3$  precursor reduced. The obtained morphology of the as-growth  $\text{WS}_2$  is largely related to the reaction conditions, such as the precursor concentration ratio, substrates used, gas flow rate. In pretreated precursors, the highly volatile tungsten suboxide will result in an increase of the amount of tungsten precursors, increase the rate of reaction toward sulfur and hence promote the growth of  $\text{WS}_2$ . Overall, the thermal annealing process generates more oxygen vacancies in the  $\text{WO}_3$  precursor, which effectively promotes the growth of  $\text{WS}_2$  monolayers with larger size and better crystallinity. Besides, the PL results also suggest that the monolayer  $\text{WS}_2$  samples synthesized from thermal annealing pretreated precursors may have a lower lattice structure defect concentration.

To better reveal the superiority of the monolayer  $\text{WS}_2$  obtained from the  $\text{AWO}_3$  powder, we further explored the effect of the annealing atmosphere on the structure of the  $\text{WS}_2$ . As aforementioned above, in previous studies, hydrogen gas ( $\text{H}_2$ ) was introduced to promote the reduction of  $\text{WO}_3$  and hence promote the growth of  $\text{WS}_2$  monolayers.<sup>16,19,26,44</sup> However, an excessive hydrogen supply could also induce defects. Therefore, we further study the quality of  $\text{WS}_2$  monolayers synthesized with a thermally annealed precursor. The thermally annealed precursor synthesized  $\text{WS}_2$  ( $\text{AWS}_2$ ) sample shows a uniform PL intensity feature on the whole surface and still retains its optical properties after being transferred onto a silicon dioxide substrate or more than one-month after the synthesis (see Fig. S11 and S12†). There is no aggregation/restacking effect observed for the  $\text{AWS}_2$  monolayers for prolonged periods (after one month). The optical image and optical characterization such as Raman and PL characterization (see Fig. S12†) show the good stability of the as-grown monolayer  $\text{AWS}_2$  after being exposed to ambient air for more than one month. The XPS spectra of W4f and S2p peak in  $\text{AWS}_2$  as shown in Fig. S13† confirm the presence of  $\text{WS}_2$ .

(d) STEMADF image of the as-transferred HWS<sub>2</sub> monolayer onto a Quantifoil grid. (e–f) Atomic resolution ADF/STEM image of the HWS<sub>2</sub> crystal. (g) Defect mapping of the HWS<sub>2</sub> monolayer. (h) Atomic resolution ADF/STEM images of various intrinsic point defects present in monolayer HWS<sub>2</sub>, including monosulfur vacancies ( $V_s$ ), disulfur vacancies ( $V_{S_2}$ ), and antisite defects where a W atom substituting a S<sub>2</sub>/S column ( $W_{S_2}$ ,  $W_s$ ) or a S<sub>2</sub> column substituting a W atom ( $S_{2w}$ ) is observed. (i) Processed atomic resolution ADF/STEM image of various intrinsic point defects present in monolayer HWS<sub>2</sub>. (j) Relaxed structural models of the experimentally observed point defects of HWS<sub>2</sub>.

images for the AWS<sub>2</sub> and hydrogenated environmentally synthesized WS<sub>2</sub> (HWS<sub>2</sub>) samples were also obtained to study the atomic defect level in both samples (see Fig. 6). The obtained ADF-STEM image and the defect mapping analysis (see Fig. 6b and S14<sup>†</sup>) show that the AWS<sub>2</sub> sample is almost defect-free, while there are a considerable number of lattice defects, including monosulfur vacancies ( $V_s$ ), disulfur vacancies ( $V_{S_2}$ ), and antisite defects where a W atom substituting a S<sub>2</sub>/S column ( $W_{S_2}$ ,  $W_s$ ) or a S<sub>2</sub> column substituting a W atom ( $S_{2w}$ ) is observed in the HWS<sub>2</sub> sample (see Fig. 6d–j). These results suggest that the HWS<sub>2</sub> sample contains more lattice defects than the AWS<sub>2</sub> sample. This clearly illustrated that the AWS<sub>2</sub> exhibits better crystallinity and fewer structural defects.

## Conclusions

In conclusion, we have comprehensively studied the effects of various stoichiometric WO<sub>3</sub> precursors on the growth of WS<sub>2</sub> monolayers. The morphology of WS<sub>2</sub> monolayers transforms from a truncated triangle to a triangular shape when the oxygen vacancies in the WO<sub>3</sub> precursor increase, resulting in the change of PL properties and crystallinity in the as-growth WS<sub>2</sub>

monolayers. The number of oxygen vacancies in WO<sub>3</sub> induces a change in the growth atmosphere and hence significantly affects the lateral growth morphology as well as the optical properties of monolayer WS<sub>2</sub>. In our study, the annealed WO<sub>3</sub> precursor with the highest oxygen vacancy concentration generates monolayer WS<sub>2</sub> crystals with improved quality in terms of lateral size, surface coverage, and crystallinity, while PTWO<sub>3</sub> and AWO<sub>3</sub> powders with a lower oxygen vacancy concentration suppress the growth of monolayer WS<sub>2</sub>. Our results demonstrate the possibility of tailoring the morphology and crystal quality of WS<sub>2</sub> monolayers by the tuning of oxygen vacancy content in the metal oxide precursor. The investigation on various non-stoichiometric WO<sub>3</sub> precursors provides better understanding on the growth mechanism of large-area, high-quality WS<sub>2</sub> monolayers.

## Conflicts of interest

There are no conflicts to declare.
