Introduction

Acid orange 7 (AO7) dye is one of the most common synthetic dyes in various industries ranging from dyeing to printing.¹⁻³ AO7 is considered toxic and could cause harmful health effects to human and aquatic organisms, such as skin diseases and carcinogenesis.4,5 Moreover, it is difficult to biologically degrade AO7 in wastewaters because of its recalcitrant azo bond with an aromatic structure.⁶ Therefore, it is essential to treat the industrial wastewaters containing AO7.⁷⁻⁹ To date, many approaches have been conducted to control organic pollutants, such as biodegradation,¹⁰⁻¹² photooxidation,^{13,14} chemical oxidation,¹⁵⁻¹⁷ electrochemistry,^{18,19} ultrasonic destruction^{20,21} and adsorption.²²–²⁴ Among these techniques, adsorption using adsorbents is considered to be one of the most convenient and

An eco-friendly route for template-free synthesis of high specific surface area mesoporous $CeO₂$ powders and their adsorption for acid orange 7†

Yaohu[i](http://orcid.org/0000-0001-5277-2481) Xu,^a Ruixing Li ^{b *b} and Yang Zhou^{*c}

An eco-friendly route was developed for the synthesis of mesoporous $CeO₂$ powders without any additional template. The original cerium precursors were separated from Ce^{3+} aqueous solution by $(NH_4)_2CO_3$ or Na₂CO₃ via a chemical precipitation method, then H₂O₂ was introduced to induce the phase transformation from original cerium precursors to CeO₂ precursors with initial porous structures, finally the crystallinities of $CeO₂$ precursors were improved by a hydrothermal treatment, meanwhile the mesoporous structures of final CeO₂ powders were formed. The BET surface areas of mesoporous CeO₂ powders synthesized using $(NH_4)_2CO_3$ and Na_2CO_3 as precipitants were 106.1 and 76.9 m² g⁻¹, respectively. Moreover, a mesoporous CeO₂ sample with BET surface area of 100.0 m² g⁻¹ was also synthesized using commercial $Ce_2(CO_3)_3 \cdot xH_2O$ as an existing cerium precursor under the same conditions as control, which could shorten experimental processes and reduce costs. The oxidationinduced phase transformation from original cerium precursors to $CeO₂$ precursors with initial porous structures was the precondition for further forming of mesoporous structures of final $CeO₂$ powders during the hydrothermal process. These mesoporous $CeO₂$ powders showed the rapid and effective adsorption for acid orange 7 dye from simulated wastewater without pH pre-adjustment at room temperature. Furthermore, the adsorption capacities of these mesoporous $CeO₂$ powders for removal of acid orange 7 dye were determined according to the Langmuir linear fits. **PAPER**
 CAUSE THE SUBATE CONSULTER SUBATE SU

cost-efficient methods.²⁵ Huang et al. prepared a nitrilotriacetic acid anhydride modified ligno-cellulosic bio-adsorbent for removal of Cd^{2+} and Pb²⁺, the maximum sorption capacities for Cd^{2+} and Pb²⁺ could reach 143.4 and 303.5 mg g⁻¹ at 298.0 K, respectively.²⁶ Lu et al. reported the removal of acenaphthene by biochar and raw biomass, and investigated the effects of coexisting metal ions and organic compounds on their sorption performances.²⁷ Moreover, Wu et al. reviewed the role of biochar on composting of organic wastes and remediation of contaminated soils.²⁸ The mesoporous ceria $(CeO₂)$ can serve as a promising candidate for removal of AO7 because of its high specific surface area and well-defined pore topology.

Generally, mesoporous $CeO₂$ powders are prepared by template methods with either surfactants as soft templates^{29,30} or other porous material as hard templates.^{31,32} However, the template methods require either additional procedures or high energy consumption in order to eliminate the hard or so sacrificial templates, such as dissolution or heat treatment.³³⁻³⁵ Moreover, the crystallinity of mesoporous $CeO₂$ even needs to be improved again by calcination, which easily causes the collapse of pore structures and thus reduces the specific surface area of CeO₂.³⁶ To date, there are limited reports for template-free synthesis of $CeO₂$ powders with mesoporous structures. For example, Wei et al. fabricated mesoporous $CeO₂$ nanoflowers with a BET surface area ($S_{\rm BET}$) of 95.7 $\rm m^2$ $\rm g^{-1}$, however,

polyvinylpyrrolidone (PVP) was introduced as a structuredirecting agent to synthesize $Ce(HCOO)_3$ precursor in alcoholic solution, in which formic acid and ammonia solution were also added. Then, hydrogen peroxide was introduced as an oxidant to induce the phase transformation from $Ce(HCOO)_3$ to $CeO₂$ with inherited morphology. Finally, mesoporous $CeO₂$ nanoflowers were obtained by following solvothermal treatment at 150 °C for 6 h and drying at 70 °C for 10 h.³⁷ In another study, Xie et al. reported a template-free hydrothermal synthesis of flower-like CeO $_2$ powders, and its S_{BET} was 38.8 $\mathrm{m}^2\mathrm{~g}^{-1}.$ The potassium chlorate and dimethyl formamide were employed, and the interaction effect of them played an important role in the formation of flower-like $CeO₂$.³⁸ Moreover, He et al. synthesized mesoporous $CeO₂$ colloidal spheres by the assembly of $CeO₂$ nanoparticles and nanocubes, respectively. The S_{BET} of mesoporous CeO₂ colloidal spheres assembled by nanoparticles and nanocubes were 114.3 and 122.5 $\mathrm{m^2~g^{-1}}\mathrm{,}$ respectively. The whole process could be divided into three steps: the $CeO₂$ nanoparticles and nanocubes were first synthesized by a hydrothermal method and CO-assisted hydrothermal approach, respectively. Then, the $CeO₂$ nanocrystals self-assembled into colloidal spheres via an emulsionbased bottom-up self-assembling method. Finally, the colloidal spheres were obtained after following drying at 70 °C and calcination at 350 °C for 4 h.³⁹ From the above, one sample, mild, low-cost and environment-friendly route for template-free synthesis of mesoporous $CeO₂$ powders is desirable. of the creating the creating term in the same signified by Antonio Co, Ltd, Article initialized under the same

In the previous work, we presented a combined bottom-up and top-down route for template-free synthesis of mesostructured CeO₂ particles using Ce(NO₃)₃.6H₂O (cerium source), NH_4HCO_3 (precipitant), H_2O_2 (oxidant) and H_2O (solvent) as starting reagents, and its specific surface area was 166.5 $m²$ $\rm g^{-1.40}$ In this work, $\rm (NH_4)_2CO_3$ or $\rm Na_2CO_3$ was employed in place of NH₄HCO₃ as a precipitant for separation of cerium precursors from Ce^{3+} aqueous solution. As an expansive research, commercial $Ce_2(CO_3)_3 \cdot xH_2O$ powders were used as an existing precursor for synthesis of mesoporous $CeO₂$ powders. The roles of H_2O_2 were discussed, and the effects of calcination on the grain sizes and S_{BET} of mesoporous CeO₂ powders were investigated. Additionally, the absorption characteristics of these mesoporous $CeO₂$ powders for AO7 dye were investigated.

Furthermore, it is worth noting that the mesoporous $CeO₂$ powders were synthesized in this work just using $(NH_4)_2CO_3$, $Na₂CO₃$, $H₂O₂$ and $H₂O$ without any additional reagent and post-treatment. $(NH_4)_2CO_3$, Na_2CO_3 and H_2O_2 are accessible, cheap and safe chemistry reagents, which not only can save the cost, but also reduce the pollution degree to environment. Moreover, the route, using commercial $Ce_2(CO_3)_3 \cdot xH_2O$ as an existing precursor for synthesis of mesoporous $CeO₂$ powders, can shorten experimental processes and reduce costs.

Experimental

Materials

Cerium nitrate hexahydrate $(Ce(NO₃)₃·6H₂O, 99.95%)$, ammonium carbonate ((NH₄)₂CO₃, 99.999%), sodium carbonate (Na₂CO₃, 99.5%), hydrogen peroxide (H₂O₂, 30 wt%) and commercial cerium carbonate hydrate $(Ce_2(CO_3)_3 \cdot xH_2O, 99.9\%)$ were supplied by Aladdin Co. Ltd. Acid orange 7 (AO7, >97.0%) was obtained from Tokyo Chemical Industry Co. Ltd.

Synthesis of mesoporous $CeO₂$ powders

As shown in Fig. 1, firstly, the original cerium precursors were separated from Ce³⁺ aqueous solution by $(NH_4)_2CO_3$ or Na_2CO_3 via a chemical precipitation method. Typically, 4 mmol $Ce(NO₃)₃·6H₂O$ was dissolved into 28 mL distilled water to form a clear Ce³⁺ solution, and 16 mmol precipitant $((NH₄)₂CO₃$ or $Na₂CO₃$) was added to the above solution under continuous stirring, immediately forming a white precipitate (labelled as Precursor 1 and Precursor 2, respectively). Meanwhile, as an extension experiment, commercial $Ce_2(CO_3)_3 \cdot xH_2O$ powders were used as an existing precursor. The commercial Ce_2 . $CO₃$ ₃ $xH₂O$ powders were dispersed in 28 mL distilled water, and the subsequent experimental steps were similar to that of the suspension of Precursor 1 and Precursor 2.

Then, H_2O_2 was introduced to induce the phase transformation from original cerium precursors to $CeO₂$ precursors. Typically, 7 mL H_2O_2 was added to the above suspension containing Precursor 1, Precursor 2 and commercial $Ce_2(CO_3)_{3}$ $xH₂O$, then stirring for 30 min and aging for 3 h. The asprepared orange precipitates using $(NH_4)_2CO_3$, Na_2CO_3 as precipitants and using commercial $Ce_2(CO_3)_3 \cdot xH_2O$ as an existing precursor were labelled as Precursor 1-1, Precursor 2-1 and Precursor 3-1, respectively. Note that all operations were performed at room temperature.

The last step was the synthesis of mesoporous $CeO₂$ powders by a hydrothermal treatment. Typically, the above $CeO₂$ precursors in the total mother liquor were transferred into a 50 mL Teflon-lined stainless steel autoclave. After reacting at 200 °C for 24 h, the autoclave was cooled down. Then the resulting precipitates were washed with distilled water and ethanol, and dried at 60 $^{\circ}$ C for 24 h. These hydrothermally produced $CeO₂$ powders were labelled as Sample 1, Sample 2 and Sample 3, respectively.

Fig. 1 Synthesis of mesoporous CeO₂ using $(NH_4)_2CO_3$, Na₂CO₃ as precipitants, and using commercial $Ce₂(CO₃)₃·xH₂O$ as an existing precursor in the presence of H_2O_2 .

For comparison, the samples were synthesized under the same conditions as control, however, in the absence of H_2O_2 . Moreover, in order to investigate the effects of calcination on the grain sizes and S_{BET} of mesoporous CeO₂, these samples (Sample 1, Sample 2 and Sample 3) were treated by following calcination at 500 °C for 2 h, and their S_{BET} were also determined.

Characterization

The crystallographic phases of precursors and samples were characterized by X-ray diffraction (XRD, D/Max 2200PC). The microstructures of precursors and samples were evaluated by transmission electron microscopy (TEM, JEM-2100F). The specific surface areas, pore volumes and pore size distributions of mesoporous $CeO₂$ powders were obtained from nitrogen adsorption–desorption measurements (QuadraSorb SI).

Adsorption studies

About 10.3 g of AO7 powders (>97.0%) were dissolved in distilled water, and diluted to 100 mL with distilled water, the as-obtained concentration of AO7 solution was 10 g L^{-1} . The different concentrations of AO7 solution (20-120 mg L^{-1}) were obtained by pipetting varied volume of the above 10 g L^{-1} AO7 solution into 100 mL volumetric flask and bringing to volume by distilled water. Subsequently, 0.2 g CeO₂ sample was dispersed into 100 mL of AO7 solution at varying initial concentrations (adsorbent dosage: 2.0 $g L^{-1}$) without pH preadjustments. The mixture was stirred at a constant speed (200 rpm) and temperature (298.0 K). Then, 4 mL suspension was withdrawn at regular intervals and centrifuged. The absorbance of supernatant was measured using an UV-2600 spectrophotometer.

The Beer–Lambert law is linear relationship between the absorbance and concentration of absorbing species.⁴¹ So, the concentration of AO7 dye can be converted from its absorbance based on Beer-Lambert law. The adsorption efficiency $(\eta, \%)$ and adsorption amount $(q,\, \mathrm{mg\,g}^{-1})$ for AO7 dye were calculated using eqn (1) and (2) , respectively.⁴²

$$
\eta_t = \frac{C_0 - C_t}{C_0} \times 100\% \tag{1}
$$

$$
q = \frac{(C_0 - C_e)V}{m} \tag{2}
$$

where $C_0 \, (\text{mg L}^{-1})$ is the initial concentration of AO7 dye, $C_t \, (\text{mg}$ L^{-1}) is the concentration of AO7 dye at a given time t ($t = 0$ –60 min), $C_{\rm e}$ (mg ${\rm L}^{-1})$ is the concentration of AO7 dye at equilibrium, $m(g)$ is the mass of CeO₂ powders, and $V(L)$ is the volume of AO7 solution.

Langmuir model as shown in eqn (3) was used to examine the adsorption characteristics of the as-obtained mesoporous CeO₂ powders.⁴³ And the saturated adsorption amount (q_m , mg g^{-1}) was obtained based on Langmuir linear fitting of adsorption isotherm curve.

$$
q = \frac{K_{\rm L}q_{\rm m}C_{\rm e}}{1 + K_{\rm L}C_{\rm e}}\tag{3}
$$

where $K_{\rm L}$ $\rm (L~mg^{-1})$ is Langmuir constant. The eqn $\rm (3)$ can be rearranged to a linear form as shown in eqn (4). As observed, the plot of C_e/q against C_e can give a straight line with the slope of 1/ q_m and intercept of 1/($K_L q_m$), and the values of q_m and K_L can be evaluated according to the slope and intercept.

$$
\frac{C_{\rm e}}{q} = \frac{1}{q_{\rm m}} C_{\rm e} + \frac{1}{K_{\rm L} q_{\rm m}} \tag{4}
$$

Results and discussion

Phase characterizations of precursors

The crystallographic phases of precursors after adding the precipitant and H_2O_2 were determined by XRD. Fig. 2a and b show the XRD patterns of Precursor 1 and Precursor 2 obtained by adding $(NH_4)_2CO_3$ and Na_2CO_3 to Ce^{3+} aqueous solution, respectively. As an verification and comparison, the XRD analysis of commercial Ce₂(CO₃)₃ · xH_2O powders also were performed, and its XRD pattern was showed in Fig. 2c. As observed in Fig. 2a, the phase structure of Precursor 1 synthesized following adding $(NH_4)_2CO_3$ to Ce^{3+} aqueous solution was o-Ce(CO₃)OH (JCPDS no. 41-0013; density = 4.545 g cm⁻³). The XRD pattern of Precursor 2 in Fig. 2b was similar to that of commercial Ce₂(CO₃)₃ xH₂O in Fig. 2c, indicating its major phase of $Ce_2(CO_3)_3.8H_2O$ (JCPDS no. 38-0377; density = 2.790 $g \text{ cm}^{-3}$). Moreover, the phase of precursor synthesized following adding NH_4HCO_3 to Ce^{3+} aqueous solution in our previous report⁴⁰ was similar to that of Precursor 2 in Fig. 2b and commercial $Ce_2(CO_3)_3 \cdot xH_2O$ in Fig. 2c. However, the difference in phase structure of original cerium precursors will subtly affect the S_{BET} of final CeO₂ samples. Interestingly, the Precursor 1 synthesized following adding $(NH_4)_2CO_3$ to Ce^{3+} aqueous solution depended on the amount of $(NH_4)_2CO_3$. When the amount of $(NH_4)_2CO_3$ was less than 8 mmol, the major phase of as-obtained precursor was $Ce_2(CO_3)_3.8H_2O$. And the major phase structure was o-Ce (CO_3) OH when the amount of $(NH_4)_2CO_3$ was more than 10 mmol (see Fig. S1†). BSC Advances Articles. Published onter the systems of the system of

> Fig. 3a–c show the XRD patterns of precursors obtained following addition of H_2O_2 (Precursor 1-1, Precursor 2-1 and Precursor 3-1, respectively). As observed in Fig. 3a–c, the peaks

related to $Ce_2(CO_3)_3.8H_2O$ and o-Ce(CO₃)OH were no longer present. The XRD pattern of Precursor 1-1 in Fig. 3a displayed several relatively well-resolved peaks that could be indexed to the (111) , (200) , (220) and (311) planes of face-centred cubic CeO₂ (JCPDS no. 34-0394; density = 7.215 g cm⁻³). The XRD pattern of Precursor 2-1 in Fig. 3b and Precursor 3-1 in Fig. 3c all showed three broad featureless peaks centred at $2\theta = 29$, 47 and 56°, and the broad featureless peaks centred at $2\theta = 29^\circ$ was more easily observed than others. Compared with the XRD pattern in Fig. 3a, the broad featureless peaks centred at $2\theta =$ 29° in Fig. 3b and c could be indexed to the (111) plane of CeO₂ phase, but with relatively low crystallinities. Combining with the XRD analyses in Fig. 2, we can derive a conclusion that H_2O_2 can induce the phase transformations from original cerium precursor $(Ce_2(CO_3)_3 \cdot xH_2O$ or o-Ce(CO₃)OH) to CeO_2 precursor because of its oxidation.

Physical characterizations of the hydrothermally produced CeO₂ powders

Fig. 4a–c show the XRD patterns of the hydrothermally produced $CeO₂$ samples (Sample 1, Sample 2 and Sample 3, respectively). As observed, all the hydrothermally produced samples displayed several well-resolved peaks that indexed to the (111), (200), (220), (311), (222), (400) and (331) planes of face-centred cubic $CeO₂$ (JCPDS no. 34-0394), and no additional phases were observed.

Fig. 4 XRD patterns of (a) Sample 1, (b) Sample 2 and (c) Sample 3.

Moreover, the crystallinities of the hydrothermally produced $CeO₂$ in Fig. 4 were improved compared with that of the $CeO₂$ precursors in Fig. 3, which may be attributed to the rearrangement of $CeO₂$ grains with good crystallinities under certain temperatures and pressures during the hydrothermal process.⁴⁰ Combining with the results of XRD analyses in Fig. 3, we can draw a conclusion that the crystallinities of $CeO₂$ precursors could be improved and the pure $CeO₂$ samples can be obtained through a hydrothermal treatment.

To understand the microstructures of the hydrothermally produced $CeO₂$ samples, TEM analyses were performed. Fig. 5a, c and e show the TEM images of the hydrothermally produced $CeO₂$ (Sample 1, Sample 2 and Sample 3, respectively). As observed in Fig. 5a, c and e, the porous structure of $CeO₂$ particles and the presence of pores around $CeO₂$ grains can be observed. In addition, the grain size of Sample 1 was obviously greater than that of Sample 2 and Sample 3. The corresponding high-magnification TEM images of Sample 1, Sample 2 and Sample 3 were showed in Fig. 5b, d and f, respectively. The porous structures of these $CeO₂$ particles could be further evidenced, and these $CeO₂$ particles consisted of aggregated grains. Moreover, these pores resulted from these aggregated grains, and the calculated grain sizes were about 7.7, 4.3 and 4.8 nm for Sample 1, Sample 2 and Sample 3, respectively. The existence of pore structure resulted from these $CeO₂$ particles possessing bigger specific surface area, consequently, more active sites can be provided for the adsorption of pollutants, which are beneficial to improving their capture capability.⁴⁴ The grain size of $CeO₂$ will have an impact on the pore diameter and pore volume of $CeO₂$ powders, and then affected their S_{BET} . Further analysis of S_{BET} was conducted by nitrogen adsorption– desorption experiments as discussed later. Paper West Computer and Computer and Commonstration on 18 July 2019. Download on 18 July 2019. Download and the paper of the second computer and the commonstration of the Creative Computer and the common computer and the

Fig. 5 TEM images of (a) Sample 1, (c) Sample 2 and (e) Sample 3 ((b), (d) and (f) show the corresponding high-magnification TEM images, respectively).

To further clarify the porous structures of the final hydrothermally produced $CeO₂$ samples (Sample 1, Sample 2 and Sample 3, respectively), nitrogen adsorption–desorption experiments were conducted to determine their S_{BET} , average pore sizes and pore volumes. Fig. 6a–c show the nitrogen adsorption–desorption isotherms of Sample 1, Sample 2 and Sample 3, respectively. From Fig. 6a–c, the recorded adsorption–desorption isotherms exhibited the hysteresis loops ranging from 0.4 to 1.0, suggesting their mesoporous structures.⁴⁵ Furthermore, the profiles of the nitrogen adsorption-desorption isotherms were similar to that of the mesoporous $CeO₂$ reported in previous literature.²⁹ The insets in Fig. 6a–c show the corresponding Barrett–Joyner–Halenda (BJH) pore size distribution curves. As observed the inset in Fig. 6a and b, BJH calculations for the pore size distributions presented a single distribution centred at about 7.8 and 3.4 nm for Sample 1 and Sample 2, respectively. By contrast, the BJH pore size distribution curves of Sample 3 presented two distributions centred at about 3.8 and 5.5 nm as observed the inset in Fig. 6c.

The specific surface areas were determined using Brunauer– Emmett–Teller (BET) method, the average pore sizes and pore volumes were determined by BJH analysis, and these calculated textural parameters were compiled in Table 1. From Table 1, the S_{BET} of 106.1 and 76.9 m² g⁻¹ were obtained for Sample 1, Sample 2 and Sample 3, respectively, which had a lower S_{BET} than one using NH₄HCO₃ as a precipitant (166.5 $\mathrm{m^{2}\,g^{-1}}$) in our previous report.⁴⁰ The average pore size and pore volume were 7.8 nm and 0.19 cm³ g^{-1} for Sample 1, while 3.4 nm and 0.05 $\text{cm}^3 \text{ g}^{-1}$ for Sample 2. Moreover, the mesoporous CeO₂ powders synthesized using commercial $Ce_2(CO_3)_3 \cdot xH_2O$ as an existing precursor (Sample 3) showed a S_{BET} of 100.0 $\mathrm{m^2\,g^{-1}}$, the average pore size and pore volume were 3.8 nm and 0.10 $\mathrm{cm^{3}\,g^{-1}}.$

In summary, the presented route for template-free synthesis of mesoporous $CeO₂$ powders with different S_{BET} was feasible, in which $(NH_4)_2CO_3$ or Na_2CO_3 as a precipitant was used to separate original cerium precursors $(Ce_2(CO_3)_3.8H_2O$ or o- $Ce(CO₃)OH$) from $Ce³⁺$ aqueous solution, $H₂O₂$ as an oxidant

was introduced to induce the phase transformation from these original cerium precursors to $CeO₂$ precursors, finally the mesoporous $CeO₂$ were obtained by following hydrothermal treatment at 200 °C for 24 h. It is worth noting that $(NH_4)_2CO_3$, $Na₂CO₃$ and $H₂O₂$ are common, cheap, accessible and safe chemistry reagents, which not only can save the cost, but also can reduce the pollution degree to environment. Moreover, the route, using commercial $Ce_2(CO_3)_3 \cdot xH_2O$ as an existing precursor for synthesis of mesoporous $CeO₂$, can shorten experimental processes and reduce costs, and the S_{BET} of the asobtained mesoporous CeO₂ powders was 100.0 $\mathrm{m^2\,g^{-1}}.$ Inspired by the template-free synthesis of mesoporous $CeO₂$ powders using commercial $Ce_2(CO_3)_3 \cdot xH_2O$ as an existing precursor, the commercial $Ce(CO₃)OH$ should be a feasible precursor for synthesis of mesoporous $CeO₂$ powders. However, it is with great regret that the existing $Ce(CO₃)OH$ precursor cannot be obtained through purchase, so the experiment with commercial $Ce(CO₃)OH$ as an existing precursor cannot be performed. Next, the effects of H_2O_2 on the phase structures and microstructures of samples will be investigated. **BSC Advances**

Role of H_2O_2

To clarify the effects of H_2O_2 on the phase structures of samples, the XRD analyses of samples synthesized in the absence of H_2O_2 was performed. Fig. 7 shows the XRD patterns of the hydrothermally produced samples synthesized under the same conditions as control, however, in the absence of H_2O_2 . From Fig. 7a and c, the hydrothermally produced Sample 1 and Sample 3 obtained in the absence of H_2O_2 showed similar XRD patterns, and both consisted of h-Ce (CO_3) OH (JCPDS no. 32-0189) and $CeO₂$ (JCPDS no. 34-0394). From Fig. 7b, the hydrothermally produced Sample 2 obtained in the absence of H_2O_2 consisted of $Ce(CO_3)_2$ (JCPDS no. 22-0542), h-Ce (CO_3) OH and CeO2. The results of XRD analyses in Fig. 7 indicates that the pure CeO₂ cannot be synthesized in the absence of H_2O_2 , which can be attributed to the missing link of the oxidation-induced phase transformation from original cerium precursors to $CeO₂$ precursors (see Fig. 3). In other words, the phase transformations from original cerium precursor $(Ce_2(CO_3)_3.8H_2O$ or $o\text{-}Ce(CO_3)OH$) to pure CeO_2 cannot be achieved by depending upon the following hydrothermal treatment only. Combining

Fig. 7 XRD patterns of (a) Sample 1, (b) Sample 2 and (c) Sample 3 synthesized in the absence of H_2O_2 .

the XRD results in Fig. 2–4, it further indicates that the link of addition of H_2O_2 acts as a relay station for CeO_2 precursors from original cerium precursors that are then forwarded to the link of hydrothermal treatment for the formation of final $CeO₂$ products.

To understand the effects of H_2O_2 on the microstructures of precursors obtained in the absence and presence of H_2O_2 , TEM analyses were performed. Fig. 8a, c and e show the TEM images of Precursor 1-1, Precursor 2-1 and Precursor 3-1 synthesized in the absence of H_2O_2 , respectively. As observed, all precursors synthesized in the absence of H_2O_2 were dense. In contrast, the TEM images of precursors synthesized in the presence of H_2O_2 in Fig. 8b, d and f revealed the porous structures. The area with lower contrast showed more and clearer pores compared to one with higher contrast, and the similar phenomenon could be observed in Fig. 5a, c and e. The formation of pore structures could be explained by the oxidation-induced phase

50 nm 50 nm (e) **50 nm 50 nm**

transformation from original cerium precursor $(Ce_2(CO_3)_3$ - \cdot 8H₂O or o-Ce(CO₃)OH) to CeO₂ precursor that accompanied by the evolution of porous structure. It indicates that H_2O_2 plays a key role in the formation of initial pore structures of $CeO₂$ precursors, which provides the precondition for the further growth of pores during the hydrothermal process (see Fig. 5).

From the above, it can be found that H_2O_2 plays an indispensable role in the development of pure $CeO₂$, which induces the phase transformation from original cerium precursors to $CeO₂$ precursors with initial pore structures in the aqueous solution. Interestingly, the initial pore structures are the prerequisite for formation of final mesoporous $CeO₂$ products during the hydrothermal process. From a chemical perspective, the formation mechanism of the original cerium precursors with dense structures and the $CeO₂$ precursors with pore structures are summarized as eqn (5)–(8). In eqn (5) and (6), the original precipitate $(Ce_2(CO_3)_3.8H_2O$ or $Ce_2(CO_3)_3OH$) is obtained upon the addition of $(NH_4)_2CO_3$ or Na_2CO_3 to Ce^{3+} aqueous solution, respectively (see Fig. 2). After adding H_2O_2 , the original precipitates are oxidized, and $CeO₂$ precursors with low crystallinities are formed (see eqn (7) and (8)), which supported by the XRD analyses in Fig. 3. At the same time, the byproducts of H_2O and CO_2 are produced. So, the phase transformation from original cerium precursors to $CeO₂$ precursors could be due to the oxidation of H_2O_2 , while the initial pores on $CeO₂$ precursors (see Fig. 8b, d and f) could be attributed to the density difference between the original cerium precursors and CeO₂ precursors and the loss of by-products $(H_2O \text{ and } CO_2)$. Above all, the formation of pore structures could be essentially ascribed to the oxidation-induced phase transformation from original cerium precursors to $CeO₂$ precursors that accompanied by the evolution of porous structures. After addition of H_2O_2 , cerium precursors are oxidized into CeO₂ and simultaneously with the formation of by-products H_2O and CO_2 as shown in eqn (7) and (8). The difference in density between cerium precursors $(Ce_2(CO_3)_3.8H_2O (2.790 g cm^{-3})$ and o-Ce(CO₃)OH $(4.545~{\rm g~cm}^{-3})$) and CeO₂ (7.215 ${\rm g~cm}^{-3})$ is the main cause for the formation of pore structures of $CeO₂$, while the byproduct $CO₂$ bubbles play a stirring role, which are beneficial to the process of oxidation reaction and the homogeneity of $CeO₂$ particles. Moreover, the crystallinities of $CeO₂$ precursors could be improved and the pores grow further by following hydrothermal treatment, which supported by the XRD analyses in Fig. 4 and TEM analyses in Fig. 5. The S_{BET} of final mesoporous CeO₂ powders not only relates to the difference in density between cerium precursors and

CeO2, but also to the particle size of original cerium precursors. The phase transformation from original cerium precursors to CeO₂ precursors under the stimulation of H_2O_2 could be considered to be a diffusion process of H_2O_2 . The surface of cerium precursors is first oxidized to $CeO₂$, these original $CeO₂$ grains have the tendency to aggregate with time to decrease their energy, and the hole between the grains are consider as the initial porous structures, which was the precondition for further forming of mesoporous structures of final $CeO₂$ powders during the hydrothermal process. However, the content of H_2O_2 decreases as the reaction progress, and the framework of cerium precursor is filled by the aqueous solution or by-product $CO₂$ bubbles, which could influence the diffusion of $H₂O₂$ from the surface to the inside of the cerium precursor framework, and then will result in the lesser porosity (see the darker areas in Fig. 8b, d, f and 5a, c, e). Moreover, the small particle sizes of cerium precursor are favorable to the diffusion of H_2O_2 from its surface to internal framework. The greater the difference in density, and the smaller its particle size, the more its S_{BET} . So, the S_{BET} of final CeO₂ products is the outcome of both the difference in density between cerium precursors and $CeO₂$ and the diffusion of H_2O_2 from surface to internal framework of cerium precursors. This can be used to explain why Sample 1, Sample 2, Sample 3 in this work and the $CeO₂$ sample in our previous report (ref. 40) possess different S_{BET} , even if some CeO2 powders are synthesized with same phase of precursor. Effect of calcination on S_{BET} of mesoporous CeO₂

In order to investigate the effect of calcination on the grain sizes and S_{BET} of samples, the hydrothermally produced mesoporous $CeO₂$ powders were furthermore treated by following calcination at 500 °C for 2 h, and the grain sizes were estimated using Scherrer's formula. Fig. 9a shows the effect of calcination on the grain sizes of mesoporous $CeO₂$ (Sample 1, Sample 2 and Sample 3, respectively). As observed, the mean grain sizes were 9.0, 4.9 and 5.7 nm for Sample 1, Sample 2 and Sample 3, respectively. After calcination, the mean grain sizes of samples increased by 14.4, 125.5 and 78.9%, which implied that the high temperature could cause the grains to grow. In addition, the hydrothermally produced $CeO₂$ using Na₂CO₃ as a precipitant (Sample 2) treated by calcination showed the biggest change in grain size, which could ascribed to the minimum grain size in

all hydrothermally produced $CeO₂$ samples. Fig. 9b shows the effect of calcination on the S_{BET} of mesoporous CeO₂ (Sample 1, Sample 2 and Sample 3, respectively). As observed, the S_{BET} of samples decreased by 18.7, 43.8 and 39.4% after calcination for Sample 1, Sample 2 and Sample 3, respectively. Moreover, the hydrothermally produced $CeO₂$ powders using $NH₄HCO₃$ as a precipitant in our previous report (ref. 40) were also treated by calcination, the mean grain size increased from 5.4 to 10.9 nm with a gain of 101.8%, and the S_{BET} decreased from 166.5 to 105.9 m² g⁻¹ with a gain of 36.4%. The reduction of S_{BET} could be explained by the growing of grains or the collapse of pores during the calcination process. Obviously, the subsequent postcalcination treatment could lead to the growth of $CeO₂$ grains, which in turn reduced the S_{BET} of mesoporous CeO₂ powders.

Adsorption properties

AO7 dye was selected as a model target to evaluate the adsorption abilities of mesoporous $CeO₂$ powders. Fig. 10a-c depicts the time-dependence of adsorption profiles of AO7 dye on mesoporous CeO₂ powders synthesized in the presence of H_2O_2 (Sample 1, Sample 2 and Sample 3, respectively). As observed, the adsorption efficiencies of AO7 dye achieved within 60 min were 94.2, 83.4 and 89.3% for Sample 1, Sample 2 and Sample 3, respectively. Furthermore, the adsorption of AO7 dye was rapid at the early stages, and the adsorption process was mostly completed within 40 min of reaction. The rapid adsorption of these mesoporous $Co₂$ powders for AO7 dye could be ascribed to their high S_{BET} and pore structures. The high S_{BET} could provide numerous adsorption sites for AO7 molecules, while the pore structures were conducive to the transportation of AO7 molecules to $CeO₂$ framework and increasing the effective contact areas between $CeO₂$ and AO7 molecule. Interestingly, $CeO₂$ also can serve as an alternative photocatalyst for degradation of dye.⁴⁶ The high S_{BET} of mesoporous CeO₂ powders contribute to providing more active adsorption and photocatalytic reaction sites, which favor the augmentation of photocatalytic performance.⁴⁷ So, the proposed mesoporous $CeO₂$ powders in this work have potential to photodegrade high density dye and dye intermediate from industrial effluents. The

Table 2 Recent literatures on $CeO₂$ development for the adsorption of AO7 dve

Table 2 shows the adsorption efficiencies from the recent literatures on $CeO₂$ development for the adsorption of AO7 dye.^{48–56} By comparing the adsorption efficiencies of $CeO₂$ in

Fig. 11 Effects of AO7 initial concentration on the AO7 adsorption efficiency and adsorption amount measured in the dark and presence of mesoporous CeO₂: (a) Sample 1, (b) Sample 2 and (c) Sample 3 synthesized in the presence of H_2O_2 .

these reported literatures, we can find the mesoporous $CeO₂$ in this work showed stronger adsorption ability and achieved the absorption equilibrium more quickly, which ascribed to the higher S_{BET} of mesoporous CeO₂ in this work. The adsorption mode of AO7 on $CeO₂$ could be described as a Lewis acid-base reaction between the electron-rich groups (sulfonate group, SO^{3-}) of AO7 and empty 4f orbital of cerium ion on the surface of CeO₂, which eventually formed an inner-sphere complex.^{48,57} Moreover, $CeO₂$ could serve as an excellent adsorbent for the adsorption of other azo dyes, such methyl orange,⁵⁸ congo red,⁵⁹ alizarin red S and eriochrome black-T,⁶⁰ and the adsorption of the azo dyes onto $CeO₂$ was solely associated with the oxygen atoms of $SO³⁻$ group.⁵⁷

Fig. 12 Langmuir linear fits of AO7 dye adsorbed onto mesoporous CeO2: (a) Sample 1, (b) Sample 2 and (c) Sample 3 synthesized in the presence of H_2O_2 .

Table 3 Relevant parameters of Langmuir fitting for mesoporous CeO₂: Sample 1 and Sample 2 synthesized using (NH₄)₂CO₃, Na₂CO₃ as precipitants, and Sample 3 synthesized using commercial Ce₂(CO₃)₃ xH_2O as an existing precursor in the presence of H₂O₂

The effects of AO7 initial concentration on the AO7 adsorption amount and adsorption efficiency are shown in Fig. 11. For all samples, the adsorption amount increased with increasing AO7 initial concentrations until $[AO7] = 100$ mg L⁻¹. In contrast, the removal efficiency decreased with increasing AO7 initial concentrations. More specifically, the removal efficiencies could reach 99.6, 99.2 and 99.5% at $[AO7] = 20$ mg L⁻¹ for Sample 1, Sample 2 and Sample 3 synthesized in the presence of H_2O_2 , respectively.

The adsorption experiments of AO7 dye at varying initial concentrations onto mesoporous $CeO₂$ powders were performed, and the saturated adsorption amount of AO7 dye was obtained according to Langmuir linear fits. Fig. 12a-c shows the Langmuir linear fits of experimental data of adsorption of AO7 dye onto mesoporous $CeO₂$ powders, and the resulting isotherm constants and correlation coefficients are presented in Table 3. From Table 3, we can see that the saturated adsorption amounts (q_m) are 378.8, 261.1 and 332.2 $\mathrm{mg\ g}^{-1}$, and Langmuir adsorption constants (K_L) are 0.4740, 0.3460 and 0.3830 for Sample 1, Sample 2 and Sample 3, respectively. In addition, all associated correlation coefficients (R^2) are greater than 0.9920, confirming that Langmuir isotherm model is a good fit for modelling the adsorption of AO7 dye onto mesoporous $CeO₂$ surface. The results indicate that the proposed route for template-free synthesis of mesoporous $CeO₂$ powders is one marker of success to effectively and rapidly remove AO7 dye. **PSC Arbaness**

Conclusions

The accessible, cheap and safe chemistry reagents $(NH_4)_2CO_3$, $Na₂CO₃$ and $H₂O₂$ were employed for template-free synthesis of mesoporous $CeO₂$ powders with high BET surface areas. $(NH₄)₂CO₃$ or Na₂CO₃ as a precipitant was used to separate original cerium precursors from Ce^{3+} aqueous solution, while $H₂O₂$ served as an oxidant to induce the phase transformation from original cerium precursors to $CeO₂$ precursors with initial porous structures, which was the precondition for the formation of final $CeO₂$ phase and mesoporous structures during the following hydrothermal process at 200 \degree C for 24 h. The BET surface areas of mesoporous $CeO₂$ powders synthesized using $(NH_4)_2CO_3$ and Na₂CO₃ as precipitants were 106.1 and 76.9 m² g^{-1} . Moreover, another route, using commercial Ce₂(CO₃)₃- $\cdot xH_2O$ as existing precursor for synthesis of mesoporous CeO₂ powders with a BET surface area of 100.0 $\mathrm{m^{2}}\ \mathrm{g^{-1}}$, can shorten experimental processes and reduce costs. These mesoporous CeO2 powders could be used as a suitable sorbent for rapid and

effective removal of AO7 dye. Moreover, the saturated adsorption amounts could reach up to 378.8, 261.1 and 332.2 mg g^{-1} without pH pre-adjustments for these mesoporous $CeO₂$ powders using $(NH_4)_2CO_3$, Na_2CO_3 as precipitants and using commercial $Ce_2(CO_3)_3 \cdot xH_2O$ as an existing precursor, respectively. Prompted by the high BET surface area, low cost, environmental friendliness and omissible calcination process, these mesoporous CeO₂ powders synthesized with the routes in this work could be a promising candidate for practical application. In subsequent study, the optimization of experimental parameters will be explored, such as the additive amount of $H₂O₂$, hydrothermal treatment temperature and time, and so on.
