Indium sulfide nanotubes with sulfur vacancies as an efficient photocatalyst for nitrogen fixation

Zhiyi He, Yu Wang,* Xiaoli Dong, * Nan Zheng, Hongchao Ma and Xiufang Zhang

We have designed and manufactured In_2S_3 nanotubes containing sulfur vacancies as effective and stable photocatalysts for nitrogen fixation and ammonia production. In the preparation process of In_2S_3 , a self-templated strategy was used to obtain the nanotubes. The sulfur vacancies were then manufactured by calcination under a nitrogen atmosphere. The existence of sulfur vacancies enhances the light absorption and promotes the separation and migration of the photoinduced charge carriers. In addition, sulfur vacancies can serve as the active sites to achieve strong N_2 adsorption and activation. Thus the obtained samples show enhanced photocatalytic performance with a high NH_3 generation rate ($52.49 \mu\text{mol h}^{-1} \text{g}^{-1}$) and excellent stability under UV-vis light.

Introduction

Ammonia (NH_3), as an extremely important raw material for synthesis of chemicals and fertilizers, is widely used in both industry and agriculture.^{1,2} From the outset, the traditional method of NH_3 generation in industry has been the Haber-Bosch process, which is usually conducted under harsh reaction conditions (high temperature and high pressure).^{3–5} This process has a high energy consumption and hampers efforts toward energy conservation and environmental protection. Therefore, it is necessary to develop a method that can convert nitrogen into ammonia with low energy consumption and in a clean and safe manner.^{6,7} Among the many methods available at present, photocatalytic technology has received particular attention from researchers for its simplicity, efficiency and environment-friendly nature. Therefore, it is urgent to establish a catalytic reaction system using an efficient and green catalyst to convert N_2 into NH_3 at room temperature and pressure.

Recently, photocatalytic nitrogen fixation has become the most favorable alternative technology to traditional industrial nitrogen fixation methods due to its merits of environmental friendliness, mild reaction conditions and low energy consumption.^{8–10} In 1977, Schrauzer *et al.* first reported that N_2 could be reduced to NH_3 over Fe-doped TiO_2 under UV light.¹¹ During the reaction, high-energy electrons generated by the semiconductor can activate $\text{N}\equiv\text{N}$ and facilitate its dissociation, making the process of fixing N_2 to NH_3 feasible.¹² Unfortunately, photocatalytic nitrogen fixation techniques using TiO_2 are still dissatisfactory. On the one hand, TiO_2 can only take advantage of the ultraviolet range of sunlight.^{13–15} On the other hand, the

recombination of photogenerated electrons and holes makes it difficult to achieve higher photocatalytic efficiency. These disadvantages make it difficult to put photocatalytic nitrogen fixation into large-scale application. In order to solve these problems, a promising method is to synthesize visible light responsive photocatalysts and improve the generation and migration rate of carriers.¹⁶

Among many materials with visible light response, indium sulfide (In_2S_3) has gained wide attention because of its high responsiveness, excellent photoelectric sensitivity and low toxicity.^{17–22} However, single-metal sulfides do not have satisfactory catalytic properties, mainly due to the separation of charge carriers, slow migration kinetics of charge carriers and low quantum efficiency.^{23,24} In order to solve these problems, one possible approach is to carry out surface defect engineering.²⁵ Extensive research has been conducted on surface defect engineering, in which surface vacancy defects provide more active sites for materials and facilitate the chemical adsorption and activation of N_2 , thus improving the photocatalytic activity.^{26–28} There are many examples of sulfur vacancies and oxygen vacancies used in photocatalysts (e.g. MoS_2 , TiO_2), which confirm that the presence of vacancies can significantly improve the photocatalytic properties of catalysts. After being modified, materials usually possess more hole-electron pairs, faster carrier transmission rates, and better photocatalytic performance. Therefore, it should be feasible to create sulfur vacancies in In_2S_3 to improve its photocatalytic properties.

To improve the photocatalytic performance, another effective method is to change the morphology of the material to improve its specific surface area and to increase the contact area with the reaction medium.²⁹ Two-dimensional hollow nanotubes with high surface area are beneficial to reduce the diffusion distance of carriers and increase the contact area with the

School of Light Industry and Chemical Engineering, Dalian Polytechnic University, #1 Qinggongyuan, Dalian 116034, P. R. China. E-mail: wang_yu@dlpu.edu.cn; dongxiaoli65@163.com

water medium in the reaction. In addition, the hollow space can also enhance the capture of photons by internal light scattering and reflection.^{30–33} As a new type of porous crystal materials, metal–organic frameworks (MOFs) are the preferred template.^{34,35} Because of their unique composition of metal clusters and organic bridges, they are promising templates for vulcanization *in situ* to obtain In₂S₃ catalysts that retain their 2D morphology. At the same time, due to the loss of organic linkers in the process of solvothermal treatment, a hollow structure is formed.

In this article, In₂S₃ hollow nanotubes were successfully prepared using MIL-68 (In) prism as a precursor *via* self-assembly technology. Subsequently, the as-prepared In₂S₃ nanotubes were annealed in a nitrogen atmosphere under different temperatures to form sulfur vacancies. The nitrogen fixation performance of the obtained samples was determined using deionized water as the medium under mild reaction conditions. The crystal structure, morphology, chemical element composition, optical and electrochemical properties of the as-obtained sulfide-vacancy-decorated In₂S₃ nanotubes were investigated. In the presence of sulfur vacancies, the photocatalytic properties show a significant improvement. Therefore, this work may indicate new directions and useful insights for the design of metal sulfide photocatalysts and their application for nitrogen fixation.

Experimental

Materials and reagents

Indium nitrate (In(NO₃)₃·xH₂O) and 1,4-benzenedicarboxylic acid (H₂BDC) were supplied by Aladdin Reagent Co., Ltd. (Shanghai, China). Thiourea was obtained from Tianjin Bodi Chemical Co., Ltd. *N,N*-Dimethylformamide (DMF) was supplied by Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China), and absolute ethanol (EtOH, 99.7%) was obtained from Tianli Chemical Reagent Co., Ltd. (Tianjin, China). All reagents and solvents were used as received without further purification.

Synthesis of MIL-68 (In) prisms. The MIL-68 (In) hexagonal prisms were synthesized according to a reported method with some modifications.³⁶ Firstly, 0.408 g of In(NO₃)₃·xH₂O and 0.2 g of H₂BDC were dissolved in 12 mL DMF and stirred for 20 min. The resultant mixture was then transferred into a Teflon-lined autoclave, which was sealed and heated at 100 °C for 48 h. After the reaction, the white precipitate was filtrated and washed with DMF and ethanol several times, and dried in vacuum at 60 °C for 12 h.

Synthesis of In₂S₃ nanotubes. The In₂S₃ nanotubes were synthesized according to a modification of a previously reported solvothermal method.³⁷ In brief, 0.6 g of thiourea was initially dissolved in 80 mL of ethanol. Subsequently, 0.012 g of MIL-68 (In) was added into the solution with stirring. The obtained mixture was transferred into a Teflon-lined autoclave, sealed and heated at 180 °C for 3 h. After cooling to room temperature, the yellow precipitate was filtrated and washed with water and ethanol four times, and finally dried at 60 °C.

Synthesis of SV-In₂S₃ nanotubes. The sulfur vacancy-containing (SV)-In₂S₃ nanotubes were prepared through

a simple annealing process from In₂S₃ nanotubes. A moderate amount of In₂S₃ nanotubes was loaded in an alumina boat and placed in a tube furnace, and the furnace was heated to 200 °C or 300 °C with a heating rate of 3 °C min⁻¹ and maintained for 2 h in nitrogen atmosphere. The materials obtained were designated as SV-In₂S₃-200 and SV-In₂S₃-300, respectively.

Materials characterization

The transmission electron microscopy (TEM) analyses were performed by a JEOL JEM-2100F transmission electron microscope. Scanning electron microscopy (SEM) images were taken using a field emission scanning electron microscope (JSM-7800F, JEOL). The crystallinity and the purity of the as-prepared samples were characterized by powder X-ray diffraction (XRD) analysis on a Shimadzu XRD-6100 diffractometer at 40 kV and 40 mA with Cu K α radiation. Light absorption properties were evaluated by UV-vis diffuse reflectance spectroscopy (UV-vis DRS, CARY 100&300, VARIAN), for which BaSO₄ was used as a reflectance standard. The photoluminescence (PL) spectra of the photocatalysts were acquired using a Hitachi F-7000 fluorescence spectrophotometer. Electron spin resonance (ESR) spectra were recorded on a JES-FA200 electron spin resonance spectrometer operating at room temperature. Nitrogen temperature-programmed desorption experiments (N₂-TPD) were performed by a NOVA 2000e Surface Area & Pore Size Analyzer. X-ray photoelectron spectroscopy (XPS) spectra were conducted on a VG Scientific ESCALAB 250 XPS instrument.

Photocatalytic activity measurements

All the photocatalytic N₂ fixation experiments were conducted in a sealed quartz reactor under UV-vis light irradiation by a 300 W Xe lamp (PLS-SXE 300, Beijing Perfect Light Co., Ltd.). Typically, 20 mg of catalysts was dispersed in 100 mL of ultrapure water in a quartz reactor, which was equipped with a water circulator. The mixture solution was stirred in the dark with pure N₂ bubbled at a flow rate of 80 mL min⁻¹ for 30 min to reach adsorption equilibrium. In the reaction process, 5 mL of reaction solution was taken out every 30 min and the catalyst was further removed through centrifugation. Throughout this reaction, the temperature of the reaction system was kept at 15 °C. The concentration of product was detected using the Nessler's reagent method at 420 nm with an optical power meter (SDPTOP, UV2800S).

Electrode preparation and electrochemical characterization

Electrochemical and photochemical measurements of the samples were performed with a standard three-electrode setup (CHI760E Instruments). For working electrode modification, 5 mg catalyst and 10 μ L Nafion solution (5 wt%) were dispersed in a 3 mL volume ratio of 1 : 3 water–ethanol solution. After 20 minutes of ultrasonication, a 5 μ L aliquot of the mixture solution was pipetted onto the glassy carbon electrode to achieve catalyst loading, and finally dried at room temperature. Before the measurements, the Na₂SO₄ solution was purged with Ar gas for 30 min to remove the dissolved molecular oxygen, and purging was continued during the measurements.

Results and discussion

As shown in Scheme 1, In_2S_3 nanotubes were prepared in two steps. First of all, MIL-68 (In) was prepared as a precursor *via* the solvothermal method using $\text{In}(\text{NO}_3)_3 \cdot x\text{H}_2\text{O}$ and H_2BDC as reactants. Afterward, through a liquid phase sulfidation process, the as-prepared sample was transformed into In_2S_3 nanotubes with thiourea as a reactant. Finally, the In_2S_3 nanotubes were calcined in a nitrogen atmosphere to produce sulfur vacancies.

The morphologies and structures of the prepared samples were illuminated by SEM, TEM and energy dispersive spectroscopy (EDS). As shown in Fig. 1a, the uniform MIL-68 (In) precursor was a hexagonal prism with a smooth surface, and its average length and average diameter were about 4–5 μm and 2 μm , respectively. After sulfidation by the solvothermal method, the synthesized In_2S_3 material perfectly maintained its 1D morphology with ultrathin nanosheets evenly distributed on the surface (Fig. 1b and c). TEM images show that the hexagonal prism was transformed into a hollow structure with a shell thickness of 100 nm after the solvothermal reaction (Fig. 1d–f). After calcination at various temperatures, no significant changes were found in the morphology and size of the samples through SEM and TEM imaging.

Elemental mappings of an individual SV- In_2S_3 -200 nanotube show a uniform distribution of S and In elements across the whole nanostructure. EDS analysis reveals that the In_2S_3 sample possesses an In/S molar ratio of 1 : 1.3. In comparison, the In/S molar ratio of SV- In_2S_3 -200 is 1 : 1.17, which can be attributed to the escape of sulfur atoms.

The XRD patterns of MIL-68 (In), In_2S_3 , SV- In_2S_3 -200 and SV- In_2S_3 -300 are shown in Fig. 2. First, MIL-68 (In) was synthesized

Fig. 1 SEM images of (a) MIL-68 hexagonal prisms, (b) In_2S_3 nanotubes, and (c) SV- In_2S_3 -200 nanotubes, TEM images of (d) In_2S_3 nanotubes, and (e and f) SV- In_2S_3 -200 nanotubes, and (g and h) elemental mapping of an individual SV- In_2S_3 -200 nanotube.

as a precursor, and its successful synthesis was confirmed by XRD analysis as shown in Fig. 2a.³⁸ The XRD patterns of In_2S_3 , SV- In_2S_3 -200 and SV- In_2S_3 -300 are shown in Fig. 2b. In the XRD pattern of In_2S_3 , the diffraction peaks located at 28.7° , 33.2° and 47.7° perfectly correspond to the (222), (400) and (440) planes of In_2S_3 (well matched with JCPDS card no. 65-0459). No diffraction peaks of MIL-68 (In) were found, indicating that MIL-68 (In) was completely converted into In_2S_3 . Moreover, it can be seen that after annealing, the peaks of In_2S_3 were not changed, and no other impurities, such as In_2O_3 or InS, were detected, indicating the phase purity of the sample. It is worth noting that the peak positions of the samples did not change after calcination, but the strength of the peaks was reduced, which is due to the production of sulfur vacancies.

The optical properties of the samples were also evaluated by DRS. As shown in Fig. 3a, In_2S_3 responded to visible light, with an absorption edge at about 587 nm. Compared to pure In_2S_3 , SV- In_2S_3 -200 and SV- In_2S_3 -300 exhibit enhanced absorption in

Scheme 1 A schematic illustration of the synthetic process for MIL-68 (In) and In_2S_3 nanotubes.

Fig. 2 XRD patterns of (a) MIL-68 (In), and (b) In_2S_3 , SV- In_2S_3 -200 and SV- In_2S_3 -300.

the visible light region. The absorption edge values of the SV-In₂S₃-200 and SV-In₂S₃-300 are 590 nm and 608 nm, respectively. The absorption intensity is proportional to the calcination temperature in nitrogen, indicating an increase in the number of sulfur vacancies with increasing calcination temperature. The estimated band gap energies of In₂S₃, SV-In₂S₃-200 and SV-In₂S₃-300 are 2.17, 2.14 and 2.10 eV, respectively, corresponding to the Tauc plots shown in Fig. 3b.

In order to further investigate the mechanism of photocatalytic activity, the relative band positions of these materials were calculated, because the edge positions play key roles in determining the transmission of photoinduced charge carriers. The X-ray photoelectron spectroscopy (XPS) VB spectra (Fig. 3c) show that the valence bands (VB) of In₂S₃ and SV-In₂S₃-200 are 1.31 eV and 1.27 eV, respectively. Furthermore, the conduction bands (CB) of the materials were determined from the Mott-Schottky plots (Fig. 3d). The corresponding flat band potentials of the In₂S₃ and SV-In₂S₃-200 samples are estimated to be -1.05 V and -1.03 V versus Ag/AgCl, respectively. If the obtained flat band potential values are converted to normal hydrogen electrode (NHE) potentials, the values are equal to -0.85 V and -0.83 V versus the NHE. The CB potential (E_{CB}) is very close to the flat band potential for n-type semiconductors. Thus, the E_{CB} values are -0.85 V and -0.83 V vs. NHE for the In₂S₃ and SV-In₂S₃-200.

Meanwhile, to further study the surface composition and chemical state of the samples, XPS measurements were carried out. As shown in Fig. 4a, the XPS spectra of the In₂S₃ and SV-In₂S₃-200 samples are consistent with the previously reported In₂S₃ spectra. The only elements for which peaks were detected were In, S, O and C. The peaks of C and O possibly arose from the adsorption of gas molecules and partial oxidation of the sample due to their exposure to the atmosphere. High-resolution XPS spectra of In 3d for In₂S₃ and SV-In₂S₃-200 samples are shown in Fig. 4b. For the In₂S₃, the two strong peaks at 444.5 eV and 452.1 eV are attributed to bonding energies of In 3d_{5/2} and In 3d_{3/2}, respectively. These results indicated

Fig. 4 (a) XPS survey spectra, and (b) In 3d and (c) S 2p XPS spectra of In₂S₃ and SV-In₂S₃-200 and (d) ESR spectra of In₂S₃, SV-In₂S₃-200 and SV-In₂S₃-300.

that the valence state of In was +3. Meanwhile, for the SV-In₂S₃-200 the two peaks shifted to lower binding energies, *i.e.* 444.3 eV for In 3d_{5/2} and 451.8 eV for In 3d_{3/2}. Fig. 4c shows the S 2p spectra of In₂S₃ and SV-In₂S₃-200 samples. For the In₂S₃, two peaks at 161.1 eV and 162.1 eV can be assigned to the bonding energy of S 2p_{3/2} and S 2p_{1/2}. Meanwhile, for the SV-In₂S₃-200, the peak positions shifted to lower binding energies, demonstrating the existence of sulfur vacancies. The combined energy values of the detected In 3d and S 2p are consistent with the previously reported In₂S₃ data.

ESR spectroscopy is considered as a powerful tool to probe the presence and the concentration of vacancies.³⁹ As shown in the ESR spectra (Fig. 4d), the two calcined samples display stronger ESR signals than the original In₂S₃, wherein the SV-In₂S₃-300 sample exhibits the highest peak among all three samples, suggesting the greatest number of unpaired electrons. This indicated that the amount of sulfur atoms in the material decreased when the calcination temperature was increased. Vacancies not only improve the photoabsorption ability of semiconductors, but also act as traps for photogenerated electrons to constrain the recombination of electron/hole pairs, thereby enhancing the photoreactivity.

The N₂ adsorption-desorption measurements revealed that the In₂S₃ possessed a high BET surface area of 110.42 m² g⁻¹, while the SV-In₂S₃-200 nanotubes had a BET surface area of 82.97 m² g⁻¹ (Fig. 5a). Thus, after calcination of indium sulfide, the specific surface area decreased to a certain extent. This can be attributed to the partial collapse of the structure during the calcination process, after which the material structure was no longer completely hollow. The N₂ sorption isotherm shows a hysteresis loop, indicating the existence of mesopores in the structure. This mesoporous characteristic is beneficial to the adsorption of nitrogen in the photocatalytic nitrogen fixation reaction. Moreover, the presence of mesopores in the catalyst can provide more active sites for the reaction and accelerate charge transfer to promote the occurrence of photocatalytic reactions.

Fig. 3 (a) UV-vis diffuse reflectance spectra and (b) Tauc plots of In₂S₃, SV-In₂S₃-200 and SV-In₂S₃-300, and (c) XPS VB spectra and (d) Mott-Schottky plots of In₂S₃ and SV-In₂S₃-200.

Fig. 5 (a) N₂ adsorption isotherms of In₂S₃ and SV-In₂S₃-200, (b) PL spectra of In₂S₃, SV-In₂S₃-200 and SV-In₂S₃-300, (c) TGA curve of MIL-68 (In), and (d) TGA curves of In₂S₃ and SV-In₂S₃-200.

The separation–recombination rate of photogenerated charge carriers in these materials was estimated by PL characterization (Fig. 5b). The results demonstrated that the SV-In₂S₃-200 sample exhibited a remarkable fluorescence quenching compared with the In₂S₃ and SV-In₂S₃-300 samples. This result confirms that electron–hole recombination in materials containing the appropriate amount of vacancies is greatly inhibited, which is beneficial to the photocatalytic reaction.⁴⁰

The thermal gravimetric analysis (TGA) curves under N₂ atmosphere are shown in Fig. 5c and d. For MIL-68 (In), as seen in Fig. 5c, there is a weight loss before 200 °C, which can be attributed to the loss of the guest molecules in the micropores. Then, the MIL-68 (In) completely decomposes at 500 °C. For In₂S₃ and the SV-In₂S₃-300, the first weight loss is attributed to the adsorbed water and solvent molecules in the sample (Fig. 5d). With the increase of temperature, the sulfur atoms in the materials escape, and the weight of the material is finally stabilized at temperatures above 700 °C. This shows that the catalyst has good thermal stability and is not easily decomposed at high temperature.

In order to investigate the charge separation efficiencies of the samples, the photocurrent responses of the as-obtained samples were tested. As can be seen from Fig. 6a, In₂S₃ shows the lowest transient photocurrent responses, indicating the highest recombination rate of photogenerated electron–hole pairs in the In₂S₃ crystal. Comparatively, SV-In₂S₃-200 shows the strongest photocurrent densities, indicating the separation efficiency of photogenerated charges is notably strengthened. This may be because the appropriate amount of sulfur vacancies can facilitate the trapping of electrons from the CB of In₂S₃ and result in enhanced charge separation ability. However, SV-In₂S₃-300 shows a lower photocurrent response than that of SV-In₂S₃-200, which suggests that excessive sulfur vacancies can act as recombination centers to inhibit the separation of the electron and hole pairs. On the other hand, as Fig. 6b shows, the electrochemical impedance spectra (EIS) reveal

Fig. 6 (a) Transient photocurrent spectra, and (b) EIS spectra of In₂S₃, SV-In₂S₃-200 and SV-In₂S₃-300.

that SV-In₂S₃-200 manifests the smallest arc radius, demonstrating the most desirable interfacial charge transfer ability among the as-obtained samples. The existence of sulfur vacancies causes a reduction in impedance, attributed to the transportation of photogenerated electron–hole pairs, which could be beneficial for enhancing the photocatalytic performance of the SV-In₂S₃-200.

The photocatalytic nitrogen fixation properties of the In₂S₃, SV-In₂S₃-200 and SV-In₂S₃-300 were tested under UV-vis light, and the results are shown in Fig. 7a. It can be seen that In₂S₃ shows a lower nitrogen fixation ability, with the photocatalytic nitrogen fixation rate of 35.56 μmol h⁻¹ g⁻¹. However, the samples containing sulfur vacancies behave better than the original In₂S₃, which confirmed that sulfur vacancies can improve the photocatalytic properties of materials. SV-In₂S₃-200 exhibits a remarkable performance for nitrogen fixation of 52.49 μmol h⁻¹ g⁻¹. The high nitrogen fixation rate is mainly due to an appropriate number of sulfur vacancies. In contrast, the nitrogen fixation efficiency of SV-In₂S₃-300 is 47.41 μmol h⁻¹ g⁻¹. The lower N₂ fixation performance of SV-In₂S₃-300 may be due to the excessive sulfur vacancies, which can act as recombination centers to inhibit the separation of the electron and hole pairs, inhibiting the photocatalytic properties. The calcination-optimized SV-In₂S₃-200 catalyst has excellent stability of nitrogen fixation and ammonia production performance under UV-vis light (Fig. 7b). After three cycles, SV-In₂S₃-200 still exhibits an excellent photo-nitrogen fixation rate with only a slight change. The used SV-In₂S₃-200 samples were repeatedly tested by XRD and SEM (Fig. 8), and no obvious changes were detected, indicating the stability and recyclable properties of the material. Besides, a blank experiment, shown in Fig. 7c, revealed that ammonia was not produced in the solution without light irradiation, confirming that the carrier generation is excited by light irradiation.

In the photocatalytic nitrogen fixation reaction, the sulfur vacancies can serve as the active sites to capture and activate N₂ molecules. Due to the large amount of S vacancies in the SV-In₂S₃, the N₂ molecules are most probably captured by these S vacancies and activated by donating electrons from their bonding orbitals and accepting electrons into their three antibonding orbitals. From the crystal structure in Scheme 2, it can be seen that the adsorbed N₂ molecules on the S vacancies are most likely surrounded by In atoms. Under solar light irradiation, the photogenerated charged excitons on these In atoms may cooperate with the center-adsorbed N₂ molecule and result in a possible redox

Fig. 7 (a) N₂ fixation performance of as-prepared In₂S₃, SV-In₂S₃-200 and SV-In₂S₃-300, (b) cycling runs for N₂ fixation, and (c) the influence of light on the N₂ fixation performance of SV-In₂S₃-200.

reaction. The mechanism of the nitrogen fixation reaction is shown in Scheme 3. Due to the existence of sulfur vacancies, an impurity energy level between the CB and the VB is introduced into the catalyst. Consequently, the as-obtained SV-In₂S₃-200 sample

Fig. 8 (a) XRD patterns of fresh SV-In₂S₃-200 and used SV-In₂S₃-200, and (b) an SEM image of used SV-In₂S₃-200.

Scheme 3 The proposed photocatalytic mechanism for N₂ fixation over SV-In₂S₃-200.

displays a narrower band gap and better utilization of visible light than pure In₂S₃. Besides, SV-In₂S₃-200 is excited by light with an energy higher than the band gap, *i.e.*, the energy needed to excite electrons from the VB to the CB or into the sulfur vacancies to form photogenerated electron–hole pairs. As active sites, sulfur vacancies accelerate the separation efficiency of photogenerated electron–hole pairs. Moreover, sulfur vacancies can also promote the adsorption and activation of N₂ molecules and increase the efficiency of photocatalytic nitrogen fixation.

Conclusions

In summary, In₂S₃ hollow nanotubes were synthesized by using a self-templated strategy, and then sulfur vacancies were introduced by calcination. The obtained samples were used as an efficient and stable photocatalyst to synthesize ammonia under UV-vis light. In the process of photocatalysis, sulfur

vacancies not only enhance the visible-light harvesting ability, but also facilitate the separation and transfer efficiency of the photogenerated electron/hole pairs. In addition, the sulfur vacancies play a key role in photocatalytic nitrogen fixation. As a result, the In_2S_3 photocatalyst with optimized sulfur vacancies exhibits remarkable performance and outstanding stability for N_2 fixation, with a stable NH_3 generation rate of $52.49 \mu\text{mol h}^{-1} \text{g}^{-1}$, which is 1.48 and 1.1 times higher than those of In_2S_3 and $\text{SV-In}_2\text{S}_3$ -300. Besides, the unique structure and composition of these layered tubular nanostructures reduces the diffusion distance of charge carrier separation and migration, and provides a large surface area for N_2 adsorption and abundant catalytically active sites for photochemical reactions. This work may provide guidelines for the design and construction of complex semiconductor-based photocatalysts for solar energy-related applications.
