Amphiphilic cationic cyclodextrin nanovesicles: a versatile cue for guiding cell adhesion†

Francesco Valle,^{‡*}ab Silvia Tortorella,[‡]c Angela Scala,[‡]d Annalaura Cordaro,^{de} Marianna Barbalinardo,^a Fabio Biscarini,[‡]fg and Antonino Mazzaglia,[‡]*e

It is well known that amphiphilic cationic β -cyclodextrins ($\text{am}\beta\text{CDs}$) form nanovesicles able to release their cargo in aqueous solution upon applying different stimuli. In addition they can be selectively positioned onto substrates by unconventional soft lithography. This makes them a powerful tool for designing environments where different cues can be externally supplied to the cells helping to achieve good control of their fate. Lithographically controlled wetting (LCW) of $\text{am}\beta\text{CD}$ nanovesicles loaded with fluorescein isothiocyanate (FITC), $\text{am}\beta\text{CD}/\text{FITC}$, has been used here to fabricate geometrically functionalized surfaces, thus achieving multiscale control of the cell environment. The $\text{am}\beta\text{CD}$ functionalization was strongly influenced by the surface energy of the underlying substrates that, according to their hydrophobicity, orient the $\text{am}\beta\text{CD}$ in a different way, thus “offering” different portions to the cells. The structure of the pattern was characterized both over large scales exploiting the FITC fluorescence and at the nanoscale by atomic force microscopy. Cell guidance and $\text{am}\beta\text{CD}/\text{FITC}$ cell internalization were demonstrated in human neuroblastoma SHSY5Y cells.

Introduction

Cell behavior is influenced by the 3D environment dynamically sensed by the cell.¹ This includes topographical–chemical–mechanical stimuli, electromagnetic fields, gradients of chemo-attractants and haptotaxis.^{2–5}

Multiscale control of the cell environment is crucial to many aspects of cell research and medical applications. Observed changes in the gene expression profile of primary cells *in vitro*, compared to that of cells in organs for example, raised serious concerns in the pharmaceutical industry, because drug-screening technology is largely based on cell culture data. Regenerative medicine requires the control of stem cell commitment at the level of individual cells and colonies⁶ and the correct tissue regeneration can be either hindered or promoted by means of an accurate positioning of the cells and by the local supply of molecules (differentiation agents, adhesion molecules).⁷ Long-term applications including diagnostics, loco-regional therapy of neurological diseases, and sorting and localization of cancer cells before metastasis occurs cannot be achieved with traditional culture plates or scaffolds that do not mimic the multiscale cell environment. The mimicking of the natural environment of the cells in an organ should achieve control of cell–cell contacts that are one of the key factors in cell behavior.⁸ In addition, endocrine signaling should also be taken into account and included in the biomimicking system.^{9,10} Such an approach requires spatial and dimensional control of the structures making up the environment along with temporal control of the cues at the surface and in the solution. Investigation of selected cues has highlighted the importance of topographical, chemical, and more recently mechanical/viscoelastic interactions of the cell and the surface.^{11–13}

In this framework cell patterning has received in the recent past some attention both to define technological pathways for building complex environments and to study the cell behaviour

under the chosen conditions. The first attempts were made by patterning adhesion promoting or antifouling molecules to obtain a good cell positioning;^{14,15} then the fabrication strategies tackled higher cellular processes such as differentiation by patterning topographical–chemical–mechanical stimuli.^{16–18}

To date, molecular recognition has been fruitfully exploited for surface functionalization; in particular, the host–guest interactions between covalent or non-covalent immobilized β -cyclodextrin (β CD) derivatives and suitable groups or biochemical moieties (*i.e.* carbohydrate, biotin, *etc.*) have been reported.^{19,20} In this context, polymeric adhesive membranes functionalized with ferrocene and cyclodextrins (CDs) were investigated,²¹ and more recently, surfaces patterned with CD-based polymers have been proposed as supramolecular glues, exploiting the host–guest inclusion between CD and azobenzene polymer brushes²² or photoresponsive arylazopyrazoles.²³ Liposomes and amphiphilic β CD vesicles were also selectively positioned on surfaces by microcontact printing using a coiled-coil binding motif.²⁴ In this direction, some of us reported the electrical release of dopamine and levodopa mediated by amphiphilic cationic β CD (am β CD) immobilized on polycrystalline gold,²⁵ while the controlled and tunable entrapment and release of cargo by polymer-shelled vesicles prepared from amphiphilic β CD by using gigahertz acoustics was proposed for addressing site-specific therapeutic activity.²⁶

The amphiphilic β CD vesicles may in addition form various nanocomplexes in aqueous dispersions either with chemotherapeutic²⁷ or photosensitizer drugs^{28–30} or a proper combination of both.³¹ Hence, amphiphilic β CD nanovesicles are able to act at two levels: locally changing the chemical–physical properties of the surface³² and delivering the drug hosted both in their cavities and within the bilayer to the cells.³¹ By tailoring the different moieties of β CD (the hydrophilic portions, the hydrophobic ones and the terminal groups that can be exposed to the solution), the orientation assumed by amphiphilic β CD nanovesicles interacting with surfaces can be suitably exploited to tune the chemical–physical properties of the surface. In addition, being dispersible in water they can be used as biocompatible building blocks for soft lithography.³³

These techniques in the last decade turned out to be a useful toolbox for generating patterns able to guide the adhesion and migration of cells,^{34,35} different mechanical properties or topographical features have been locally patterned,^{36–38} as well as chemical cues such as adhesion molecules,³⁹ small peptides or whole proteins.^{11,40,41}

Beyond the proof-of-concepts, several important questions related to the complexity of the cell environment remain still at an infancy level: what is the effect of combined cues? Is there a synergy or a compensation between different cues? How can cell behavior on a surface be reprogrammed by a dynamic change of the environment (*e.g.* adhesion or detachment upon switching interfacial energy)? Are there correlations among different cues? How does the cell fate emerge from combined cues? Other important aspects concern the adhesion and the migration driven by the environmental stimuli. In this work we developed a platform easily tunable as a proof of concept with

the aim of addressing some of these questions. We patterned surfaces with am β CD nanovesicles, exploiting the ability of these nanostructures to entrap dyes and release them into the biological environment.^{42–44} Specifically, we selected am β CD able to form nanovesicles in water,⁴⁵ with high charge affinity for glass coverslips, and we loaded fluorescein isothiocyanate (FITC) as a drug model. The unmistakable green fluorescence makes FITC a useful dye in many bioanalytical processes, both for characterizing the pattern and for detecting and monitoring the cell internalization of the nanocomplexes. To the best of our knowledge, this approach can be preparatory to directly investigate cell behavior upon their spatial organization on surfaces patterned with nanodrugs by means of fluorescence microscopy.

Materials and methods

Materials

Heptakis[2- ω -amino-oligo(ethyleneglycol)-6-deoxy-6-hexadecylthio]- β -cyclodextrin heptahydrochloride salt (am β CD, SC16NH2), corresponding to the exact masses with 7–14 units of ethylene oxide (EO) and 7 units of ethylene amino; exact mass: [M11EO] = 3545.20; mol. wt = 3551.2; found: 3546.25, and nEO = 1–2 in Fig. 1; MALDI is reported in Fig. S1†) was synthesized and characterized by NMR (Varian 500 MHz) in CDCl₃ and MALDI-TOF according to the general procedures.⁴⁵ Fluorescein 5-isothiocyanate (FITC, MW = 389.38), MEM Non-Essential Amino Acids (NEAA), Dulbecco's phosphate buffered saline (DPBS), and Dulbecco's modified Eagle's medium/Nutrient Mixture F-12 Ham (DMEM/F-12), L-glutamine, penicillin and streptomycin were purchased from Sigma-Aldrich. Fetal bovine serum (FBS) was purchased from Gibco. The nanovesicle dispersions used for spectroscopic characterization were prepared in ultrapure microfiltered water (Galenica Senese). Dichloromethane (DCM) of spectrophotometric grade was purchased from Romil. All other reagents and solvents were of the highest available commercial grade.

Fig. 1 Sketch of the nanosystem used in this work. Vesicles are formed by am β CD structured in a bilayer and incorporating the FITC dye.

Preparation and spectroscopic characterization of aqueous dispersions of am β CD/FITC nanovesicles

Nanovesicles of am β CD and am β CD/FITC were prepared with a 20 : 1 molar ratio of [am β CD] : [FITC] ([am β CD] = 120 μ M, [FITC] = 6 μ M) according to a previously reported procedure.⁴⁵ Briefly, SC16NH2 (1.1 mg) was dissolved in DCM and evaporated overnight to form a thin film which was hydrated with an FITC solution in ultrapure water ([FITC] = 6 μ M) at 50 °C followed by 5 h of sonication in an ultrasonic bath. am β CD/FITC was purified from free dye by gel filtration on a 30 \times 2 cm Sephadex G-25 column using H₂O as an eluent. Entrapment efficiency (EE%) was estimated from the difference of fluorescence emission spectra before and after column purification, using a calibration curve by fluorescence emission of FITC ([FITC] = 1–10 μ M). Spectroscopic characterization was carried out by dispersing am β CD, FITC and am β CD/FITC in ultrapure water and in physiological aqueous solution (NaCl, 0.9% w/w), respectively. The pH of am β CD/FITC, measured with a Metrohm 744 pH meter, in ultrapure water and physiological aqueous solution (NaCl, 0.9% w/w) was 5.2 and 6.30 (\pm 0.01), respectively.

Steady-state fluorescence and excitation measurements were performed on a Jasco model FP-750 spectrofluorimeter by using a 1 cm path length quartz cell at room temperature (r.t. \approx 25 °C). Spectra were not corrected by extinction. Dynamic Light Scattering (DLS) was carried out using a Zetasizer Nano ZS (Malvern Instrument, Malvern, U.K.) utilizing a Non-Invasive Back-Scattering (NIBS) technique. The measurements were performed at a 173° angle with respect to the incident beam at 25 \pm 1 °C for each dispersion. The deconvolution of the measured correlation curve to an intensity size distribution was achieved by using a non-negative least-squares algorithm. The ζ -potential values were determined using a Zetasizer Nano ZS from Malvern Instruments equipped with a He–Ne laser at power P = 4.0 mW and λ = 633 nm.

Atomic force microscopy imaging was performed in the SPM@ISMN facility using a Multimode VIII microscope equipped with a Nanoscope V controller (Bruker, Santa Barbara, CA). Images were collected with a microscope operated in PeakForce Tapping mode using an SNL10 cantilever with a nominal spring constant of 0.24 N m⁻¹. Images were analyzed with Gwyddion⁴⁶ open source software used in this work for background subtraction and profile analysis.

Patterning of nanovesicles

For patterning experiments, am β CD was stored at 4 °C as a thin film in glass vials. am β CD film was reconstituted in physiological solution (NaCl 0.9% w/w) by sonication at 50 °C for 5 h (final concentration 120 μ M). am β CD/FITC was prepared by hydration of am β CD organic film with FITC solution (NaCl 0.9% w/w) as described above.

am β CD and am β CD/FITC nanovesicles were patterned on the surface of glass coverslips (Corning, Sigma-Aldrich) by Lithographically Controlled Wetting (LCW) as previously described.³⁴ Electron microscope grids (Pelco, Ted Pella) were used as patterning stamps due to the large variability both in

the motifs and in the size of the features available. Coverslips (diameter d = 0.8 cm) were cleaned by 1 h dipping in 37% HCl, sonication for 15 min in acetone, 15 min in isopropanol, and 15 min in ethanol and drying in a stream of nitrogen; sterilization was performed both by UV lamp treatment overnight and in an autoclave. A portion of the substrates was then additionally exposed for 1 minute to an O₂ plasma at 60 W. The patterns were then coated with 10 nm gold and then imaged by Scanning Electron Microscopy using an FEG-SEM Hitachi S4000.

Cell culture and morphology

Human neuroblastoma SHSY5Y cells (ECACC 94030304; Sigma Aldrich, St. Louis, MO, USA) were cultured in Dulbecco's modified Eagle's medium/Nutrient Mixture F-12 Ham (DMEM F-12) with 2 mM L-glutamine, 100 IU mL⁻¹ penicillin, 100 μ g mL⁻¹ streptomycin and supplemented 15% fetal bovine serum (FBS). Cells were maintained under standard conditions at 37 °C in a humidified atmosphere (95% humidity, 5% CO₂) and split regularly (rate 1 : 10) by trypsinization. SHSY5Y cells were seeded (7500 cells per cm²) and cultured on glass samples in 24-well plates, for 48 hours. For the actin and nucleus staining, cells were fixed with 4% paraformaldehyde in Dulbecco's phosphate-buffered saline DPBS 1 \times and washed with DPBS 1 \times . They were then permeabilized with 0.01% Triton-X 100. The cells were labelled with TRITC-conjugated phalloidin to map the local orientation of actin filaments followed by rinsing with DPBS 1 \times . Nuclear counterstaining was performed by incubation with DAPI for 3 min, followed by rinsing with DPBS 1 \times . Samples were examined using a Nikon Eclipse 80i microscope equipped for fluorescence analysis.

Statistical analysis

All data represented the mean \pm standard deviation (SD) of at least three independent culture experiments; a blank control was always included in every multi-well plate. Statistical significance was determined using a one-way analysis of variance with Tukey's test for multiple comparisons using Origin 8 software (OriginLab Corporation). Differences were considered significant when p < 0.005 and p < 0.001. Analysis of cell adhesion was performed using ImageJ software (NIH); AFM image elaboration was performed using open source software Gwyddion (Department of Nanometrology, Czech Metrology Institute).

Results and discussion

am β CD/FITC nanovesicles (Fig. 1) were prepared by a solvent-evaporation method, hydrating an organic film of am β CD carrier with an aqueous solution of the guest (FITC), followed by sonication and purification by gel permeation chromatography. The coincident fluorescence emission spectra of am β CD/FITC before and after purification (data not shown) suggested that FITC EE% was \approx 100%. Initially am β CD/FITC nanocomplexes were characterized in an aqueous dispersion using steady-state fluorescence spectra (Fig. 2). The excitation spectrum of free FITC showed a band centered at 496 nm, which was shifted to

Fig. 2 (a) Excitation ($\lambda_{em} = 550$ nm) and (b) fluorescence emission spectra ($\lambda_{exc} = 400$ nm) of FITC (red line) and am β CD/FITC (black line) in ultrapure water (pH \cong 5.2). (c) DLS and ζ -potential (inset) of am β CD (orange trace) and am β CD/FITC (black trace) in a physiological aqueous dispersion (NaCl 0.9% w/w), pH \cong 6.3. am β CD/FITC was prepared in a 20 : 1 molar ratio ([am β CD] = 120 μ M, [FITC] = 6 μ M). Spectra were acquired at r.t.

a longer wavelength ($\lambda = 507$ nm) upon interaction with am β CD nanovesicles. The decrease of intensity and the significant redshift clearly indicated the formation of am β CD/FITC complexes. Emission spectra of the free dye exhibited a band centered at 521 nm which was shifted to 527 nm in am β CD/FITC confirming the FITC entrapment within am β CD nanovesicles. However, the fluorescence emission intensity was virtually not changed, suggesting that FITC is plausibly complexed in am β CD in a not self-aggregated form according to other previous reports on dyes entrapped in other cationic amphiphilic β CD⁴⁷ or nanoparticles.⁴⁸ Moreover, fluorescence emission spectra recorded in the presence of Triton X (Fig. S2†) indicated that FITC was probably entrapped more in the lumen of the am β CD nanovesicles than in the layer. Indeed, upon addition of Triton X to

the am β CD/FITC aqueous dispersion, the FITC fluorescence emission increased, without affecting the wavelength of the emission maximum. This could be tentatively ascribed to the leaking of FITC from the vesicle aqueous core and its dispersion in aqueous solution as free molecules, following the disintegration of nanovesicles mediated by Triton X.⁴² DLS (Fig. 2 and Table S1†) revealed the presence of small and large am β CD aggregates (\sim 60 and 600 nm sized) with a positive ζ -potential (32 ± 3 mV). A similar value ($\zeta = 38 \pm 3$ mV) was confirmed in am β CD/FITC which has a size of \sim 100 nm, pointing to a moderate increase of the size of the smaller aggregates while the larger sized population nearly totally disappeared (see Table S1†). All these results suggested a certain rearrangement of am β CD nanovesicles upon FITC entrapment, even if their external charge surface seemed to be almost unaffected.

am β CD nanovesicles were patterned using lithographically controlled wetting (LCW)⁴⁹ (Fig. 3) based on the controlled formation of the menisci of a solution pinned between the surface to be functionalized and the protrusions of the stamp. am β CD vesicles were deposited where the menisci formed, thus reproducing the positive pattern made by the protrusions of the stamp on the surface (Fig. 3a). Specifically, using both metallic linear and hexagonal copper grids, a glass surface can be functionalized with the same pattern over a macroscopic scale (Fig. 3b and c).

Atomic force microscopy (AFM) (Fig. 4) was used to characterize at high resolution the am β CD/FITC nanovesicles patterned on the surfaces (see Fig. 3). Fig. 4 shows the shape assumed by the nanovesicles adsorbed on the glass during LCW; the image and the section analysis confirm that under these conditions they mostly do not preserve their spherical shape⁵⁰ but they open and likely release the liquid entrapped in their lumen, thus forming either a bilayer or double bilayer. Scanning Electron Microscopy (SEM) was also used to provide information about the fabricated am β CD/FITC nanovesicle

Fig. 3 Patterning am β CD/FITC complexes by lithographically controlled wetting (LCW). (a) Sketch of the patterned sample and the LCW technique. (b) and (c) FITC fluorescence images showing the patterns fabricated with linear and hexagonal features, respectively. Scale bar = 100 μ m.

(a) Images collected on a 500 nm \times 500 nm area; (b) reported profile on line 1 showing a portion 5 nm high where the nanovesicles have completely opened up forming a supported lipid bilayer and others where they are still in a double-bilayer state 10 nm high on the surface.

pattern, visible at a large scale in Fig. S3a \dagger and more in detail in Fig. S3b. \dagger ⁵¹

The am β CDs used here to entrap FITC are cationic amphiphilic building blocks; thus the functionalization of the glass substrates by am β CD/FITC nanovesicles is locally influenced by surface chemistry of the glass substrate that drives their orientation. To test whether this effect might affect cell adhesion and growth, glass coverslips were functionalised, without any lateral confinement, by drop casting the am β CD/FITC aqueous dispersion onto their surfaces. Then, am β CD/FITC was adsorbed both on a very hydrophilic glass surface obtained upon O₂ plasma treatment (Fig. S4a \dagger) and on a more hydrophobic one consisting of the glass simply cleaned with ethanol/acetone (Fig. S4b \dagger). A rather homogeneous coating was thus obtained with different am β CD/FITC portions exposed to the solvent. The am β CD/FITC coating yields a good cell adhesion and proliferation (Fig. 5a) when it was formed on the very hydrophilic glass coverslip; conversely the cells did not adhere and proliferate when the coating was done on the bare glass (Fig. 5b). To exclude the possibility of ascribing this difference to the direct interaction of the cells with the underlying surface of glass treated in different ways, cells were seeded directly onto the hydrophilic and hydrophobic coverslips (without any am β CD/FITC coating) and no differences were visible as shown in Fig. 5c and d. It can thus be hypothesized that the am β CD/FITC when adsorbed on a more hydrophobic surface exposes cues able to interfere with the formation of the focal adhesion points. This is probably due to the orientation assumed that exposes the oligoethylene-glycol (OEG) portions to the solvent. OEG is in fact known to be an effective antifouling agent preventing the adsorption of biomolecules and the adhesion of cells.⁵² In addition, the samples were also supplied with an am β CD/FITC aqueous dispersion, revealing the uptake of am β CD/FITC by the adhered cells. This indicates that the effect shown in Fig. 5a and b was due to the way the glass shaped the am β CD/FITC layer. The reported results are quantitatively summed up in Fig. 5e where it can be seen that only the am β CD/FITC coated hydrophobic glass inhibits cell adhesion. Combining the patterning of the nanocarriers with these different surfaces, one can envision fabricating surfaces able to

Fig. 5 Immunofluorescence images of SH-SY5Y cell samples prepared as follows: (a) glass surface O₂ plasma treatment \rightarrow am β CD/FITC coating \rightarrow cell seeding (scale bar = 100 μ m), (b) glass surface not treated \rightarrow am β CD/FITC coating \rightarrow cell seeding (scale bar = 75 μ m), (c) glass surface O₂ plasma treatment \rightarrow cell seeding \rightarrow am β CD/FITC supplied in solution (scale bar = 100 μ m), (d) glass surface not treated \rightarrow cell seeding \rightarrow am β CD/FITC supplied in solution (scale bar = 100 μ m). confine or guide the adhesion and migration of cells. This can be achieved by designing surfaces where regions allowing the cell adhesion (as in Fig. 5a, c and d) are flanked by antifouling ones (as in Fig. 5b). Soft lithography (as sketched in Fig. 3) was thus used for patterning am β CD/FITC, with the aim to locally guide cell adhesion and proliferation. Fig. 6 shows how SH-SY5Y cells respond to these surfaces; where the pattern was fabricated on plasma treated glass (Fig. 6a), the cells grew throughout the surface, and no discrimination between the presence or absence of the am β CD/FITC on the surfaces was evident due to the similar cell adhesion propensity shown in Fig. 5e.

On the other hand, in Fig. 6b the presence of two types of areas with markedly different cell adhesion propensities leads SH-SY5Y to be confined to the portions of the surface where the am β CD/FITC is not present, due to the tendency of the cells to move away from the regions where the adhesion is depleted by the surface chemistry. In this case the presence of neighboring areas where the am β CD/FITC is absent or present under the rather anti-fouling conditions (am β CD adsorbed on raw glass) led to a strong confinement of the cells. This is in our view a valuable result because it adds to the presently explored cell patterning experiments the possibility to achieve the guidance with molecular assemblies able to act also as a delivery system.

Fig. 6 Cell adhesion and proliferation on the patterned $\text{am}\beta\text{CD}/\text{FITC}$ characterized by fluorescence imaging (green, FITC; red and blue, immunofluorescence of actin filaments and DNA, respectively). The samples were prepared as follows: (a) glass O_2 plasma treatment \rightarrow $\text{am}\beta\text{CD}/\text{FITC}$ LCW \rightarrow cell seeding, the cells do not discriminate between the areas within and outside the pattern; (b) glass surface not treated \rightarrow $\text{am}\beta\text{CD}/\text{FITC}$ LCW \rightarrow cell seeding, the cells are confined in the regions where the $\text{am}\beta\text{CD}/\text{FITC}$ is not present. (c and d) Lower magnifications of (a) and (b), respectively. Scale bar is 100 μm .

Fig. 7 $\text{am}\beta\text{CD}/\text{FITC}$ supplied to the cells in an aqueous dispersion (a) and from the patterned areas (scale bar 100 μm , glass surface not treated) (b). Images of DAPI stained nuclei and FITC showing clearly the colocalization of the vesicles and the cells (scale bar 75 μm).

This can be appreciated in Fig. 7 that describes the colocalization of the vesicles and the cells. As reported in Fig. 4, it seems that vesicles held a double bilayer structure and just leaked the internal fluid when patterned. It is likely that these vesicles upon rehydration in the cell culture media swell again and can reach the cells. A similar effect seems more pronounced when $\text{am}\beta\text{CD}/\text{FITC}$ is supplied from the aqueous dispersion to the culture media (Fig. 7a). On the other hand, the patterned $\text{am}\beta\text{CD}/\text{FITC}$ is only mildly internalized by the cells (Fig. 7b); this effect is probably due to the release in the solution from the surface of the nanovesicles that maintained their structure within the pattern in the proximity of the cells.

The delivery from the pattern can be seen as an additional cue that can be given to the cell besides the topographic one (control of the adhesion); cells are thus effectively guided and positioned in a precise location where they could receive a chemical/biological stimulus for further uptake and transport of the nanocarrier, indicating a net increase of the complexity in the artificial environment provided to the cells.

Conclusions

The possibility to fabricate smart surfaces able to guide cell adhesion and migration combining amphiphilic cationic βCD nanocarriers and soft lithography techniques was investigated. Concerning the advantage brought by our approach with respect to the questions listed above, we would like to underline that here we fabricated a platform as a proof-of-concept demonstrating the combination of two different cues: the surface treatment, leading to an external control of the cell positioning and the patterning with drug delivery systems based on amphiphilic CD which can act within the cellular machinery. Lithographically controlled wetting allowed us to pattern $\text{am}\beta\text{CD}/\text{FITC}$ nanovesicles within defined portions of a surface and to orient them according to the surface features. Also, the cell internalization of the drug delivered by nanocarriers present on the surface was shown. In particular a more hydrophilic surface (obtained by O_2 plasma treatment) combined with the $\text{am}\beta\text{CD}$ pattern permitted the adhesion of SH-SY5Y cells while a more hydrophobic surface (obtained without O_2 plasma treatment) inhibited the cell adhesion where the surface is rich in $\text{am}\beta\text{CD}$. From this perspective, the spatial distribution of $\text{am}\beta\text{CD}$ nanovesicles on the treated surface could be exploited to confine or to guide cells to different areas. As $\text{am}\beta\text{CD}$ nanovesicles can be tailored with further cues (*i.e.* drugs, cell targeting groups, and stimuli-responsive functionalities), according to the surface arrangement of amphiphilic cationic βCD , spatial control of the involved cues in cellular pathways could be achieved. Altogether, we believe that this strategy could be useful for building microenvironments where a variety of stimuli can be supplied also dynamically to the cells as cues exposed by the patterned surfaces and/or molecules released and internalized by the cells according to their position on the surface.

Author contributions

A. M. suggested this work. F. V., F. B. and A. M. conceived the experiments. F. V. and S. T. followed the patterning experiments and performed the imaging. S. T. and M. B. performed the cell culture experiments. S. T. performed the fabrication experiments. A. M., A. S. and A. C. performed the synthesis and the characterization of the nanocarriers. F. V. and A. M. prepared the original draft and F. B. reviewed it.
