The function of metal–organic frameworks in the application of MOF-based composites

Luning Chen, Xibo Zhang, Xiqing Cheng, Zhaoxiong Xie,  Qin Kuang *
and Lansun Zheng

In the last two decades, metal–organic frameworks (MOFs), as a class of porous crystalline materials formed by organic linkers coordinated-metal ions, have attracted increasing attention due to their unique structures and wide applications. Compared to single components, various well-designed MOF-based composites combining MOFs with other functional materials, such as nanoparticles, quantum dots, natural enzymes and polymers with remarkably enhanced or novel properties have recently been reported. To efficiently and directionally synthesize high-performance MOF-based composites for specific applications, it is vital to understand the structural–functional relationships and role of MOFs. In this review, preparation methods of MOF-based composites are first summarized and then the relationship between the structure and performance is determined. The functions of MOFs in practical use are classified and discussed through various examples, which may help chemists to understand the structural–functional relationship in MOF-based composites from a new perspective.

1. Introduction

Metal–Organic Frameworks (MOFs) are crystalline porous materials formed by self-assembly of central metal ions or clusters with bidentate or multidentate organic ligands *via* coordination bonds.^{1–4} MOFs have extensively been investigated since their discovery in the early 1990s due to their highly ordered porosity, incredibly elevated internal surface areas, and adjustable structures. Hence, MOFs quickly became popular materials for almost twenty years.^{5,6} So far, great efforts have been devoted to the design and preparation of MOFs with new structures and functions, as well as exploration of their potential applications in various fields like gas adsorption/separation, catalysis, sensors, drug delivery, magnetic materials and optical devices.^{7–12} Unfortunately, in some cases, the performance of MOF materials is not very satisfactory, and there is still a long way to go in order to achieve enhanced practicality.¹³

Compared to traditional porous materials, MOFs are advantageous in terms of geometry and properties, where open channels in MOFs can be designed and finely adjusted using different metal nodes/organic ligands according to targeted applications.^{14,15} Due to their structural diversity and adjustability, MOFs are ideal host platforms for the immobilization or encapsulation of other functional materials, such as nanoparticles (NPs), quantum dots, polyoxometalates, enzymes, and

polymers.^{16–19} Interestingly, MOF composites always exhibit significantly enhanced or even novel properties when compared to single-component materials owing to the synergy between the materials.^{20–22} Technically, the catalytic activity of embedded NP catalysts could remarkably be enhanced due to the confined environment provided by the MOF cavities.^{23–25} By taking advantage of the barrier effect in MOF channels on the diffusion of foreign molecules, MOF composites could be designed as sensors with recognition of molecular size.^{26,27} In addition, it was found that fragile enzymes may exhibit excellent tolerability under harsh conditions while maintaining high activities after encapsulation in MOFs.^{28–30} Therefore, MOF-based composites have attracted increasing research interest, and great efforts have been devoted to the design and construction of various MOF-based composites in an effort to further enhance their performances and expand their applications. However, despite the great progress, achieving functionality between the MOF host and guest species is still challenging for specific applications of MOF-based composites. Hence, it is vital to identify the structural–functional relationship in MOF composites to efficiently and directionally synthesize specific MOF composites for particular applications.

Numerous excellent reviews discussing the synergistic effect between MOFs and other functional materials have so far been published.^{31–34} Most of them focused on the synthesis of MOF-based composites or their applications in catalysis or sensing fields.^{35–37} By contrast, the functions of MOF components determining their practical applications are still not well identified. In fact, some studies suggested that enhanced performances and expansion of MOF-based composite functions

Department of Chemistry, State Key Laboratory of Physical Chemistry of Solid Surfaces, College of Chemistry and Chemical Engineering, Xiamen University, Xiamen 361005, P. R. China. E-mail: qkuang@xmu.edu.cn; Tel: +86-592-2183047

essentially result from the unique internal structures and properties of MOFs instead of those of other incorporated functional materials.^{38,39} Therefore, it is important to clarify the role of MOFs in composites to better understand the relationship between the structure and function of MOF-based materials.

In this review, recent progress in MOF-based composites is summarized in an effort to clarify the structure–performance relationship of MOF-based composites, with particular emphasis on the functions of MOF components for practical applications. Common fabrication methods of MOF-based composites with their advantages and disadvantages are first introduced. Then, the influence of internal composition, structures and properties, as well as external encapsulation status characteristics of MOFs on the performance of composites is then discussed according to the functions of MOF components in applications of MOF-based composites. Finally, current challenging issues of such composites are presented and analyzed. We believe that the review will provide a better understanding of MOF-based composites for better-controlled construction and application to further stimulate the interest of chemistry enthusiasts.

2. Construction methods of MOF-based composites

The application performances of MOF-based composites are closely related to the MOF intrinsic structure, as well as composite apparent morphology and structure. To construct MOF-based composites, numerous synthetic methods have so far been developed, which could be divided into five types: (i) surface modified encapsulation, (ii) *in situ* generation in MOF's cavities, (iii) self-sacrificed template method, (iv) step-by-step construction of the sandwich-like heterostructure, and (v) one-pot synthetic method (Scheme 1).

2.1. Surface modified encapsulation

The encapsulation method, also called “build-bottle-around-ship”, is based on two main steps: (i) NPs with uniform size, structure and morphology are prepared; (ii) MOF shells are grown on presynthesized NPs. Generally, great lattice structure barriers between MOFs and encapsulated materials often exist, leading to self-nucleation of MOFs instead of forming the encapsulation structure. To overcome such barriers, structure-flexible materials have been used bridges to connect MOFs with encapsulated materials. For instance, Huo *et al.* and Tsung *et al.* subsequently modified NPs with surfactants PVP and CTAB to compensate the lattice mismatch at NP@MOF interfaces (Fig. 1).^{40–42} Using such organic surfactants, MOFs could easily nucleate on the NP surface. Besides surfactants, some metal oxides or hydroxides could be employed to modify NPs and grow MOFs.^{43–45} Using encapsulation, NPs with various morphologies and sizes can be encapsulated within MOF shells. Apart from NPs, some other functional materials, including carbon materials, molecular catalysts, enzymes and so on, as well can be embedded in MOF cavities *via* this method.^{30,46,47}

Scheme 1 Main approaches used for the construction of MOF-based composites.

Unfortunately, the activity of embedded NPs reduced to some extent due to the presence of surface capping agents or metal oxide layers. Furthermore, the complicated interfacial structures make it challenging to study the structural–functional relationship in these composite materials.

2.2. *In situ* generation in MOF cavities

The “ship-in-a-bottle” is another common approach to construct MOF-based composites. Using this method, MOFs are first synthesized. Precursors of the embedded material are then introduced into MOF cavities by diffusion or other ways followed by *in situ* transformations of desired materials in the MOF cavities *via* chemical reduction, photoreduction or thermolysis, among others.^{48–51} The challenge of this synthetic route is to restrict the formation of embedded materials inside the MOF matrix and not on their surfaces. Xu *et al.* developed a double-solvent method to solve this problem, in which all precursors were made to diffuse into MOF cavities.⁴⁸ MIL-101 is selected as a favorable host material to construct a NP-embedded structure due to its high stability, elevated pore volume, and two large hydrophilic cavities. To this end, MIL-101 was first dispersed in a hydrophobic solvent (hexane). Precursors dissolved in the hydrophilic solvent (water) were then added to *n*-hexane. The hydrophilicity of MOF cavities led to adsorption of the precursors dissolved in water in the cavities to

further *in situ* transform into desired materials (Fig. 2a). Note that this double-solvent strategy is not only applied to the *in situ* generation of monometallic NPs in MOF cavities, but also to bimetallic alloys and core-shell structures (Fig. 2b).^{52–54} Apart from the double-solvent approach, precursors can controllably diffuse into the MOF cavities by other methods, such as solution impregnation, chemical vapor deposition, and solid grinding.^{55,56}

Without modification with organic surfactants, such as CTAB and PVP, NPs embedded by the *in situ* generation method have shown clean surface topographies. In addition, NPs restricted by MOF cavities looked very small and uniform in size, beneficial for practical applications. Strikingly, NPs with some special structures and compositions can readily be produced by an *in situ* reaction in MOF cavities acting as nanoreactors under mild conditions. For instance, Zhou *et al.* fabricated uniform truncated octahedral face-centered-cubic (*fcc*) ruthenium (Ru) NPs with exposed {111} and {100} planes, which is often difficult to form by traditional approaches, using a truncated octahedral inner cavity (diameter 2.5 nm) of a porous coordination cage (PCC-2) as the nanoreactor.⁵⁷ The obtained unique structure of Ru NPs yielded high catalytic activities towards methanolysis of ammonia borane (Fig. 3). Furthermore, the authors successfully constructed super reactive cobalt nanoclusters in highly negatively charged porous

coordination cages (PCC-2a) *via in situ* reduction.⁵⁸ Chen and Zhou *et al.* applied ZIF-8 cavities as a confined template to form sub-2 nm atomically ordered intermetallic PdZn NPs by a co-reduction method.^{59–61}

Nevertheless, *in situ* generation still suffers from some problems. Firstly, the formation process of embedded materials may destroy the internal structures of MOF templates to some extent. In addition, the morphology, surface structure and

density of embedded materials cannot well be controlled, thereby not conducive to understanding the structure–performance relationship of MOF-based composites.

2.3. Self-sacrificed template method

For MOF-based composites, it is very important to control the encapsulation status of embedded materials within the MOF matrix finely, which will significantly affect the practical performances, especially in catalysis and sensing. Although many construction methods of well-defined NP@MOF composites have been attempted, finding generalized routes is quite challenging. The nature of solid reaction and relatively slow kinetics makes the self-sacrificed template strategy effective for the fabrication of core–shell or hollow nanostructures.^{26,62–64} The key to the successful fabrication of NPs@MOF composites by using a self-sacrificed template is to find appropriate template materials and reaction conditions, in which the release rate of metal ions from the template must match the coordination rate with organic linkers to guarantee the formation of the MOF shell on the self-sacrificed template surface instead of solution. Our group was the first to apply the self-sacrificed template method to fabricate metal oxide semiconductor@MOF composites, where ZnO nanorods did not only act as template but as a Zn source for the formation of ZIF shells (Fig. 4a–c).^{26,65} The self-sacrificed template method is simple and universal, where both metal oxides and alloys containing transition metals can be utilized as template materials.^{66–68} For example, Wu and Li *et al.* employed PtNi alloy NPs as template to successfully fabricate PtNi@MOF-74 composites *via* a coordination-assisted oxidative etching process (Fig. 4d).⁶²

Compared to other approaches, the self-sacrificed template route suffers from some limitations when it comes to template selection, but it provides a possible route to finely control the

structure, thickness and morphology of MOF shells. For example, in the nanoflower-like RhNi@MOF-74(Ni) synthesis, our group successfully controlled the thickness of the MOF shell by tuning the Ni content in the self-sacrificed RhNi alloy template.⁶⁶ Furthermore, we used 2-methylimidazole or 2,5-dihydroxyterephthalic acid as etching agents to selectively dissolve Ni or Co elements of RhCoNi ternary alloy NCs to respectively form MOF-74(Ni) and ZIF-67(Co) shells on the alloy surface.⁶⁷ Due to great differences between the two obtained MOF shells in terms of aperture/cavity size, the as-prepared composites looked promising as versatile platforms to systematically study the relationship between performance of composites and structure of MOF shells. Moreover, multi-component MOF shells can be realized by introducing another metal source during the formation of MOFs.⁶⁹

Apart from constructing MOF-based composite nanoparticles, the self-sacrificed template method was also applied to fabricate some MOF film-based devices in sensor or catalysis applications.^{70–72} For example, the ZnO@ZIF-CoZn gas sensor was prepared by coating a layer of ZIF-CoZn thin film on a ZnO nanowire array *via* a self-sacrificed template method. In addition to the dissolved Zn²⁺ from the ZnO nanorod, foreign Co²⁺ was also involved in the synthesis of ZnO@ZIF-CoZn, leading to the formation of the dual metal MOF thin film on the ZnO nanowire array (Fig. 5).⁷³

Thus, excellent controllability of the self-sacrificed template method provides more space to achieve different structured MOFs on the NP catalyst surface, facilitating in-depth exploration of the structural–functional relationship in MOF-based composites.

2.4. Step-by-step construction of the sandwich-like heterostructure

As mentioned above, restricting the formation of functional materials inside or outside MOF matrices is often challenging. The random distribution of functional NPs in the MOF matrix does not only lead to poor practical repeatability of MOF-based composites but also greatly affect the analysis of the relationship between real structure–function. To solve this problem,

Fig. 5 Schematic illustration of the preparation of ZnO@ZIF-CoZn gas sensors. Reproduced with permission.⁷³ Copyright©2016 WILEY-VCH Verlag GmbH & Co. KGaA.

Tang *et al.* fabricated MOF-supported metal catalysts by growing additional MOF layers on the catalysts to form a sandwich-like structure.^{23,74,75} They first synthesized MIL-101 loaded with Pt NPs and then epitaxially grew another MIL-101 shell with a different thickness outside the as-prepared Pt@MIL-101 particles.²³ As a result, all Pt NPs were embedded in the very thin MIL-101 layer, which did not affect the diffusion of substances (Fig. 6). The resulting MIL-101@Pt@MIL-101 sandwich-like catalysts exhibited high selectivity towards the hydrogenation of the C=O functional groups of α,β -unsaturated aldehydes. Note that thickness of the outer MOF shell in sandwich-like heterostructures plays a crucial role in the overall catalytic performance. Thick shells will restrict the diffusions of reactants and products, thereby reducing the reaction conversion significantly although selectivity should be improved to the same extent.⁷⁵

2.5. One-pot synthetic method

Each of the above-mentioned methods involves multiple steps. In fact, a few examples demonstrated that MOF-based composites can directly be produced in one step. For example, Liu and Tang *et al.* synthesized Au@MOF-5 by directly mixing Au precursors with MOF-5 precursors.⁷⁶ Using one-pot synthesis, the Au precursor was first reduced to Au NPs by dimethyl formamide (DMF), and then MOF-5 spontaneously grew freshly formed Au NP surfaces to yield core-shell structures. One-pot synthesis relies on rationally manipulating the reduction rate of metal ions and/or growth rate of MOFs. Accordingly, Luque and Li *et al.* succeeded to control the encapsulation of “clean” Pt clusters within UiO-66 by a novel kinetically modulated one-step strategy with the assistance of a H₂ reducing agent (Fig. 7).^{77,78} The success of their method was closely related to that using a DMF solvent. For the formation of Pt/UiO-66 composites, DMF and its trace oxidization product (Me₂NCOOH) would act as a “bridge” for connecting MOF precursors to as-reduced Pt clusters, thereby inducing the

anisotropic growth of MOFs around the Pt surface. However, unfortunately, one-pot synthesis is not a universal strategy despite being very simple and efficient.

3. Functions of MOFs in application of MOF-based composites

To gain a better understanding of performance enhancement of MOF-based composites in practical applications such as catalysis, sensors, adsorption and separation, the roles played by MOF components should be clarified. Thus, the actual functions of MOF components are discussed through specific reported examples.

3.1. MOFs as armors to protect embedded catalysts

In the catalytic process, the size effect of catalysts has been extensively investigated. With the decrease of particles in size, more active sites will be exposed, resulting in significantly enhanced activity using ultra-small NPs compared with larger NPs.^{79–81} However, under real reaction conditions, NPs always prefer to agglomerate to reduce their surface energy, inevitably leading to declined catalytic efficiency. For encapsulation of nanocatalysts within the MOF, the MOF shell may act as an armor to protect the encapsulated NPs from agglomeration. Meanwhile, owing to the adjustable porous structure, the

reaction substrates could still diffuse through the MOF shell to active sites. Li and Jiang *et al.* developed a highly efficient heterogeneous MOF-supported Pd catalyst for water-mediated Suzuki–Miyaura and Ullmann coupling reactions.⁴⁹ The clean surface and ultra-small size of Pd NPs yielded catalysts with high catalytic efficiency towards all substrates, including aryl chlorides, very stable reactants. Strikingly, the MOF shell armoring around Pd NPs led to stable catalysts with negligible metal loss and activity decrease after many cycles. Xu and co-workers successfully immobilized ultrafine Pt NPs into MIL-101 pores by the double-solvent method.⁴⁸ The MOF shell armoring around Pt NPs resulted in composites with high activity and stability towards liquid-phase ammonia borane hydrolysis, solid-phase ammonia borane thermal dehydrogenation, and gas-phase CO oxidation. In addition to ultra-small NPs, sub-nanometer clusters might also be immobilized through fabrication of the MOF armor outside to improve stability under reaction conditions.^{82–85} Pardo and co-workers chemically synthesized sub-nanometer Pt₂ clusters within thioether-functionalized MOF channels to overcome problems linked to synthesis and stabilization.⁸⁴ The obtained Pt₂-MOF materials efficiently catalyzed a series of hydrogenation reactions, including NH₄CN synthesis at room temperature, CO₂ hydrogenation at a low temperature (<140 °C), and alkene hydrogenation at 60 °C. Besides, their strategy can be employed to stabilize relatively unstable functional materials. For instance, cuprous oxide (Cu₂O) is an abundant and environmentally friendly catalyst in many application fields. However, the poor stability limited its further application, especially in solution. Hence, Ma and Cheng integrated Cu₂O NPs into ZIF-8 *via* a template protection–sacrifice (TPS) method.⁸⁶ The resulting yolk–shell structure showed excellent catalytic efficiency towards 4-nitrophenol hydrogenation. After five cycles, the conversion rate after a 20 min reaction still reached 98%, suggesting that the MOF (ZIF-8) shell effectively protected Cu₂O cores from inactivation during catalysis and promoted the recycling stability (Fig. 8).

As natural nanocatalysts, enzymes have long attracted scientists' intense attention because of their excellent selectivity, specificity, and activity. However, enzymes suffer from poor stability and reproducibility, as well as high sensitivity to environmental changes, such as temperature, pH, and presence of toxic chemicals. These factors hinder enzyme usage, especially in industrial applications. Using MOFs as armors provides a promising method to improve the stability and anti-interference ability of enzymes while maintaining their high reactivities.^{87–89} Tsung *et al.* employed a *de novo* approach to embed catalase into ZIF-90.^{28,29} The resulting MOF-shell did not only prevent catalase leaching but also provided size-selective shelter that increases the enzyme tolerance against protease with a bigger size than that of catalase. In addition, the stability of immobilized enzymes in MOF shells was much higher than that of free enzymes under denaturation media, such as organic solvents and extreme temperature/pH. Further studies have shown that an increase in stability against solvent and thermal conditions has been attributed to confinement of enzymes within MOFs. This, in turn, declines conformation changes of

Fig. 8 (a) Schematic illustration of synthesis of the Cu₂O@ZIF-8 composite, and (b) catalytic reduction equation of 4-nitrophenol to 4-aminophenol using Cu₂O@ZIF-8. Reproduced with permission.⁸⁶ Copyright©2018 WILEY-VCH Verlag GmbH & Co. KGaA.

enzymes and enhances their structural rigidity. For example, examination of stabilities of CAT@ZIF-90 and free CAT under urea and a denaturing reagent and at a high temperature (80 °C) showed that exposure to 0.05 M urea decreased the activity of free CAT to 3.5% while that of CAT@ZIF-90 reduced to only 85.5%. Surprisingly, CAT@ZIF-90 still maintained high activity at a urea concentration of 6 M. The structural conformation of embedded CAT has been further studied by fluorescence spectroscopy and the results were consistent with the above experiments (Fig. 9). Zhou and co-workers tested the catalytic efficiency and recyclability of horseradish peroxidase, cytochrome c and microperoxidase-11 encapsulated in PCN-333(Al, Fe) under harsh conditions. The results showed that the catalytic activities of encapsulated enzymes remained almost unchanged after several cycles.⁹⁰

In fact, employing MOFs to protect the embedded materials has been applied for encapsulation of some molecular catalysts. For example, a ruthenium complex molecule catalyst, (^tBuPNP) Ru(CO)–HCl (^tBuPNP = 2,6-bis((di-*tert*-butylphosphino)methyl)pyridine) was successfully embedded in UIO-66 (namely Ru@UIO-66) *via* an aperture-opening process.⁴⁷ Compared to an analogous homogeneous catalyst, the heterogeneous Ru@UIO-66 catalyst can not only maintain high catalytic activity of CO₂ hydrogenation to formic acid but can also be recycled five times without structural decomposition or catalyst poisoning. These features have been attributed to protective aspects of the MOF shell.

3.2. MOFs as filter membranes to screen substrates

MOFs possess uniform and adjustable pore structures, and thereby are widely used as filter membranes for gas separation due to the channel screening effect.⁹¹ Such functions are also utilized in practical applications of MOF-based composites in sensors or selective catalysis.

In the sensor field, sensing materials with MOFs as shells are usually used as artificial mimetic enzymes to detect specific molecules. During the sensing process, MOFs often act as filter membranes to allow specific molecules to access the surface of embedded sensing materials to generate signals while blocking other incomparable interfering substrates. We previously employed ZnO nanorod arrays as self-sacrificed templates to form ZnO@ZIF-8 core-shell nanorod arrays.²⁶ Note that ZnO is commonly employed as a semiconductor material in photoelectrochemical (PEC) detection. However, ZnO can respond to all hole scavengers during PEC detection due to its high sensitivity, limiting its application in the detection of specific molecules. In ZnO@ZIF-8 core-shell nanorod arrays, ZIF-8 shell plays the role of a molecular size filter to allow smaller sized molecules (H_2O_2) than ZIF-8 (aperture size of 3.4 Å) to pass through the MOF shell and be captured by photogenerated holes on a ZnO surface to produce an enhanced PEC signal. By contrast, bigger size molecules (AA) did not have a similar effect and they could block MOF channels, leading to declined PEC signals (Fig. 10a–c). Furthermore, we constructed a series of

Fig. 10 (a) Schematic illustration of the PEC sensor with good selectivity towards H_2O_2 . (b) Low-magnification TEM image, HAADF-STEM image, cross-sectional compositional line profiles and elemental maps of ZnO@ZIF-8 nanorods. (c1 and c2) Photocurrent response of ZnO and ZnO@ZIF-8 nanorod arrays. Reproduced with permission.²⁶ Copyright©2013 American Chemistry Society. (d) Schematic illustration of the ZnO@ZIF based PEC sensor (ZnO@ZIF-7 vs. ZnO@ZIF-71) with molecular size selectivity. Reproduced with permission.⁶⁰ Copyright©2016 The Royal Society of Chemistry.

ZnO@ZIF nanorod arrays with different MOF shells (ZnO@ZIF-7 and ZnO@ZIF-71).⁶⁵ According to PEC detection results, the flexibility of the MOF structure can easily be judged by the PEC response of the sensor towards different sized molecules (Fig. 10d). Moreover, this effect of the MOF shell may also be applied in fluorescence, electrochemical, gas or Raman sensors.^{73,92–94}

The size screening effect of MOFs has well been demonstrated in some size-dependent catalytic systems. Molecules with the same functional groups but different molecule sizes are often employed to test this effect. In the hydrogenation reaction, Jiang's group perfectly demonstrated the enhancement of size-selectivity depending on the size of MOF pores by using different sized olefins. They successfully prepared Pd nanocube@ZIF-8 catalysts with a well-defined porous structure and uniform pore size MOF shell acting as molecular sieves to screen molecules of different sizes.^{27,44} For example, 1-hexene with a molecular size of *ca.* 2.5 Å passed well through the ZIF-8 shell and was totally hydrogenated within 90 min. By contrast, the Pd nanocube@ZIF-8 catalyst exhibited negligible activity towards cyclooctene with a molecular size of 5.5 Å as it is larger than ZIF-8 pores (Fig. 11). Straight-chain molecules and corresponding aromatic molecules with the same functional groups

Fig. 11 (a) Self-assembly of Pd nanocube@ZIF-8 and plasmon-driven selective hydrogenation catalysis of olefins. (b1 and b2) Selective catalytic performance of the Pd nanocube@ZIF-8 catalyst. Reproduced with permission.²⁷ Copyright©2016 WILEY-VCH Verlag GmbH & Co. KGaA.

have also been used as comparative groups to confirm the role of MOFs as a filter membrane. For instance, Wang and Su *et al.* utilized a silica mediated sacrificial template strategy to synthesize yolk-shell structured Au@ZIF-8 nanoreactors.⁹⁵ The as-obtained ZIF-8 shell acted as size-selective filter allowing the passage of smaller sized reactants (1-butanol and 1-hexanol) arriving at Au NPs while blocking 3-phenylpropanol containing benzene groups larger than the ZIF-8 aperture. The as-prepared Au@ZIF-8 nanoreactors delivered excellent size selectivity during catalytic oxidation of alcohols with different molecular sizes. This size selectivity presented in MOF-based composites in turn confirmed completely embedding of the catalysts in the MOF shell instead of its surface.^{39,45,96,97}

Besides the size selection effect, other factors, such as specific interaction with certain molecules and hydrophobicity of MOF pores, also play important roles in the application of MOF based composites.⁹⁸ For example, Xu's group successfully fabricated van der Waals heterostructured Cu-TCPP-on-Cu-HHTP thin films on the sensor device, in which the Cu-TCPP top layer can selectively suppress the penetration of NH₃ due to strong interactions with polar gas molecules. Benefiting from the novel structure, a molecular sieving Cu-TCPP layer on a chemiresistive sensing Cu-HHTP layer, the as-prepared device realized the highest response to benzene of all reported room temperature chemiresistive sensing materials and reversed the selectivity of Cu-HHTP toward benzene and the strongly interfering molecule, NH₃.⁹⁹

3.3. MOFs as steric modulators to control the over adsorption state of reaction substrates

In addition to filters to screen out molecules with different sizes, MOF shells grown on NPs could act on selectivity by controlling the adsorption state of reaction substrates on the

catalyst surface. To obtain target products, previous studies focused on controlling the adsorption state of reactants by adsorbing large steric molecules or constructing porous shells on active site surfaces.^{100,101} Compared to traditional porous materials and simple molecular adsorption, MOF shells may provide adjustable space to construct suitable cavities to control the adsorption state of reaction substrates.

For selective hydrogenation reactions over MOF-based composite catalysts, cinnamaldehyde (CAL) is often used as a model molecule. CAL molecules containing α,β -unsaturated aldehydes with two hydrogenated sites are usually hydrogenated on "C=O" and "C=C" bonds simultaneously due to their flat adsorption on the NP surface using traditional catalytic processes (Fig. 12a).¹⁰²⁻¹⁰⁴ After modification of NPs with the MOF shell, CAL molecules would prefer to adsorb vertically on the NP surface containing aldehyde groups ("C=O") due to the confinement effect of MOF channels. Hence, CAL molecules are favorable for the selective hydrogenation to cinnamic alcohol instead of other products. This effect is also manifested in the selective synthesis of other α,β -unsaturated aldehydes and alkanes in the presence of MOF-based heterostructure

Fig. 12 (a) Reaction paths of CAL hydrogenation. (b) Schematic illustration of hydrogenation of CAL on Pt NPs embedded within flexible ZIF-8 and rigid ZIF-71, respectively. KGaA.

catalysts.^{69,105–108} It is worth noting that the inherent structure of MOFs, including cavity size and structural flexibility, would also influence the catalytic effect caused by the special adsorption state of reactants in MOF channels. For example, Huo *et al.* encapsulated Pt NPs within MOFs (ZIF-8 and UIO-66) containing different pore sizes. Their data showed that a suitable size of the MOF channel can effectively prevent the rotation of molecules, improving the catalytic selectivity.¹⁰⁹ On the other hand, we used flexible ZIF-8 and rigid ZIF-71 to encapsulate Pt NPs and studied the influence of MOF structure flexibility on the catalytic selectivity. Compared to flexible ZIF-8, rigid ZIF-71 as a shell may significantly improve the selectivity (Fig. 12b and c).⁷⁵

In addition to star model molecule CAL, such composite catalysts have also been extensively applied in other selective catalytic processes.^{62,110–112} For semi-hydrogenation of alkynes, Li and co-workers used a Pd embedded hollow Zn/Co-ZIF (Pd@H-Zn/Co-ZIF) as a catalyst for acetylene hydrogenation. Unlike naked Pd NPs, acetylene could be hydrogenated over a Pd@MOF hybrid catalyst to form ethylene instead of ethane in the presence of MOF shell.^{113,114} In addition, flower-like RhNi@MOF-74 catalysts for hydrogenation of diphenylacetylene have been successfully prepared, in which Rh–Ni alloy nanoflowers were encapsulated within MOF-74(Ni) shells of different thickness.⁶⁶ Note that the size of the semi-hydrogenated product (*cis*-diphenylethene) is similar to that of the MOF-74 aperture. Hence, its generation on the RhNi surface would inhibit *cis*–*trans* isomerization and further hydrogenation reactions by MOF shells. As a result, diphenylacetylene in the presence of the catalyst can be selectively hydrogenated to the *cis*-product instead of *trans*-product that is thermodynamically preferred.

Since Kim and co-workers first used MOFs in asymmetric catalysis, MOF-based materials have been since applied to asymmetric heterogeneous catalysis owing to their confinement effect.^{115–117} In 2005, Lin's group designed for the first time a homochiral MOF for asymmetric catalysis by introducing a privileged chiral ligand into the MOF structure to yield a high ee 1,1'-bi-2-naphthol (BINOL) product^{116,118,119} In addition, Hupp *et al.* designed a homochiral MOF with another category of chair catalysts (Mn(salen)) for asymmetric epoxidation.^{120–122} In 2015, Qi *et al.* synthesized two new polyoxometalate (POM)-based MOFs: ZnW-PYI1 and ZnW-PYI2, respectively.¹²³ This special composite proved to perform as an effective asymmetric catalyst for conversion of carbon dioxide to cyclic-carbonates in presence of *L*-BCIP (*L*-*N*-*tert*-butoxycarbonyl-2-(imidazole)-1-pyrrolidine) in MOF pores by controlling the orientation of substrate moieties in the reaction medium (Fig. 13).

3.4. MOFs as sponges to enrich reactants

With tunable structure, high surface area and functional group modified organic ligands, MOFs have been intensively investigated as ideal artificial sponge materials for selectively enriching some specific reactants.^{2,124} As a result, MOF-based composites have been widely applied in catalysis, adsorption separation and sensing, among others.

Fig. 13 Synthesis of MOF and a tandem catalytic process of asymmetric cyclic carbonate transformation from olefins and carbon dioxide. Reproduced with permission.¹²³ Copyright©2015 Nature Publishing Group.

As an excellent hydrogen storage material, some MOFs exhibit specific adsorption to hydrogen, which can be employed to improve the catalytic performance of hydrogenated reactions.^{125,126} Wu and Li *et al.* reported a novel Pt–Ni frame@Ni-MOF-74 frame structure prepared by the self-sacrificed template strategy.⁶² Since the 'breath shell' of Ni-MOF-74 could enrich the hydrogen molecules, the as-prepared catalysts showed high reactivity towards the hydrogenation reaction. Strikingly, microporous Ni-MOF-74 grown on a Pt–Ni frame surface can also be used as a molecular sieve with excellent molecular-size selectivity towards different reactants.¹²⁷ In addition, some MOFs are ideal materials for CO₂ absorption due to the presence of abundant Lewis acids. Such properties should improve the catalytic efficiency of MOF-based composites during CO₂ reduction processes.^{128–130} For example, Xiong and co-workers proposed a Cu₃(BTC)₂@TiO₂ core-shell structure for CO₂ photocatalytic reduction.¹³¹ The synergy between TiO₂ microporous shell producing excitons and MOF microporous core capturing gas molecules led to a dramatic enhancement in activity and selectivity of CO₂ photocatalytic reduction to CH₄ (Fig. 14).^{132,133}

Apart from gas-phase reactions, this effect can also be reflected in liquid-phase reactions. For example, core-shell Ag@ZIF-8 nanostructures have been reported for renewable

adsorptive separation of low concentrations of butanol from aqueous media under solar light irradiation.¹³⁴ The selective hydrophobic interaction between butanol and ZIF-8 induced Ag@ZIF-8 composites with high adsorption capacity of low concentration butanol from aqueous solutions. The surface plasmon resonance allowed the Ag core to generate heat under solar light irradiation, leading to butanol release from the ZIF-8 shell (Fig. 15). In addition, the adsorption and separation effect of MOFs has been further confirmed in other environmental fields, such as water purification and dye absorption.^{135–138} Moreover, after loading some fluorescent molecules, accompanied by the enrichment effect of the MOF structure, these kinds of composite structures are employed in the detection of heavy metal ions and some other molecules as well.^{139–141}

3.5. MOFs as catalysts to provide other active sites

In catalysis, MOFs are promising heterogeneous catalysts due to the presence of unsaturated coordinated metal sites and/or special functional groups of ligands. The active sites are highly dispersed on both the external and internal surfaces of the MOF matrix due to its unique framework structure built with metal nodes and organic linkers. However, metal nodes in the framework of some MOFs are fully coordinated with organic linkers, leading to lack of uncoordinated active sites for reaction. Two common approaches are used to solve this problem. First, special treatment of MOFs (such as heating under vacuum and linker exchange) is required to activate the metal nodes by removing weak-coordinated linkers or solvents (Fig. 16a).^{142–144} In addition, the apparent morphology of MOF crystals should be regulated elaborately through transformation into two-dimensional nanostructures (*e.g.*, metal-organic monolayer, MOL) to expose more unsaturated coordinated sites (Fig. 16b).^{145–149} On the other hand, well-designed catalytic sites can be anchored onto the organic linkers of MOFs by

introducing specific modification ligands, such as porphyrin, dipyrindine, and *N,N*-dimethylaniline (Fig. 16c and d).^{150–159}

Since highly dispersed active sites are present on MOFs, MOF-based composites with other embedded functional catalysts possess great potentials in tandem reactions. This could better be achieved if synergic catalysis of the MOF matrix and embedded materials is rationally engineered. In most cases, designable functional organic ligands always act as additional Lewis acid or base reactive sites during catalysis. Among these catalysts, amino-modified MOFs have widely been studied, in which –NH₂ groups did not only stabilize NPs but also served as active sites in some reactions.^{160,161} For formic acid dehydrogenation at ambient temperature, the catalyst with amino-functionalized MIL-125 embedding Pd NPs showed higher activity when compared to Pd NPs loaded in pure MIL-125.¹⁶² The reason for this has to do with the weakly basic –NH₂, which could accept a proton under the reaction conditions to form –⁺HNH₂ and facilitate the dissociation of O–H bonds. Meanwhile, the Pd format intermediately undergoes β-hydride elimination to produce CO₂ while leaving the Pd hydride species, subsequently producing H₂. The amino group is typically employed in some basic reactions like Knoevenagel condensation due to its weakly alkaline sites. For example, uniform core-shell Pd@IRMOF-3 nanostructures with single Pd nanoparticles surrounded by amino-functionalized IRMOF-3 have been successfully prepared.^{163,164} The as-obtained composite catalyst showed very high catalytic efficiency in a cascade reaction with 4-nitrobenzaldehyde as the reactant. The Knoevenagel

condensation first occurred at the $-\text{NH}_2$ group, and the nitro group was subsequently hydrogenated on embedded Pd NPs to produce the final product. Besides the $-\text{NH}_2$ group, some acidic groups can as well play the part of second active sites for some tandem reaction by cooperation with embedded functional materials. Our group successfully fabricated highly distributed Pd NPs supported on a sulfonic acid functionalized MOF catalyst, Pd/MIL-101- SO_3H , by a simple thermal decomposition. With the cooperation of Pd NPs and $-\text{SO}_3\text{H}$ acidic sites in Pd/MIL-101- SO_3H , this catalyst performed outstanding activity in one-pot synthesis of ethyl tetrahydro-2-furoate (ETF) from furoic acid (FA).¹⁶⁵

Besides organic linkers alone, some metal-sites anchored on organic linkers might cooperate with embedded species. Lin's group introduced Pt NPs into stable, porous and phosphorescent metal-organic frameworks built from $[\text{Ir}(\text{ppy})_2(\text{bpy})]^+$ linkers and Zr based secondary building units by the *in situ* photoreduction method.¹⁶⁶ The as-prepared hybrid catalysts displayed high activity towards photocatalytic hydrogen evolution due to the synergistic photoexcitation of MOFs and electron acceptors of embedded Pt NPs. Coincidentally, Yang and Yaghi *et al.* anchored $\text{Re}^{\text{I}}(\text{CO})_3(\text{BPYDC})\text{Cl}$ (BPYDC = 2,2'-bipyridine-5,5'-dicarboxylate) into zirconium MOFs, UiO-67, (Re_n -MOF) near the surface of Ag nanocubes.¹⁶⁷ Intensified near-surface electric fields at the Ag nanocube surface led to enhanced CO_2 -to- CO conversion by about 7-fold under visible light.

The unsaturated coordinated sites of metal nodes could also synergize with embedded materials to facilitate tandem reactions. In general, open metal sites of MOFs serve as Lewis acid sites. Among MOFs, MIL-101 is popular and widely employed as support in cooperative work with embedded materials thanks to its abundant open chromium centers.^{168,169} A tandem catalyst with Pd NPs supported on MIL-101(Cr) has been prepared to achieve efficient one-step methyl isobutyl ketone (MIBK) synthesis.¹⁷⁰ For catalysis, acetone was first converted to mesityl oxide (MO) through high density unsaturated Cr Lewis acid sites. The resulting MO molecule was then further hydrogenated to produce the final product MIBK at Pd active sites. Multi-functional catalysts have also been applied in tandem reactions involving nitroarene reduction and reductive amination of carbonyl compounds.¹⁷¹ In such reactions, nitroarene is first reduced to an aromatic amine on noble metal NPs followed by further reaction with aldehyde or ketone at Cr Lewis acid sites to produce the final secondary arylamine products. For instance, Jiang and Xu *et al.* encapsulated a PdAg alloy in MIL-101 by cascade reaction.¹⁷² Although the doping of Ag slowed down the reaction rate to a certain degree, the selectivity of the target product significantly improved (Fig. 17). Such a construction strategy of synergetic catalysts can also be extended to other MOFs, including UiO-66 with Zr-oxo clusters.^{173,174} Huang's group developed bifunctional Zr-MOF based catalysts containing a Pd nanocluster ($\text{Pd}@\text{UiO-66-NH}_2$) with improved properties reaching 99.9% selectivity and 99% conversion in a one-pot oxidation-acetalization tandem reaction.¹⁷⁵ Later, ultras-small Pt clusters had been introduced into UiO-66- NH_2 cavities to fabricate the $\text{Pt}@\text{UiO-66-NH}_2$

heterostructure. In the one-step synthesis of nitrones, the catalyst exhibited remarkable selectivity and activity due to synergy between selective hydrogenation activity provided by Pt clusters and Lewis acidity/basicity contributed by MOFs.¹⁶⁴

In addition to the function of Lewis acid sites, unsaturated metal-sites of MOFs may influence catalytic performance in other ways.^{176,177} In 2016, Yaghi and Somorjai *et al.* showed for the first time the existence of strong interaction between embedded functional species and metal nodes of MOF matrixes.¹⁷⁷ Comparison between the activity and selectivity of two MOF-based composite catalysts (Cu NPs dispersed on UiO-66, denoted as Cu-on-UiO-66, and encapsulated within UiO-66, denoted as Cu@UiO-66) for CO_2 hydrogenation to methanol revealed the performance of Cu@UiO-66 to largely exceed that of common Cu/ZnO/ Al_2O_3 catalysts with 8-fold enhanced yield and 100% selectivity towards methanol. The turnover frequency (TOF) of methanol formation was twice that of the Cu-on-UiO-66 catalyst. X-ray photoelectron spectroscopy displayed strong interaction between Cu NPs and Zr oxide secondary building units (SBUs) of MOFs, conducive to enhancement of the catalytic activity. Note that for selective hydrogenation of α,β -unsaturated aldehydes to unsaturated alcohols catalyzed by NP@MOF catalysts, the increase in selectivity was usually attributed to the confinement effect of MOF shells. Later, Tang and co-workers explain the phenomenon according to CAL hydrogenation over sandwich-structured catalyst MIL-101@Pt@MIL-101.²³ They found the selectivity of cinnamyl alcohol over MIL-101(Fe)@Pt (86.4%) much higher than that performed over MIL-101(Cr)@Pt (44.0%). Considering the same

structure of MIL-101(Fe) and MIL-101(Cr), the increase in product selectivity may be due to interactions between MOF coordinatively unsaturated metal sites (CUBs) and the "C=O" bond. From DFT calculations, the adsorption energies of "C=O" bonds on $\text{Fe}_3\text{OCl}(\text{COO})_6\text{H}_2\text{O}$ and $\text{Cr}_3\text{OCl}(\text{COO})_6\text{H}_2\text{O}$ metal nodes were estimated to be -1.26 eV and -1.01 eV, respectively. This led to the different hydrogenation efficiency of "C=O" on Fe and Cr metal nodes.⁹⁵ Recently, Xu and Tsumori *et al.* successfully prepared a "quasi-MOF" through thermal transformation. The material did not only retain its porous structure but also possessed a large number of unsaturated coordinated nodes, which strengthened the metal-NP/MOF interactions through controlled deligandation of metal/MOF composites.¹⁷⁸ In turn, the strengthened interactions between Au NPs and Cr-O nodes of the quasi-MOF dramatically improved the catalytic activity of the prepared Au@quasi-MOF catalyst towards low-temperature CO oxidation (Fig. 18).

3.6. MOFs as nano-reactors

In recent decades, nano-reactors with active substances embedded within porous materials to allow specific reaction to take place in limited suitable locations have attracted increasing interest in research and development.^{179–181} Compared to traditional porous materials, MOFs have more flexible space to immobilize different functional species and create a comfortable micro-environment in the cavity for specific reactions to occur.

In 2015, Somorjai and Yaghi *et al.* incorporated sulfonic acid ($-\text{SO}_3\text{H}$, S) and ammonium ($-\text{NH}_3^+$, N), serving as strong acid and weak acid functional groups, into UIO-66 separately or together to regulate the acidity of MOF cavities. After embedding Pt NPs in MOF cavities, all three prepared MOF-based composite catalysts (Pt@UIO-66-S, Pt@UIO-66-N, and

Pt@UIO-66-SN) exhibited distinct catalytic performances towards gas-phase conversion of methylcyclopentane (Fig. 19).²⁴ In 2017, the cavity acidity was further regulated by encapsulating considerable amounts of phosphotungstic acid (PTA) in the MIL-101 cavity during the synthetic process of Pt@MIL-101. For hydrogenation isomerization of *n*-hexane, the prepared MOF composite catalysts with 60% PTA capacity exhibited 100% selectivity towards isoalkanes. Furthermore, mass activity was 9-fold higher than that of traditional aluminosilicate catalysts.²⁵ On the other hand, the activity and selectivity of some reactions are related to the hydrophilicity/hydrophobicity of catalysts, which may also be tuned by modifying the MOF shell. Jiang and co-workers encapsulated Pd NPs in MOF matrixes modified with a hydrophobic polydimethylsiloxane (PDMS) layer to create a hydrophobic micro-environment in MOF cavities. This method greatly enhanced the affinity for hydrophobic substrates.^{182,183} In addition, Zhang and Huo *et al.* modified the Pt@UIO-66 catalyst with graphene oxide (GO) to create a hydrophilic environment and promote hydrogenation of hydrophilic substrates, such as 4-nitrophenol.¹⁸⁴ Interestingly, the micro-environment of MOF cavities became hydrophobic after the reduction of GO. In turn, this was conducive to reactions with hydrophobic substrates, such as nitrobenzene hydrogenation.¹⁸⁵

As nano-reactors, MOFs not only provide a suitable reaction environment but also could integrate different functional catalysts in specific zones by simultaneously constructing multiple active sites in the frameworks or encapsulating different functional active species in the cavities. The diversity of metal ions and functional organic linkers makes MOFs suitable for the design of further multifunctional catalysts for specific reactions. As for MOF-based composites, MOFs always provide second reactive sites to cooperate with guest species as mentioned previously.^{114,186–194}

Compared to designable fabrication of specific multi-site structures, embedding two or more functional materials would help achieve multifunctional catalysts.^{60,194,195} Zeng and co-workers confined efficient CO_2 hydrogenation catalysts, Pt nanocubes and photo-thermal active Au nanocages in a limited

space by ZIF-8 encapsulation.¹⁹⁶ For hydrogenation of CO₂ under light irradiation, MOF shells acted as heat insulators to prevent generated heat by Au nanocages from escaping, generating a localized high-temperature region and improving the reaction conversion.¹⁶⁷ On the other hand, MOFs with two or more different functional catalysts in cavities are ideal for cascade reactions that attracted increasing attention owing to a sustainable green process and atom economy efficiency.³⁴ We previously synthesized PtNi@MOF-74-POM catalysts by a facile one-step self-sacrificed template process, in which phosphotungstic acid (POM) was encapsulated during *in situ* formation of MOF-74 on the surface of branched PtNi NCs.¹⁹⁷ The superior hydrogenation activity of the PtNi alloy and esterification activity of the POM yielded PtNi@MOF-74-POM catalysts with superior tandem reaction activity towards one-pot synthesis of amino-ester-type local anesthetic (benzocaine) (Fig. 20).

Besides traditional inorganic solid catalysts, some enzymes or biocatalytic molecules could also be embedded in MOF cavities to imitate some biocatalytic processes.^{198,199} Willner *et al.* imitated the biocatalytic transformation in cells to demonstrate biocatalytic cascades in ZIF-8 cavities by encapsulating two/three enzymes or enzyme/cofactor components.³⁰ Compared to directly dispersed cascade catalysts in solution, high local concentrations of substrates were generated around

the enzymes due to the confined environment of MOF cavities, thereby enhancing the efficiency of biocatalytic cascades over enzymes@MOFs. For this reason, the catalytic cascade activity of the two-enzyme system (glucose oxidase and horseradish peroxidase) (Fig. 21a) and three-enzyme system (β -galactosidase, glucose oxidase, and horseradish peroxidase) (Fig. 21b) enhanced by 7.5 and 5.3-fold, respectively. Additionally, NAD⁺ and NADH operating diffusively in nature could also enable communication between two enzymes in MOF reactors. Thus, the enzyme@ZIF-8 reactor (alcohol dehydrogenase, NAD⁺-polymer, and lactate dehydrogenase embedded in ZIF-8) successfully triggered the catalytic reduction of pyruvic acid to lactic acid by ethanol (Fig. 21c and d). Apart from catalysis, MOFs may also be employed for tandem reaction nanoreactors in other fields, such as sensors and drug delivery. Zhang and Dong *et al.* designed an artificial enzyme system for tandem catalysis using ZIF-8 encapsulated glucose oxidase (GOx) and PdNi NPs.²⁰⁰ The as-prepared GOx@ZIF-8-(NiPd) nanoflowers yielded rapid electrochemical response towards the detection of glucose. In practical applications, glucose is first oxidized to gluconic acid accompanied by generation of H₂O₂, which then is further oxidized on a NiPd surface to generate electrochemical signals.

3.7. MOFs as co-catalysts in photocatalysis

Recently, photocatalysis has attracted increasing interest in an effort to solve the energy shortage and environmental problems.²⁰¹ Some MOFs with semiconductor-like properties are considered as

Fig. 20 (a) Schematic illustration of tandem catalytic mechanism on PtNi@MOF-74-POM. (b) Catalysis of tandem reaction with different catalysts. Reproduced with permission.¹⁸⁹ Copyright©2019 The Royal Society of Chemistry.

a new kind of photocatalytic material. Compared to traditional inorganic semiconductor materials, the perfect porous crystalline structure of MOFs does not only inhibit the recombination of electron-hole pairs but also facilitate the utilization of charge carriers. Therefore, those MOF materials are promising for photocatalysis, as well as dye degradation, organic transformation, hydrogen production by water splitting, water oxidation, and carbon dioxide reduction.^{201,202}

In most photocatalytic processes using MOF-based composites as catalysts, MOFs serve as photosensitizers, absorbing light to generate charge carriers. The photo-excited electrons or holes then transfer to the active sites for further reactions, such as H₂-production, O₂-production and other organic reactions. Matsuoka *et al.* first synthesized Ti-MOF-NH₂ and then assembled Pt/Ti-MOF-NH₂ by photodeposition.²⁰³ In visible-light photocatalytic H₂ production, light is first absorbed by organic linkers of Ti-MOF-NH₂ and the generated electrons then transfer to catalytically active titanium-oxo clusters and further to Pt NPs for producing H₂ (Fig. 22a), in a process known as “linker to cluster charge transfer” (LCCT) mechanism. Meanwhile, Rosseinsky's group presented another linker to metal charge transfer (LMCT) mechanism in the photocatalytic H₂ production by an aluminum-porphyrin-MOF (Al-PMOF)/Pt composite catalyst (Fig. 22b).²⁰⁴ Similar phenomena have also been noticed in POM-MOF, dye-MOF, and semiconductor-MOF composites. For instance, Lin and co-workers encapsulated polyoxometalate (POM) inside a porous phosphorescent metal-organic framework (MOF) consisting of [Ru(bpy)₃]²⁺-derived dicarboxylate ligands and Zr₆(μ₃-O)₄(μ₃-OH)₄ SBUs for visible-light-driven proton reduction. Fontecave and Dolbecq *et al.* constructed MOF-based composites with POM ([PW₉O₃₄]¹⁰⁻) embedded in Zr(IV) porphyritic MOF-545 channels for water oxidation, where MOF played the role of a photosensitizer.^{205,206}

In addition to photosensitizers, MOFs can greatly accelerate charge transfer by forming heterojunctions with semiconductors. For example, Banerjee *et al.* successfully *in situ* synthesized CdS quantum dots in a Zn(II)-based low-molecular-weight metallohydrogel (ZAVA) followed by tuning to form CdS@ZAVA-MOF crystals (Fig. 23).²⁰⁷ In the visible light photocatalysis of H₂ production over the CdS@ZAVA-MOF with a Pt co-catalyst, electrons were first separated with holes on CdS QDs and then transported to the MOF LUMO orbit, while leaving

Fig. 23 (a) SEM images of CdS@ZAVCl and (b–d) TEM images of CdS@ZAVCl-MOF. (e) Mechanism of water splitting by the CdS@ZAVCl photocatalyst (30 mg) using 0.5 wt% co-catalyst Pt at $\lambda > 420$ nm. (f) Stability tests of photocatalyst (CdS@ZAVCl-MOF) for 12 cycles of the water splitting reaction. Reproduced with permission.²⁰⁷ Copyright©2014 American Chemistry Society.

holes on CdS. Next, electrons were further transferred to Pt NPs to reduce H⁺. In this process, CdS QD/MOF heterojunction inhibited electron-hole recombination, thereby leading to improved catalytic performances. To further boost electron-hole separation efficiency, two-dimension materials like rGO and MoS₂ have been used to construct MOF-based composites,^{208–210} due to their excellent electrical conductivity.²¹¹ To improve the separation of electrons and holes during CO₂ photo-reduction, capture and concentration of MOF toward CO₂ is essential. Ye *et al.* constructed carbon nitride nanosheets (CNNs) and UIO-66 composites (UIO-66/CNNs) for CO₂ photo-reduction.²¹² Benefiting from large surface area and strong CO₂ capture ability of UIO-66, the as-prepared UIO-66/CNN heterostructure photocatalyst exhibited much higher photocatalytic activity towards CO₂ reduction when compared to naked CNNs.

In addition, MOFs have other functions in some photocatalytic systems. For example, Pt@MOF/Au composites have been successfully fabricated by Jiang and co-workers, where the presence of MOF did not only extend the light absorption but accelerated charge transfer from Au to Pt active sites (Fig. 24a). Also, hybrid photocatalysts containing Pt NPs and porphyrinic metal-organic frameworks (MOFs) and Pt/PCN-224(M) have been used for selective oxidation of aromatic alcohols (Fig. 24b).

The excellent catalytic performance of Pt/PCN-224(M) resulted from the pronounced photothermal effect and singlet oxygen produced by cooperation between Pt NPs and PCN-224(Zn). In addition, competition between the Schottky junction and plasmonic effect may allow adjustment of the surface electronic state of Pt NPs by controlling the incident light intensity to achieve best catalytic performances.^{213–215} Luo *et al.* decorated ZIF-8 on electrostatic spinning TiO₂ nanofibers (TiO₂ ESNFs) to form a TiO₂/ZIF-8 hybrid photocatalyst with great photocatalytic activity towards Rhodamine B (RhB) photodegradation since the N–Ti–O bond reduced the electron–hole pair recombination.^{216,217}

4. Conclusions and perspectives

In this review, we summarized the structure–performance relationships of MOF-based composites from a new perspective, focusing on identifying the functions of MOF moieties in practical applications. With the assistance of MOFs, composites always showed significantly enhanced or even novel properties when compared to single-component materials. For practical applications, MOFs can be employed as armors to protect catalytic species, as membranes to screen substrates or control molecular configuration, as active site supporters, as nano-reactors for some specific reactions, and so on. To be noticed, in many cases MOF components play more than one role.

However, despite the progress in functional MOF-based composites, some challenges still limit their practical applications. For instance, the instability of the MOF structure constrains the application and recycling of MOF-based composites in some reactions, especially at high temperatures. Hence, the development of stable MOF structures for fabrication of MOF-based composites is necessary for better applications. On the other hand, despite the large number of synthesis methods of MOF-based composites, all of them still suffer from some limitations. Therefore, exploring novel universal approaches to construct specific functional MOF-based materials is important, especially for the precious control of guest species in MOF matrices. Moreover, more attention has been paid to environmentally sensitive MOF materials with structures responding to external stimuli, such as electrical or optical signals. The preparation of such MOFs will lead to new avenues for constructing intelligent functional materials by integrating environmentally sensitive MOFs with functional materials. In short, further development of MOF-based composites will clarify the structural–functional relationship of MOF-based composites and benefit the future design and fabrication of new MOF-based functional materials for various applications.
