Synthesis of a semi-conductor-like MOF with black phosphorous as a composite for visible light-driven photocatalysis†

Philani Vusumuzi Hlophe and Langelihle Nsikayezwe Dlamini *

The fabrication of nanocomposites of a metal–organic framework with two-dimensional materials for photocatalytic water splitting and environmental remediation has been the focus of the scientific community for many years now. In the work reported here, MIL-125 (Ti) was functionalized using few-layer black phosphorus (FLBP) via a two-step hydrothermal and sonication approach. The as-synthesized composite materials were characterized using transmission electron microscopy (TEM), scanning electron microscopy (SEM), X-ray diffraction (XRD), ultraviolet-visible diffuse reflectance spectroscopy (UV-Vis DRS) and photoluminescence (PL) spectroscopy. The techniques revealed that the nanocomposites exhibited circular blocks and a sheet-like morphology; they also showed enhanced visible light absorption and thus could be applied in visible-light-driven photocatalytic water treatment or water splitting. Electrochemical impedance spectroscopy (EIS) showed that the composite referred to as 4%BpMIL displayed the lowest recombination of all the composites (MIL-125(Ti) > 12%BpMIL > 6%BpMIL > 4%BpMIL > FLBP) with high effectual charge transfer between FLBP and MIL-125(Ti) via a p–n junction.

Introduction

Environmental remediation and the splitting of water into hydrogen and oxygen using photocatalysis technology has been explored as a cost effective strategy to address environmental problems such as water pollution and production of eco-friendly fuels.¹ The premise of photocatalysis involves a semi-conductor material which when excited by solar irradiation produces electron–hole pairs which are separated and transferred to the conduction band and valence band, where they initiate redox reactions.² Several traditional semiconductors have been utilised such as TiO₂ (ref. 3) and ZnO,⁴ however these materials are disadvantaged by fast recombination of photo-generated charge transporters which affects their charge separation ability.⁵ In addition to the fast recombination setback, these materials are UV active which invariably limits their effectual utilization of the solar spectrum and thus they exhibit poor photocatalytic activity.⁶

Due to these drawbacks, current research focus is aimed at fabricating visible light responsive materials with good separation of photo-irradiated electrons and holes. This can be achieved by synthesizing semiconductor composite materials which involves combining the merits of two or more

semiconductors. These composite materials aim to enhance the charge carrier separation and thus improve the photocatalytic activity. Semiconductor composites rely on staggered alignment of the band edge positions, which ensures that electrons and holes are directed to different units via a junction formed between the semiconductors.⁷ The separation of the charge carriers is vital for redox reactions to occur.² Heterojunctions such as metal oxides@MOFs have been utilized as visible light irradiated materials where the separation of charges was the paramount focus. However in the work reported here, a 2D@MOF composite is fabricated which relies on the effectiveness of black phosphorus as an excellent charge transporter in addition to the separation of charge carriers between the two semiconductor materials.^{8,9}

Metal–Organic Frameworks (MOFs) are a category of translucent substances that comprise of coordinate bonds between metal nodes and organic ligands.¹⁰ MOFs have come to the fore as a comprehensive set of crystalline materials with well-defined porosity. MOFs are different from other permeable materials, they boast many merits such as well-defined porosity, large surface area, ease of synthesis, thermal stability, ultra-low densities and with extensive properties convenient for physical and chemical implementation.¹¹ These intriguing features have triumphed the implementation of MOFs in gas storage, catalysis, segregation of fluids including water purification.¹²

A great amount of research has been done to enhance the necessary conditions for introduction of new or improved functionalities of structural profile and permanent permeable

† Electronic supplementary information (ESI) available. See DOI: 10.1039/c9ra08296d

framework of MOFs to broaden applications towards magnetic and electronic devices, proton conduction, biomedicine supercapacitors, sensors and rechargeable lithium ion batteries.¹³ Numerous MOF structures with exceptional porosity have been presented and most of them are built from divalent cations such as Zn^{2+} , Cd^{2+} , Cu^{2+} . They are constructed from carboxylates, phosphonates or N contributing spacers, or a composite of all these species. This results in MOFs with different structural conformations and pore sizes, ranging from micro to mesoporous architectures and the organic linker showing or lacking functional groups. MOFs constructed from tri or tetravalent metal ions are uncommon, apart from Ln^{3+} cations and the newly discovered uranyl moieties.^{14,15} This anomaly is a result of chemical reactivity differences compared to lower valence metals.

The titanium-based MOF, MIL-125 (Ti) enjoys a high surface area, which is propitious for organic molecule absorption. A speedy photochromic behaviour is noticed upon UV-visible illumination, when alcohols accumulate on the facet of the MIL-125 (Ti) in a nitrogen atmosphere. This photochromic effect is due to the existence of the intervalence charge transfer, which results from the optically initiated movement of electrons from titanium (iii) to titanium (iv) centres in the titanium oxoclusters. However, reoxidation of produced Ti^{3+} species into Ti^{4+} species takes place rapidly in the presence of air. This reverse photo-induced oxidation of Ti^{3+} to Ti^{4+} can be related to the depletion of O_2 into dual-atomic superoxide (O_2^-) species, with no structural deformation.¹⁴

Nevertheless, the photocatalytic efficiency of MIL-125(Ti) has been probed to a restricted degree and it is of great interest to evolve novel visible light driven photocatalysts.

Two dimensional materials have for the last couple of years showed a great potential as visible light responsive photocatalysts. These materials boast remarkable electronic, optical and catalytic properties which has led to their applications in various fields including photocatalytic water splitting.¹⁶ Examples of these 2D materials include graphene, MoS_2 and transition metal dichalcogenides (TMDs). The limitation of graphene is its lack of a band gap, while MoS_2 has a low carrier mobility and TMDs have a wide band gap which limits their photocatalytic efficiency of these 2D photocatalysts.¹⁷

Black phosphorus (BP), an emerging direct band gap 2D material has come to the fore front in recent years as it bridges the gap between band gapless graphene and wide band gap TMDs.¹⁸ Black phosphorus is an allotrope of phosphorus alongside white and red phosphorus, however it is more thermodynamically stable than its two counterparts.¹⁹ This remarkable material boasts intriguing properties such as high charge carrier mobility, low toxicity, an adjustable band gap, spanning from 0.3 eV for bulk and 2.0 eV for monolayer. The tunability of the band gap allows BP to be optimized for the certain applications by exfoliating the bulk intermediate into few layers.²⁰ Additionally this p-type semiconducting 2D material also absorbs in the visible and near infrared region, which is propitious for photocatalytic applications. However, the downside of BP is by far it's unstable nature in ambient conditions.

Thus, fabricating a *n*-MOF/BP composite would greatly improve the stability of the obtained hybrid, in addition to improved photocatalytic performance. In this work we report for the first time the synthesis of a novel visible light MIL-125(Ti)/BP photocatalyst, which will exhibit an inhibited recombination of charge carriers.

Materials and methods

Chemicals

All reagents and solvents utilized were of analytical reagent grade and used as received from suppliers. Terephthalic acid (BDC), *N,N*-dimethylformamide (DMF), *N*-methylpyridine (NMP), sodium hydroxide (NaOH) titanium isopropoxide (TBOT), bulk black phosphorus, ethanol ($\geq 99.8\%$ absolute), sodium sulphate ($\geq 99\%$ Reagent Plus), polyvinylidene fluoride (PVDF) and methanol were purchased from Sigma-Aldrich Co. Ltd.

Synthesis of MIL-125

The fabrication of MIL-125(Ti) was done following the synthesis route reported by Yang *et al.*²¹ with slight modifications. Typically 2.2 g of 1,4-benzenedicarboxylic acid was dissolved in a solution of 36 mL DMF and 4 mL methanol. A volume of 2.4 mL titanium isopropoxide was then added to the resultant solution and a white solution was formed, which was then sonicated for 5 min to ensure a homogeneous dispersion. The sonicated dispersion was exposed to hydrothermal conditions in a 100 mL Teflon lined autoclave for 24 h at 150 °C. Post cooling to room temperature, a gel-like solid was secured which was washed once with DMF and twice with methanol. The solid was then dried at room temperature for 24 h at 60 °C.

Synthesis of FL-BP

The FL-BP nanosheets were synthesized according to a procedure reported by Zhu *et al.*²² In detail 20 mg of bulk BP was added to a solution of saturated NaOH/NMP (the addition of the bulk phosphorus to the NaOH/NMP solution was carried out in an argon glovebox to combat the degradation of the bulk material). The saturated NaOH/NMP solution was made by dissolving 0.05 g NaOH in 20 mL NMP. This aqueous solution was then sonicated for 4 hours in an ice bath. Post sonication the solution was centrifuged at 2000 rpm for 20 minutes to remove any non-exfoliated bulk material.

Synthesis of MIL-125(Ti)/BP composites

The composites were synthesized varying the weight loadings of MIL-125(Ti) while keeping the amount of FL-BP constant. Typically, MIL-125(Ti) (1.8×10^{-4} , 3.6×10^{-4} , and 5.4×10^{-4} mol) was added to 10 mL of FL-BP. This dispersion was then sonicated for 2 hours, after which it was centrifuged and washed with ethanol three times. The wet powders were then dried in an oven at 60 °C overnight. The composites were denoted 4%BpMIL, 6%BpMIL and 12%BpMIL (m/m) respectively.

Characterization techniques

Morphologies of the nanocomposites were captured using scanning electron microscopy (SEM) and transmission electron microscopy (TEM). The SEM (TESCAN Vega TC) was operated at 20 kV operating voltage under nitrogen gas using VEGA 3 TESCAN software. Elemental composition of the nanoparticles (NPs) was elucidated with the SEM coupled with energy dispersive spectroscopy (EDS) and was operated at 20 kV. A TEM which was operated at an accelerating voltage of 200 kV was used to further acquire images of the nanocomposites. The nanocomposites were deposited on carbon coated copper grids after being dispersed in ethanol. Furthermore, selected area electron diffraction (SAED) was conducted on the nanocomposites at 20–25k magnification to elucidate their crystal phases.

Powdered X-ray diffraction (X'Pert Philips) with $\text{CuK}\alpha$ radiation (0.1540 nm) polychromator beam in the 2θ scan range 20–80 °C was carried to confirm the polymorphs of the composite materials from the SAED patterns. A step size and step time of 0.0170 (2θ) and 87.63 s was used at 40 kV and 40 mA instrument power settings. Raman data were recorded for further confirmation of the polymorphs of the composites. A Raman spectrometer, Raman Micro 200, PerkinElmer precisely used with a single monochromator, a holographic notch and a cooled TCD. The samples were exposed for 4 s during excitation using the 514.5 nm Ar^+ line. The Raman instrument was equipped with video imaging which permitted the image capture of the nanocomposites.

The Brunauer–Emmett–Teller surface area (S_{BET}) of the NPs was determined by nitrogen adsorption in a Micrometric ASAP 2020. The samples were degassed at 100 °C for 12 h prior to analysis. Isotherm evaluation was performed at ~ 77 K, and pore volume analysis was determined at (P/P_0) of ~ 0.98 .

Optical properties were recorded to understand on which part of the electromagnetic spectrum do the composites absorb and to elucidate the electronic structure of the composite materials using diffuse reflectance spectroscopy (DRS) and photoluminescence spectroscopy (PL). The UV-Vis spectra was recorded on a Shimadzu UV-2450 UV-Vis spectrophotometer, where BaSO_4 was used as a reference. The photoluminescence spectra were recorded using a LS 45 fluorescence spectrometer (PerkinElmer, precisely) at 242 nm wavelength.

Electrochemical measurements were conducted using Metro Autolab: Nova 2.0 potentiostat in a standard three electrode system using Ag/AgCl as a reference electrode, a Pt wire as a counter electrode and a working electrode fabricated using fluorine-doped tin oxide (FTO) glass with NPs pasted on the fluorine-doped side. The working electrodes were prepared by mixing the synthesized NPs with polyvinylidene fluoride (PVDF) in a ratio 10 : 1 respectively in 1 mL *N*-methylpyridine (NMP). The PVDF was used as a binder and the NMP as a solvent to form a homogeneous slurry. The slurry was then drop casted on the FTO glass and allowed to dry overnight at room temperature. Electrical connection to the potentiostat was facilitated by attaching a copper wire using silver paste which was allowed to dry in air for 24 h at room temperature. The electrochemical impedance spectroscopy (EIS) spectra was conducted at a frequency range of 100 kHz to 0.1 Hz at an AC voltage of 10 mV rms vs. E_{ref} .

The quantitative surface sensitive elemental analysis, valence band measurements were done using X-ray photoelectron spectroscopy (XPS). Measurement of XPS was carried out with a Thermo spectroscope, model ESCALAB 250Xi using a monochromator Al $\text{K}\alpha$ (1486.7 eV) as an excitation source at a working pressure of $<10^{-8}$ mBar.

Results and discussion

The texture and structural morphology of the as-synthesized pristine materials and optimum composite were observed *via* SEM and TEM imagery presented in Fig. 1. The images presented in Fig. 1(a) show the SEM image of MIL-125(Ti) which displayed circular oriented blocks. The sheet-like morphology of black phosphorus is shown in Fig. 1(b) and SEM imagery similar to the one reported has been presented before in literature, which confirmed the successful exfoliation of few layer black phosphorus.⁵ Fig. 1(c) presents the SEM images of the optimum composite (4%BpMIL) which clearly displayed the co-existence of circular blocked MIL-125(Ti) and sheet-like FLBP. The TEM pictorial illustrations are shown in Fig. 1(d–f) and they just re-affirm the individual morphologies of the pristine materials and the subsequent optimum nanocomposite. The SEM-EDS of the pristine and composite materials are presented Fig. S1–S5,[†] which highlighted especially for the nanocomposites, the presence of the elements: titanium, oxygen, carbon and phosphorus. The morphologies of the 6%BpMIL and 12%BpMIL composites are shown *via* SEM and TEM imagery presented in Fig. S6 and S7[†] these composites also exhibited circular blocks and sheet-like morphology comparable to 4%BpMIL confirming the presence of MIL-125(Ti) and BP respectively.

The polymorphs of the as-synthesized nanocomposites were elucidated through X-ray diffraction (XRD) presented in Fig. 2. The XRD patterns of MIL-125(Ti) were similar to one reported recently,²³ demonstrating the successful synthesis of this Ti oriented MOF.

The diffraction peaks of FLBP depicted in (e) at 16° and 34° are indexed to (020), (040) respectively (JCPDS no. 73-1358), suggesting successful exfoliation of FLBP.^{5,24} This also confirmed the orthorhombic structure of FLBP as presented by the SAED patterns from TEM imagery (Fig. 1(e)). Compared to MIL-125(Ti) and exfoliated BP, the composites exhibited MIL-125 and FLBP peaks which are denoted by the (*) and (#) respectively, indicating that a heterojunction was indeed successfully fabricated. The peaks (*) of MIL-125(Ti) in the

composites became more intense as the loading of MIL-125(Ti), suggesting the MIL-125(Ti) becomes dominant as the loading is increased. The appearance of new peaks between 22–26° may infer a new polymorph as the heterostructure was formed.

To probe the bond vibration of the pristine materials and the subsequent composites, Raman spectroscopy was conducted (Fig. 3). The terephthalic acid ligand makes MIL-125(Ti) Raman active and this evidenced by the bands indexed at 1618, 1455, 1181 and 1138 cm^{−1} which relate to the in-plane vibrational modes of the aromatic rings, whereas bands centered 865 and 641 cm^{−1} represent the vibrational modes of the C–H and C=C bonds of the aromatic rings.^{10,21,25} The variation for the Raman peaks further affirmed the successful synthesis of MIL-125(Ti). The Raman bands indexed at 363, 444 and 462 cm^{−1} corresponding to A_g¹, B_{2g} and A_g² Raman modes of FLBP as shown in Fig. 3(B).^{26–28} This confirmed that bulk BP was successfully exfoliated and it had a two dimensional layered structure. New peaks for the composite, a fusion of FLBP and MIL-125(Ti) complimented the data from XRD suggesting the formation of the heterojunction. Fig. 3(C) reveals that there was a slight overlap of the MIL-125(Ti) band with the B_{2g} and A_g² bands of FLBP at around 444 to 462 cm^{−1} highlighting the co-existence of FLBP and MIL-125(Ti) in the hybrids. The Raman images displaying the morphology of the synthesized nanocomposites are presented in Fig. S8.[†]

The N₂ adsorption–desorption isotherms of the nanocomposites are presented in Fig. 4 and the full data is depicted in Table S1.[†] The synthesized photocatalysts exhibited type IV isotherm which is characteristic of mesoporous nanoparticles. The isotherms also displayed H2 hysteresis loops indicating that the nanocomposites exhibit highly regular pore structures which may be attributed to the framework of MIL-125(Ti). The BET surface area of pristine MIL-125(Ti) is 285 m² g^{−1}, whereas the 4%BpMIL exhibited the lowest surface area of the hybrid nanocomposites. The decrease of the surface area may be attributed to the blockage of the MIL-125(Ti) pores by FLBP. This is further confirmed by the pore size and pore volume data which shows a reduction for all the nanocomposites compared to pristine MIL-125(Ti).

To confirm the elemental composition, chemical state and the formation of the composite, XPS analysis was conducted. Fig. 5(a–d) depicts the XPS spectra of 4%BpMIL together with the deconvoluted peaks of Ti, C and O. The full survey spectra of FLBP is shown in Fig. S9.[†] The full survey spectra of the optimum composite in Fig. 5(a) reveals the presence of Ti, C and O, however the presence of P was not observed which may attributed to MIL-125(Ti) being dominant in the composite. The P element was observed in the full spectra of FLBP shown in Fig. S9,[†] however it also appeared as a weak peak, which might explain why it disappears when MIL-125(Ti) is hybridised with FLBP. Fig. 5(b) presents the Ti 2p spectra which displays peaks centered at 458.5 and 464.4 eV, corresponding to Ti 2p_{3/2} and Ti 2p_{1/2} indicating that titanium bounded to oxygen exists in +4 oxidation state for titanium-oxo-clusters.²⁸ The C 1s spectrum in Fig. 5(c) was deconvoluted into three peaks attributed to C–O at 284 and 286.0 eV, and O–C=O at

Fig. 2 XRD patterns of (a) MIL-125(Ti) (b) 4%BpMIL (c) 6%BpMIL (d) 12%BpMIL and (e) FLBP.

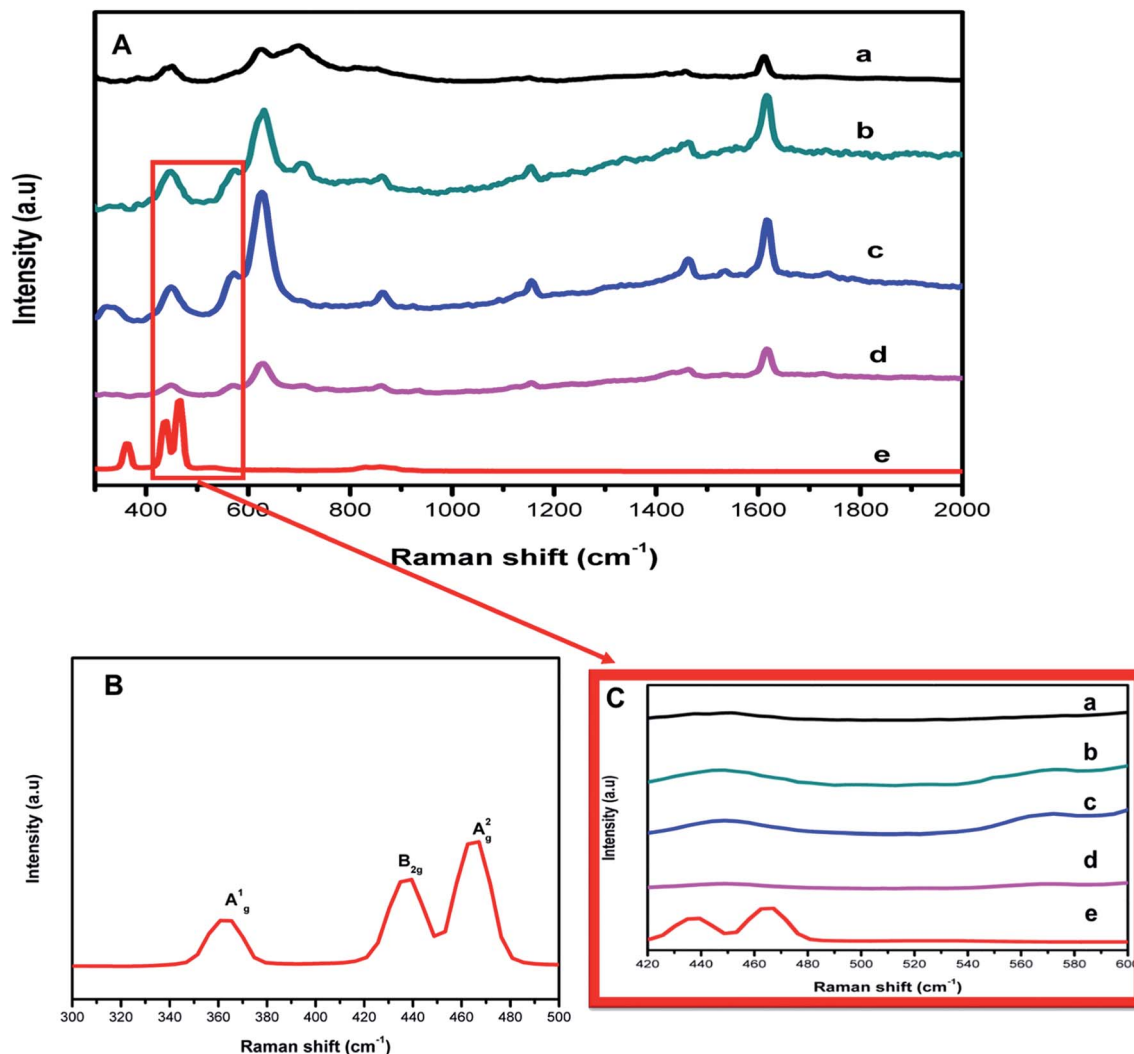

Fig. 3 (A) Raman bands of (a) MIL-125(Ti), (b) 4%BpMIL, (c) 6%BpMIL (d) 12%BpMIL and (e) FLBP. (B) Zoomed image of the Raman spectra of FLBP (C) zoomed image showing Raman bands in the composites.

288.4 eV. These peaks confirmed that MIL-125(Ti) was formed instead of TiO_2 . Fig. 5(d) depicts the O 1s spectrum of 4% BpMIL. The binding energy values at 529.8, 531.5 and 533.3 eV correspond to oxygen from Ti–O bond in the titanium-oxocluster, oxygen in hydroxyl groups and oxygen in carbonyl groups respectively.¹⁹ These results showed a discrepancy because of the absence of phosphorus, however the VBXPS data presented in Fig. 6 validated the formation of the heterojunction between MIL-125(Ti) and FLBP, as a red-shift was observed for 4%BpMIL (2.24 eV) compared to pristine FLBP (1.62 eV). These results revealed that the composite could be used for the evolution of oxygen from water. Furthermore this composite was expected to exhibit reduced recombination as XPS data gives more precise numerical values of valence band edge potentials of the composite.

UV-Vis DRS analyses (Fig. S10[†]) and Tauc plots (Fig. 7(a)) were used to probe the optical properties of the synthesized nanocomposites. These materials are indirect semiconductors, thus their band gaps were computed from DRS data by making use of (1).

$$\alpha h\nu = A(h\nu - E_g)^{n/2} \quad (1)$$

where α defines the absorption coefficient, h the Planck's constant, ν the light frequency, A is a constant, E_g represents the band gap and n is determined based on the type of optical transition of a semiconductor. As stated above, NPs are indirect semiconductors, thus $n = 2$.

The band gaps calculated from $h\nu(\text{eV}) = \frac{1240}{\lambda}$ on the Tauc plots are depicted in Fig. 7(a) with FLBP exhibiting the smallest band gap and 12%BpMIL the largest. It was observed that the band gap of the BpMIL intermediates reduced by 1.21 eV or less after formation of the composites compared with pristine MIL-125(Ti), hence inferring visible light response would be greatly enhanced upon application be it in water treatment or water splitting.

The composites exhibited an extended light absorption into the visible region and this was due FLBP serving as the visible light sensitizer. The combination of FLBP and MIL-125(Ti) to form heterojunctions leads to a red shift because of the

Fig. 4 Adsorption-desorption isotherms of (a) MIL-125(Ti), (b) 4%BpMIL, (c) 6%BpMIL and (d) 12%BpMIL.

synergistic effect between both materials. The red shift in wavelength gives insight that these composites can be utilised for visible light photocatalysts. The UV-Vis spectra supported the synergistic role of FLBP and MIL-125(Ti) as it revealed that FLBP was visible light responsive,²⁹ while MIL-125(Ti) is UV light responsive.³⁰

To substantiate the claim that heterojunction formation minimizes recombination rate, PL studies were conducted and the spectra is depicted in Fig. 7(b). The peak intensities in the PL spectra give an idea about the recombination rate of a material. More precisely, a sharp peak signifies fast recombination and flat peak represents inhibited recombination probability. FLBP displayed a flat peak, MIL-125(Ti) had a very sharp peak. However after hybridising the two materials, it was evident that all the composites displayed a reduced peak compared to MIL-125(Ti), suggesting that the formation of heterojunctions significantly reduced the recombination rate in the composites. The 6%BpMIL composite displayed the lowest recombination of all the composites.

The valence and conduction band potentials were calculated using (2) and (3) respectively

$$E_{VB} = X - E^0 + 0.5 E_g \quad (2)$$

$$E_{CB} = E_{VB} - E_g \quad (3)$$

where E_{VB} is the valence band potential, E_{CB} is the conduction band potential, E^0 is the energy of free electrons vs. normal hydrogen electrode, which is approximately 4.5 eV and X is the semiconductor electronegativity, computed from the geometric mean of the absolute electronegativity of constituent atoms.³¹ The electronegativity of MIL-125(Ti) and FLBP were computed to be approximately 6.58 eV and 4.67 eV respectively. The band positions of the pristine materials (Fig. S11†) and the composites (Fig. S12†) supported the PL data as discussed before.

The staggered alignment of the CBs and VBs are tailored for the separation of photogenerated electron and holes upon visible light excitation. This should allow the transfer of electrons from the CB (FLBP) to the CB (MIL-125(Ti)), while holes are shuttled from the VB (MIL-125(Ti)) to VB (FLBP). Resulting in the electrons being separated from the holes, thus inhibiting the recombination rate, thus affirming the composites should exhibit enhanced visible photocatalytic activity because of reduced recombination probability. The enhanced visible light response of MIL-125(Ti) could be attributed to its photochromic performance which is closely related to the intervalence electron transfer bands caused by the optically triggered shuttle of electrons from Ti^{3+} to Ti^{4+} sites in the titanium oxo-clusters of MIL-125(Ti).¹⁴ While on the other end FLBP acts as visible light sensitizer, absorbing electrons and then migrating to the Ti^{4+} sites in the titanium oxo-clusters due to the staggered band

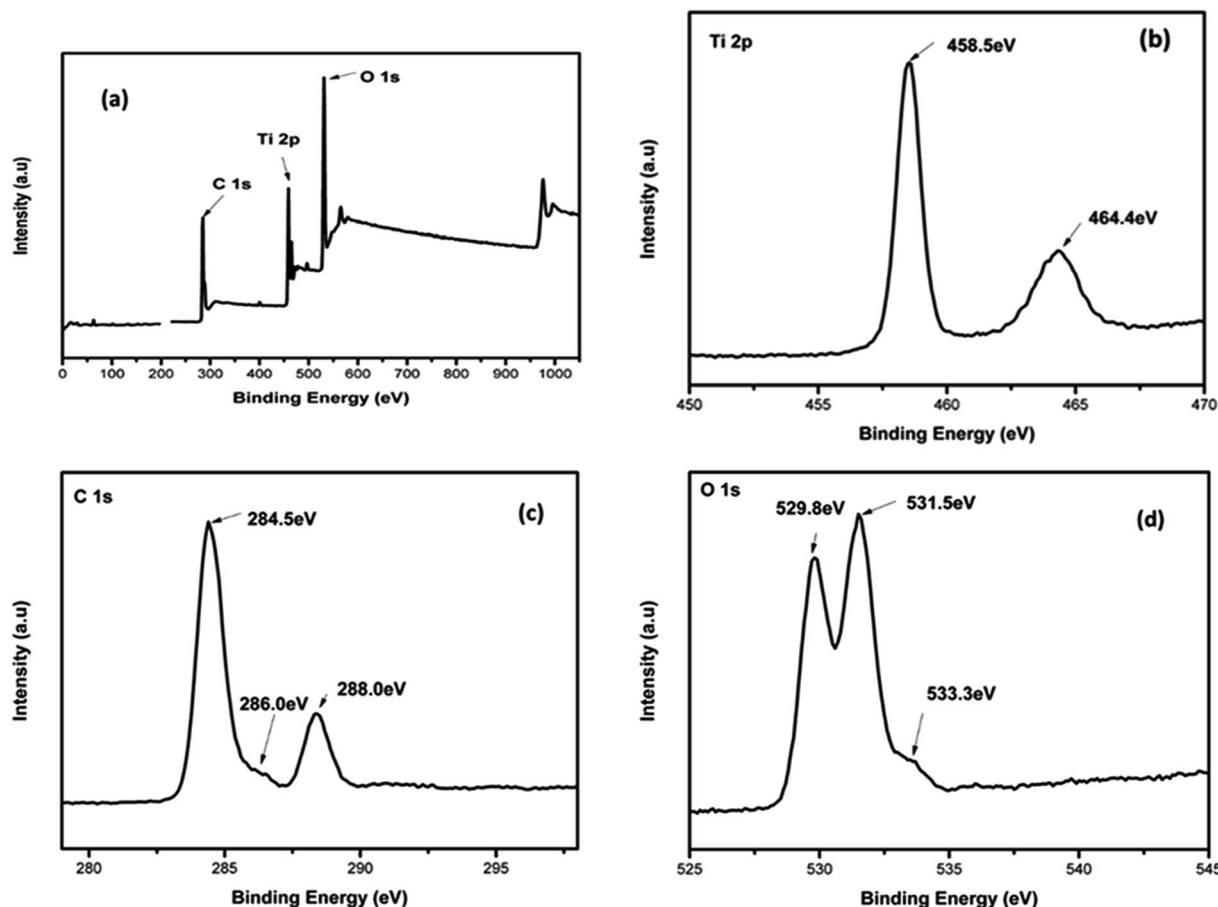

Fig. 5 The XPS spectra of 4%BpMIL composite; (a) a full spectrum (b) Ti 2p spectrum (c) C 1s spectrum and (d) O 1s spectrum.

Fig. 6 The VB XPS spectra of (a) FLBP and (b) 4%BpMIL.

alignment of the heterojunctions.³⁰ The Ti^{4+} is thus reduced to Ti^{3+} as a result of the intervalence electron transfer bands. In addition, the changes in energy levels of MIL-125(Ti) were possibly a result of the intervalence electron transfer band alignments in relation to the Fermi levels of FLBP which are near the CB, when the Schottky contact was formed. A plausible mechanism for the intervalence electron transfer is given by (4) and (5)

To validate the findings from photoluminescence studies, Mott-Schottky as deduced from the potentiostat were plotted using (6) to further validate the formation of the heterojunction.

$$\frac{1}{C^2} = \frac{2}{\varepsilon \varepsilon_0 e_0 N_D} \left(E - E_{\text{FB}} - \frac{kT}{e_0} \right) \quad (6)$$

where ε is the permittivity of the semiconductor electrode, e_0 is the elementary charge, N_D is the donor density, E the applied potential, E_{FB} the flat-band potential, k is the Boltzmann constant, T the temperature of operation and C is the space charge capacitance.

The Mott-Schottky plots are depicted in Fig. 8(A) and complemented the results from the PL (Fig. 7(b)) fairly well. The gradient of the plot of $1/C^2$ against E gives insight into the recombination of charge carriers.³¹ A small gradient after heterojunction formation represents reduced probability of recombination of charge transporters. The data presented in Fig. 8 suggests that the recombination rate decreases in the following order MIL-125(Ti) > 12%BpMIL > 6%BpMIL > 4%BpMIL > FLBP as supported by the PL findings. Pristine MIL-125(Ti) displayed a positive gradient which is characteristic of

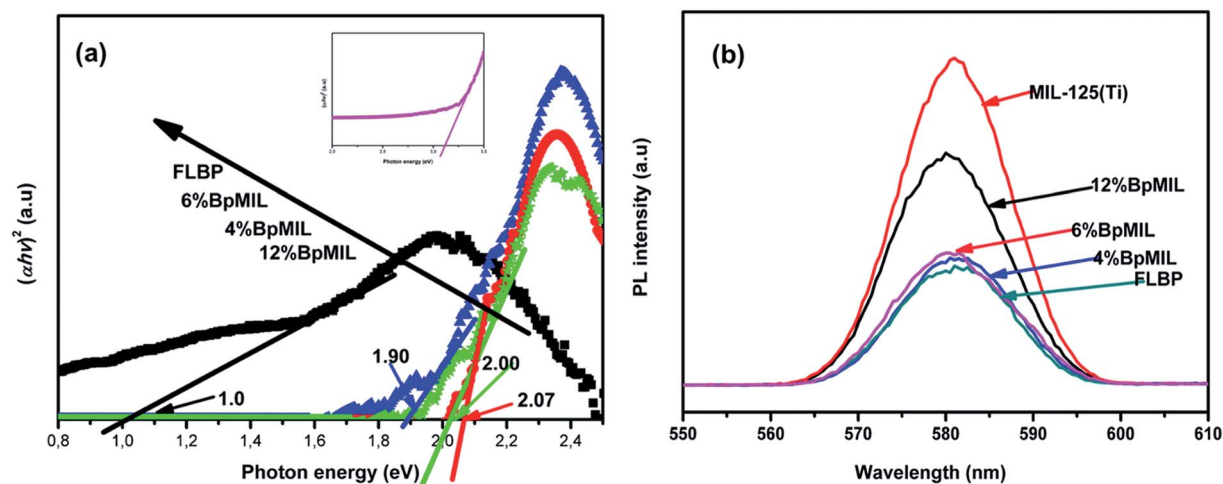

Fig. 7 (a) Tauc plots with MIL-125(Ti) (inset) and (b) PL spectra of synthesized NPs.

n-type semiconductors, however all the composites showed a negative slope which represents p-type semiconductivity.

Additionally, presented in Fig. 8(a–f), the flat band potentials (V_{FB}) of the pristine FLBP and MIL-125 were -0.90 V and 0.85 V respectively, signifying that the CB of FLBP would be positioned

above the CB of MIL-125(Ti) in a p–n heterojunction whereas the 4%BpMIL, 6%BpMIL and 12%BpMIL composites exhibited -1.40 V, -0.60 V, and -1.55 V respectively. The flat band potentials of the composite materials are more negative than that of FLBP, revealing that indeed the heterojunction

Fig. 8 (A) Mott–Schottky plots of (a) MIL-125(Ti), (b) FLBP (c) 4%BpMIL, (d) 6%BpMIL and (e) 12%BpMIL and (B) Nyquist plots of MIL and composites.

formation suppresses the recombination rate.³² Even though 6%BpMIL is more positive than FLBP, its negative flat-band potential still confirms that heterojunction formation inhibits recombination probability. The accompanying band positions are presented revealing the formation of the p–n junctions between p-type FLBP and n-type MIL-125(Ti). It is worth noting that the composites conformed to the FLBP semiconductor behaviour because FLBP is an excellent charge transporter, which has an impact on the reduction of recombination rate and is thus, propitious for photocatalytic activity.

Electrochemical impedance spectroscopy (EIS) studied for the viewpoint of Nyquist plots was used to probe the interfacial interaction between the photoelectrode and the electrolytes. Nyquist plots give insight into the recombination rates by studying the diameter of the semi-circles formed between the imaginary (Z'' (Ω)) and real (Z' (Ω)) parts of complex impedance. The interpretation of semi-circle provides information about the recombination rate in the sense that a small semi-circle diameter signifies small charge transfer resistance of the working electrode and therefore low recombination probability.³³

In other cases the Nyquist plot may have a semi-circle adjoined to another semi-circle or a nonvertical line at subsequent frequencies. The second semi-circle provides information on the roughness of the electrode. The first semi-circle represents the electrolyte resistance or the charge shuttle resistance whereas the non-vertical line signifies the ion transfer limitation in the electrolyte for porous electrode structures.³³

The Nyquist plots of the pristine and composite materials are displayed in Fig. 8(B). The recombination rate was observed to decrease in the order MIL-125(Ti) > 12%BpMIL > 6%BpMIL > 4%BpMIL > FLBP, which is the same data sourced from the Mott–Schottky plots. 4%BpMIL which was the optimum hybrid displayed the lowest charge resistance of all the composites which translates to the lowest recombination rate.

Furthermore, equivalence circuits and fitted circuits are presented in Fig. S13–S15† for the pristine materials and the optimum composite. The values of the charge transfer resistance R were found to be 61.3 Ω , 45.1 Ω and 49.7 Ω for MIL-125(Ti), FLBP and 4%BpMIL. This validates that heterojunction formation leads to efficient separation of charge carriers, however FLBP exhibited a lower R value than the composite underlining the fact that FLBP is an excellent charge transporter. The findings from the Nyquist plots further affirmed the results from PL and Mott–Schottky plots. The optical and electrochemical studies confirmed the successful fabrication of a p–n heterojunctions between FLBP and MIL-125(Ti). From the PL data, Mott–Schottky plots and Nyquist plots, we deduced that the 4%BpMIL composite as a visible light responsive heterojunction material exhibited reduced recombination rate and the effectual separation of charge carriers.

Conclusion

A series of MIL-125(Ti)/FLBP composites were synthesized using a two-step hydrothermal and sonication method by varying the

loading of MIL-125(Ti) while keeping the amount of FLBP constant. The results from different characterization data revealed that heterojunctions were successfully fabricated and they were all p–n type which is beneficial for the separation of photo-induced charge carriers. Furthermore, the optical and electrochemical data showed that the 4%BpMIL composite had the lowest recombination rate and fastest interfacial transfer as a result of FLBP and the formation of the p–n junction. Evidence of the formation of the heterojunction was substantiated by XPS data which showed a red-shift for the VB in the optimum nanocomposite. The positive shift indicates that the photocatalyst can be applied in the evolution of oxygen from water as a more positive VB is suited for water splitting into oxygen. The fabrication of 2D/MOF composites with new properties and applications can be utilized as visible light responsive materials.
