# Spectroscopic studies of the optical properties of carbon dots: recent advances and future prospects

Qingnan Zhao, Wei Song, \* Bing Zhao and Bai Yang

Carbon dots (CDs) are a new class of luminescent carbon nanomaterials possessing small size, excellent water solubility, low toxicity, tunable light-emitting properties and good biocompatibility, which display bright prospects in catalysis, drug delivery, bioimaging, biosensing and energy conservation and storage. In the past several years, great achievements on the synthetic strategies, characterization techniques, unique optical properties and novel applications of a large variety of CDs have been realized. In this review, the brilliant optical properties of CDs-based nanomaterials via a series of spectroscopic techniques are summarized. After a brief introduction of the characteristic of CDs, we will focus on the optical properties of the CDs, including photoluminescence (PL), near-infrared (NIR) fluorescence, surface-enhanced Raman scattering (SERS), phosphorescence, chemiluminescence (CL), electrochemical luminescence (ECL), and chirality. The correlation between the structure of CDs and their optical properties has been discussed. In addition, some challenges and future prospects in the field of the optical properties of CDs have been highlighted. With the rapid development of their superior optical properties, it is anticipated that CDs will be applicable in a large number of research fields.

## 1. Introduction

Carbon, one of the richest elements in the universe, usually possesses a number of interesting allotropes. Carbon family materials are mainly composed of fullerenes,<sup>1,2</sup> carbon nanotubes,<sup>3-5</sup> diamonds,<sup>6-8</sup> graphene,<sup>9,10</sup> graphdiyne<sup>11,12</sup> and carbon dots

(CDs).<sup>13-15</sup> Among these carbon materials, CDs show the smallest size and superior hydrophilic properties, and exhibit promising applications in catalysis, drug delivery, bio-imaging, bio-sensing and energy devices. CDs were firstly discovered in 2004 by Scrivens and co-workers from a crude suspension during the separation and purification of single-walled carbon nanotubes using a gel electrophoresis method.<sup>16</sup> In 2006, Sun and co-workers proposed a chemical synthetic strategy to fabricate luminescent carbon nanoparticles which are called “carbon

Her current research focuses on the fabrication of new functional surface-enhanced Raman scattering substrates with catalytic properties for biological and sensing applications.*

quantum dots" (CQDs).<sup>17</sup> Afterwards, a large number of researchers have devoted their efforts in this field and developed many new synthetic approaches to prepare CDs with varied compositions and chemical structures as well as optical properties. These CDs have shown great promising applications in light-emitting diodes (LEDs), catalysis, sensing, biotechnology, energy devices, etc.<sup>18–23</sup> Recently, to avoid energy consumption and environmental pollution, an energy-efficient and sustainable strategy has been developed to prepare green carbon nanodots (CNDs) and yellow graphene quantum dots (GQDs) as well as green CQDs by using different reactants as carbon sources at room temperature, which showed a broad application prospect for bio-imaging, bio-labelling and bio-analysis.<sup>24,25</sup>

Generally, most of the CDs show a size of less than 10 nm and intrinsic fluorescence properties. The chemical structure of CDs is made up of nitrogen/polymeric aggregations/oxygen-based groups (e.g., C=O, –OH, –COOH, C–N, C–O) and sp<sup>2</sup>/sp<sup>3</sup> hybrid conjugated carbon.<sup>26–29</sup> Typically, CDs are primarily classified into GQDs, CNDs and CQDs, which present different chemical structures and optical properties, respectively.<sup>18,30–32</sup> GQDs are a few layers of graphene sheets with lateral dimensions of less than 10 nm. The zero-dimensional (0D) GQDs converted from two-dimensional (2D) graphene sheets display anisotropism, quantum-size effect and exciton confinement. The conjugated  $\pi$ -domains and the edge structure of the GQDs contribute to their unique luminescence properties. In addition, GQDs usually show favorable crystallinity. Different from GQDs, CNDs are a type of ultrasmall carbon nanoparticles with a spherical morphology and usually an amorphous lattice structure. CNDs are composed of cross-linked or aggregated monomers and linear polymers. However, some CNDs are not entirely linear polymers or disordered monomers owing to the existence of hexagonal carbon networks in amorphous CNDs. CQDs are composed of multiple layers of graphitic sheets and possess a spherical crystalline structure. In addition to typical GQDs, CNDs and CQDs, carbonized polymer

dots (CPDs) have also been put forward to verify the vital role of the polymerization and carbonization processes in the synthesis of CDs in recent years.<sup>33</sup> So far, a large variety of approaches have been developed to synthesize CDs with different compositions and chemical structures, which are mainly divided into top-down methods based on cutting different carbon materials (e.g., carbon fiber, graphene oxide (GO), fullerenes and graphite electrodes) and bottom-up methods that are generally involved in the organic synthesis of small molecules, self-assembly of polycyclic aromatic hydrocarbons and carbonization of carbohydrates.<sup>34–37</sup>

Many characterization techniques have been employed to evaluate the chemical structure of CDs, such as ultra-violet visible (UV-vis) spectroscopy,<sup>38,39,52</sup> Fourier transform infra-red (FTIR) spectroscopy,<sup>40,53</sup> X-ray diffraction (XRD),<sup>41,47</sup> X-ray photoelectron spectroscopy (XPS),<sup>42,53</sup> nuclear magnetic resonance (NMR)<sup>43,54</sup> and Raman spectroscopy<sup>44,51</sup> (Fig. 1a–i). Typically, UV-vis absorption measurements reveal their main optical absorption in the range of 280–360 nm (Fig. 1a);<sup>52</sup> however, the characteristic absorption peaks strongly depend on the preparation methods and the functional groups on the surface of CDs.<sup>45,46</sup> XRD technology mainly provides crystallinity structure information of CDs powder,<sup>47</sup> which contributes to high-resolution TEM analysis (Fig. 1b). FTIR spectroscopy is also employed to characterize the functional groups on the surface of CDs.<sup>48</sup> The typical functional groups of CDs are shown in Fig. 1c, which have been investigated by FTIR spectroscopy.<sup>53</sup> XPS is a valuable tool to confirm the elemental composition, electronic state and chemical state of the constituent elements of CDs (Fig. 1d–g).<sup>49,53</sup> NMR can be employed to obtain the information about the surface functional groups of CDs (Fig. 1h).<sup>50</sup> Raman spectroscopy is able to reveal the ratio of sp<sup>2</sup>- and sp<sup>3</sup>-hybrid carbon atoms in the carbon core, which can mainly quantify and characterize the chemical structure of CDs (Fig. 1i).<sup>51</sup> In particular, the spectral analysis is critical to evaluate the optical properties of CDs, which is beneficial to

understand their luminescence mechanism and optoelectronic applications.

In the review, we intend to cover the optical characteristics of CDs-based nanomaterials, focusing on the development of the spectroscopic studies of CDs in photoluminescence (PL), near-infrared (NIR) fluorescence, surface-enhanced Raman scattering (SERS), phosphorescence, chemiluminescence (CL), electrochemical luminescence (ECL), and chirality. We will discuss in detail the relationship between the chemical structure and the optical properties of the CDs. Finally, we will give a brief conclusion and future prospects of CDs-based nanomaterials in applications making use of their optical properties. We hope that this review will provide valuable insights to stimulate more people to study the optical mechanism of CDs, and expand further applications of CDs in the fields of biology, catalysis, energy, and environment. Fig. 2 shows the schematic diagram of the main content of the review.

## 2. Optical properties of CDs

### 2.1 PL

PL is one of the most fascinating characteristics of CDs. CDs prepared with different approaches and materials show varied compositions and chemical structures, which can emit different

**Fig. 2** Schematic diagram of the main content of this review.

colored PL, including deep ultraviolet,<sup>55,56</sup> blue,<sup>57–59</sup> green,<sup>60–62</sup> yellow,<sup>63–65</sup> red<sup>66–68</sup> and white light emission.<sup>69–71</sup> Owing to their unique PL properties, the prepared CDs exhibit outstanding properties in fluorescence calibration, biomedical sensing, and light emitting devices.

**2.1.1 PL mechanism.** Typically, the PL of CDs may stem from the quantum size effect, surface states, and molecular states.<sup>72–75</sup> However, the exact PL mechanism of CDs still remains controversial and requires further investigations. The quantum confinement effect, also defined as the size effect, is one of the most acceptable mechanism models for studying the PL of CDs. In general, the energy gap of CDs is affected by the particle size and shape. Recently, some studies have focused on quantum size effects in CDs. For example, Lee and co-workers demonstrated that the strong emission of CDs was related to the quantum size of graphite fragments. Fig. 3a illustrates different emission colors and emission wavelengths

**Fig. 3** (a) The optical images taken under white (left) and UV light (right) with differently sized CQDs synthesized through a one-step electrochemical approach from graphite rods; (b) PL spectra of differently sized CQDs: the red, black, green, and blue curves correspond to the PL spectra for blue-, green-, yellow-, and red-emission CQDs, respectively; (c) the relationship between the different CQDs sizes and the PL intensities; (d) relationship between the HOMO–LUMO gap and the size of the graphitic fragments.<sup>76</sup> (Reprinted with permission from Wiley-VCH Verlag GmbH. (f) The PL spectra and the Gaussian peak fitting on S12F (12 h reaction grown functionalized GQDs sample). (g) The spectrum of the PL spectra and Gaussian peak fitting on S24 (24 h reaction grown GQDs sample). The peaks P1, P2, P3 and P4 refer to the zigzag and armchair edge states, the COOH/C–OH and CQO/C–O edge functional groups, respectively.<sup>81</sup> (Reprinted with permission from the Royal Society of Chemistry, Copyright 2016.)

of different sizes of CDs with a narrow size distribution.<sup>76</sup> The relationship between PL and the size of CDs was firstly investigated through theoretical calculations. Then the authors purified the as-synthesized CDs by simple column chromatography to obtain different sizes of particles with a narrow size distribution, showing different emission colors (Fig. 3b). The relationship of the highest occupied molecular orbital (HOMO)–lowest unoccupied molecular orbital (LUMO) energy gap and the size of the graphene fragments is shown in Fig. 3c. The gap gradually decreased with the increase in fragment size, which agrees with a previous study.<sup>77</sup> The gap energy in the visible light range of graphene fragments with diameters of 1.4–2.2 nm was in agreement with the visible spectral emission of CDs with diameters smaller than 3 nm (Fig. 3d), illustrating that the strong emission of CDs was affected by the quantum-sized graphite structure rather than the carbon–oxygen surface. Huang and co-workers reported that the quantum size effect played an important role in the PL mechanism, and the defect state has a secondary role.<sup>78</sup> Budyka calculated the absorption spectra of polycyclic aromatic hydrocarbons with the general formula  $C_{6n}^2H_{6n}$  serving as molecular models of GQDs.<sup>79</sup> The transition energy decreased with increasing size  $n$  according to equation  $E_1 = 4.75 \times n^{-0.633}$  eV. The author concluded that the pure graphene sheets of fully  $\pi$ -conjugated  $sp^2$  systems without defects possessed size-dependent optical properties because of the quantum confinement effect. Teng and co-workers presented that the quantum confinement resulting from a size change in the  $sp^2$  domains caused a change of the  $\pi^*-\pi$  gap rather than n-state levels.<sup>80</sup>

In addition to the quantum effect, the surface state is another important factor to determine the PL mechanism of CDs. In fact, surface states have not been accurately defined due to the diversity and uncertainty of molecular structures. The surface of CDs has abundant trap states owing to surface oxygen-related groups ( $-\text{COOH}$ ,  $-\text{OH}$  and  $\text{C}-\text{O}-\text{C}$ , etc.), dangling bonds and hybrid carbon atoms of  $sp^2$  or  $sp^3$ . Therefore, surface defect states can occur at any sites except the perfect  $sp^2$  domain. For instance, Giri and co-workers synthesized highly fluorescent and edge-controlled GQDs from different solvents.<sup>81,82</sup> The edge of CDs mainly contains zigzag and armchair structures (Fig. 3e), providing a specific chemical structure to affect the PL property. By monitoring the PL spectra, the edge state conversion in the GQDs before and after annealing in a  $\text{H}_2$  and  $\text{O}_2$  environment has been evaluated. It was found that the PL spectra of GQDs (S12F and S24) can be fitted with four Gaussian peaks (P1–P4). Typically, the blue P1 and P2 peaks are related to the zigzag and armchair edge defects, while the green P3 and P4 peaks are assigned to their edge oxygenated functional groups (Fig. 3f and g).

Liu and co-workers conjectured that an energy transfer process might exist between the carbon core and the surface state. The CDs showed five emission bands at 305, 355, 410, 445, and 500 nm corresponding to the five intrinsic C (4.1 eV), graphitic N (3.5 eV), pyridinic N (3.0 eV), amino N (2.8 eV) and  $\text{C}=\text{O}$  (2.5 eV) related levels, respectively.<sup>83</sup> Xiao and co-workers reported that the lifetime discrepancy of PL may not involve the  $sp^2$ -related states (Fig. 4a and b), but the high temperature

made decay dynamics fall sharply due to nonradiative traps of defect state electrons/the  $sp^2$  (Fig. 4c and d). The photoexcited electrons *via* the  $\pi-\pi^*$  transitions included the  $sp^2$  energy levels, the defect states and long-wavelength PL (Fig. 4e).<sup>84</sup> Yu and co-workers proposed that the PL property of CDs was the result of interactions between isolated pyridine derivative molecules and surface defect states (Fig. 4f). The PL mechanism from the defect emission of CDs was composed of some isolated  $sp^2$  clusters, connected pyridine-derivative units, abundant defect states and graphitic cores (Fig. 4g).<sup>85</sup> Xiong and co-workers reported eight types of CDs of obvious fluorescence characteristics separated by silica column chromatography with urea and *p*-phenylenediamine as reaction materials (Fig. 4h–j) and speculated that the PL from CDs surfaces were consisted of bonded oxygen atoms and conjugated carbon atoms.<sup>86</sup> The energy gap between the HOMO and LUMO was inversely proportional to the number of incorporated oxygen species. The increment of oxidation degree resulted in a PL redshift (Fig. 4k). Some electrons and excited electrons in the p-orbital might be trapped by the defect state of energy below the  $p^*$ -orbital, and then return to the holes in the p-orbital. The electrons captured by the surface defect state were eventually relaxed through radiation and non-radiation processes. The PL signal from radiation relaxation was called a defect emission.<sup>87</sup>

**2.1.2 PL emission spectroscopic studies of CDs.** One of the most significant properties of CDs is excitation-dependent-emission in terms of wavelength and intensity. The PL emission spectra of CDs are roughly wide and symmetrical on the wavelength scale. In addition, the emission spectrum of CDs is affected by excitation wavelength, pH, metal ions, solvent, solid state polymers, size and heteroatom doping (Fig. 5a–h).<sup>88–90</sup> Aslam and co-workers studied the excitation-dependent-emission PL of CDs, of which the strongest emission intensity was related to the wavelength of excitation.<sup>91</sup> The excitation-dependent-emission PL could be affected by excited electron relaxation to different energy levels as well as the surface chemistry distribution.<sup>91,92</sup> Recently, the excitation-independent-emission PL property has also been widely investigated. For example, Huang and co-workers prepared a series of CDs with different densities of amino-groups *via* a bottom-up approach by using citric acid (CA) as the carbon source and guanidine hydrochloride as the N source. It was found that the as-prepared CDs with a low N content showed an excitation-dependent-emission property; however, the samples with a high N content exhibited an excitation-independent-emission property. This result demonstrated that the surface states of CDs could be passivated by amino-groups, which is beneficial for achieving a high luminescence.<sup>93</sup> Tseng and co-workers used a multiGaussian function to fit the PL spectrum of the CDs, explaining the mechanism of the excitation-dependent and excitation-independent PL, which are related to core-state emission and surface state emissive traps, respectively.<sup>94</sup> Yong and co-workers

demonstrated that the emission wavelength of nitrogen and sulfur co-doped carbon dots (NS-CDs) was red-shifted with increasing excitation wavelength (Fig. 5a), and the PL intensity was dependent on the pH value (Fig. 5b). The authors conjectured that different sizes and various functional groups on the surface of NS-CDs caused different excited state energy levels.<sup>88</sup> Furthermore, a significant PL quenching effect was achieved in the presence of Fe<sup>3+</sup>, which could be used for Fe<sup>3+</sup> sensing (Fig. 5c). Yu and co-workers reported that the solvatochromic effect was usually attributed to the intramolecular charge transfer (Fig. 5d), and proposed that the same CDs emit different colors when mixed with different polymers (solid state) under a single excitation wavelength (Fig. 5f) which come from the change of surface electronic structures.<sup>89</sup> Using density-functional theory (DFT) and time-dependent DFT calculations, Chen and co-workers revealed that the PL of GQDs can be sensitively tuned by tailoring its size, edge configuration, shape, attached chemical functionalities, heteroatom doping and defects (Fig. 5g and h).<sup>90</sup> Doping with heteroatoms, affecting the electron levels and the overall electrical distribution, is an effective way to regulate the fluorescence properties of CDs. So far, a variety of heteroatoms (including nitrogen, boron, sulfur, tellurium, selenium, silicon, phosphorus and halogens) have been reported to be doped into CDs, which can improve their PL properties for further sensing and light-emitting applications. Jiang and co-workers analyzed the relationship between the electronegativity of heteroatom doped GQDs and their PL emission wavelength (Fig. 6a).<sup>95</sup> It was found that the emission wavelength of the doped GQDs was associated with the electronegativity of heteroatoms. The emission wavelength of GQDs doped with S or Se showed a redshift because of the low electronegativity of S and Se, instead of GQDs doped with the N element (Fig. 6b). Xing and co-workers synthesized GQDs doped with nitrogen and chlorine with double emissions by changing the reaction time and the molar ratio of nitrogen/chlorine.<sup>96</sup>

**Fig. 5** (a) The excitation-dependent normalized PL for NS-CDs *via* a one-step facile microwave-assisted pyrolysis using citric acid and thiourea, (b) pH-dependent PL spectra at different pH values, (c) the normalized PL intensity of NS-CDs in different metal ions.<sup>88</sup> (Reprinted with permission from the Royal Society of Chemistry, Copyright 2019.) (c) Predicted energy level diagrams for nitrogen-functionalized GQDs with different functional groups using *ab initio* calculations by the Gaussian 09 package. (d) Measured energy level diagram for nitrogen-functionalized GQDs. (e) PL image of nitrogen-functionalized GQDs in aqueous solution excited by a UV lamp (365 nm). (f) Normalized PL spectra (excited at 380 nm) of aqueous nitrogen-functionalized GQDs.<sup>97</sup> (Reprinted with permission from Wiley-VCH Verlag GmbH, Copyright 2016.)

The electron transitions of nonradiative processes can happen from HOMO ( $C_{\pi^*}$ ) to LUMO ( $C_{\pi^*}$ ), LUMO ( $N_{\pi^*}$ ) and LUMO ( $Cl_{\pi^*}$ ). The excited electron at the LUMO ( $C_{\pi^*}$ ) level will relax to LUMO ( $N_{\pi^*}$ ) or LUMO ( $Cl_{\pi^*}$ ). Thus, there were two emissions at 466 and 512 nm, which varied with nitrogen and chlorine doping concentrations. Surface functionalization of CDs containing heteroatomic molecules is also an effective approach to obtain heteroatom-doped CDs. Tetsuka and co-workers studied the gaps and energy levels of GQDs.<sup>97</sup> It was found that nitrogen functionalization changed the electronic structure of the system by the effective orbital resonance of doped nitrogen at the LUMO/HOMO energy levels. The authors evaluated the effects and depicted the change of the HOMO/LUMO levels of functional GQDs (Fig. 6c and d). It can be seen that GQDs with different nitrogen-containing functional groups possessed different HOMO/LUMO energy levels. Fig. 6e and f depict the PL image of nitrogen-functionalized GQDs and their normalized PL spectra ((i) azo-GQDs, (ii) primary amine-GQDs, (iii) *o*-phenylenediamine-GQDs and (iv) diaminonaphthalene-GQDs), showing completely different color emissions and PL properties. Liu and co-workers calculated the gap energy of CDs with different types of dopant functional groups.<sup>83</sup> As shown in Fig. 6d, the band gaps gradually increased with C=O, amino N and pyridine N groups, respectively. It could be concluded that the narrow band gaps of surface states were important for optical properties of CDs.

The quantum yield (QY) is defined as the number of emitted photons proportional to the number of absorbed photons. The QY of naked CDs is rather low (2% to 29.9%) because of epoxide and carboxylic groups acting as non-radiative electron-hole recombination centers, which could be determined by the fluorescence spectrum technique. Therefore, many strategies have been reported to improve the QY by changing some factors, such as the synthesis temperature,<sup>98</sup> element doping,<sup>99</sup> metal-enhanced fluorescence<sup>100</sup> and surface passivation/modification.<sup>101</sup> Among these, element doping is one of the most efficient routes to achieve high QY. For example, Li and co-workers prepared manganese doped CDs, possessing a quantum yield of 54%, which could be used to detect heavy metallic  $Hg^{2+}$  with a detection limit level of nM.<sup>102</sup> Yang and co-workers synthesized nitrogen/silicon co-doped CQDs (N, Si-CQDs) with a high QY of 97.3% through a hydrothermal approach, which had great potential to be applied in white LEDs.<sup>103</sup>

The PL decay lifetime reflects the time of the electrons in the excited state before going back to the ground state, which plays a vital role in practical applications in sensing, optoelectronics and bio-imaging.<sup>104</sup> The PL decay lifetime is usually influenced by the concentration of reporter, excitation laser power and even temperature conditions. For example, Zbořil and co-workers prepared N,S-co-doped CDs (N,S-CDs) and found that the PL lifetime reduced from 11.0 to 5.3 ns with the temperature increasing from 2 to 80 °C.<sup>105</sup> This result demonstrated the potential applications of the N,S-CDs for thermal sensing.

In a word, the unique PL properties of varied types of CDs have been investigated in recent years. It is of great importance to reveal the PL mechanism from steady PL spectroscopy. In addition, the unique chemical and electronic structure of CDs

contributes to the high QY and long PL decay lifetime. However, some new spectroscopic measurements are necessary to clarify the PL properties of CDs.

## 2.2 NIR fluorescence

So far, scientists have taken great efforts to synthesize various types of CDs with different strategies. The optimal excitation wavelength of most CDs is in the UV range, which limits their broad applications in biomedical fields. On the other hand, near-infrared emissive CDs (wavelength >650 nm) can decrease autofluorescence and penetrate a bio-sample. Therefore, NIR emitting CDs are very suitable for optical bio-imaging. For example, Hao, Zeng and co-workers developed novel NIR-II-emitting CDs excited with a 808 nm laser, which possessed a high quantum yield at 900–1200 nm and excellent biocompatibility. Furthermore, the prepared CDs showed high photo-thermal efficiency (30.6%), and were successfully applicable in *in vivo* NIR-II bioimaging (Fig. 7a).<sup>106</sup> The results showed that the tumor after intratumoral injection (i.v.) and intravenous injection (i.t.) of CDs disappeared on the sixth day compared with injection of PBS solution (Fig. 7b–e).

Recently, Qu, Rogach and co-workers reported CDs with remarkable two-photon-induced NIR emission as well as three-photon-induced red emission in dimethyl sulfoxide.<sup>107</sup> The sulfoxide/carbonyl connected to the edges and the outer side of the CDs led to an increase of the discrete energy levels and degree of surface oxidation. Moreover, the functionalized

(k) GOQD quenching modeling *via* electron transfer from the UCPL GOQDs to the  $Cu^{2+}$  ions.<sup>113</sup> (Reprinted with permission from Elsevier Ltd, Copyright 2014.)

CDs promoted the NIR absorption band and enhanced NIR luminescence, leading to their potential applications in NIR fluorescence imaging. Recently, Wu, Xiao and co-workers synthesized N-doped CDs through a solvothermal reaction, exhibiting NIR emission with two photon luminescence.<sup>108</sup> In addition, the prepared N-doped CDs displayed a piezochromic luminescence with reversibility, showing a red- and blue-shifted PL with applied pressure increasing from 0.07 to 1.70 GPa and a red- and blue-shifted PL with an external pressure from 5.18 GPa to 1 atm, which could expand their applications to detect external pressure stimuli.

Upconversion PL is an anti-Stokes type emission which exhibits emission light of shorter wavelength (single photon of higher energy) through absorption of two or more photons of longer wavelength. Then two- or multi-photon fluorescence properties can be achieved in the near-infrared region, demonstrating promising applications in the biomedical imaging field. In 2007, Sun and co-workers first reported up-converted CDs with two-photon fluorescence, which was excited using an 800 nm femtosecond infrared pulsed laser.<sup>109</sup> From then on, many researchers have focused on this field. For example, N-doped GQDs (N-GQDs) have been synthesized from GO in dimethylformamide solution *via* a solvothermal reaction, showing excellent two-photon fluorescence properties due to the rigid plane and large  $\pi$ -conjugated system of N-GQDs (Fig. 7f). Fig. 7g (the inset is a fluorescence image of N-GQDs) shows the fluorescence spectrum of N-GQDs solution induced by an 800 nm wavelength femtosecond laser.<sup>110</sup> The PL intensity had a quadratic relationship with the excited laser power (Fig. 7h). It was found that two-photon fluorescence with a much narrower bandwidth than the one-photon fluorescence spectrum was obtained. Photon absorption with NIR excitation contributes to the green fluorescence of the prepared N-GQDs. Cui and co-workers demonstrated a facile strategy to enhance the upconversion PL and tailor the red-shift fluorescence of CDs *via* the introduction of H<sub>2</sub>O<sub>2</sub> during a hydrothermal reaction.<sup>111</sup> It could be considered that the upconverted PL property resulted from a multiphoton active process.

The upconverted PL property enabled CDs promising applications in sensing, catalysis, and bio-imaging fields. Recently, highly fluorescent N-doped CDs have been prepared through a solar irradiation strategy between *o*-phenylenediamine and citric acid, exhibiting not only ultra-violet (378 nm) pumped emissions but also up-converted PL signals in the NIR range (750 nm).<sup>112</sup> The prepared N-doped CDs provides an efficient multi-modal sensing platform for Hg<sup>2+</sup>. Cho, Seo and co-workers explored quenching properties of upconversion PL on graphene oxide quantum dots (GOQDs) and Cu<sup>2+</sup> ions (Fig. 7i–k).<sup>113</sup> It was found that the PL quenching was attributed to an electron transfer instead of an energy transfer mechanism. In recent years, up-converted CDs-based hybrids have aroused a lot of attention for their promising applications in photocatalysis and cell imaging.<sup>114–117</sup> For instance, the photocatalytic activity of rutile TiO<sub>2</sub>/GQDs hybrids for methylene blue degradation under visible light was significantly improved compared with individual rutile TiO<sub>2</sub> nanoparticles and bare

GQDs. Furthermore, the photocatalytic activity of the rutile TiO<sub>2</sub>/GQDs was also higher than that of anatase TiO<sub>2</sub>/GQDs. The superior catalytic efficiency of the rutile TiO<sub>2</sub>/GQDs was owing to the upconverted PL peak of GQDs (407 nm) under visible light irradiation with an energy (3.05 eV) larger than the band gap of rutile TiO<sub>2</sub> (3.0 eV) but smaller than that of anatase TiO<sub>2</sub> (3.2 eV).<sup>114</sup> Another example of novel CQDs modified Bi<sub>20</sub>TiO<sub>32</sub> showed a rate constant 4.3 times higher than that of pure Bi<sub>20</sub>TiO<sub>32</sub> for the photodegradation of isoproturon, which was attributed to the function of CQDs as an up-conversion photosensitizer.<sup>115</sup> Recently, CDs-based hybrids have also been designed for two-photon biosensing applications. Tian and co-workers for the first time reported the preparation of a CDs-based inorganic–organic hybrid system for imaging and biosensing of pH in tumor tissue, *e.g.* mouse LLC-MK2 cells and human A549 cells at a depth of 65–185  $\mu$ m through two-photon microscopy, demonstrating the practical applications of CDs in living cells.<sup>116</sup>

### 2.3 SERS spectroscopy

SERS is a non-invasive spectroscopic technique based on molecular vibrational fingerprints that quantifies and identifies ultra-trace analytes.<sup>118,119</sup> Generally, plasmonic nanostructures composed of Ag, Au, Cu and Al have been employed as SERS substrates to boost Raman signals, which originates from two mechanisms: (1) electromagnetism (EM) based on surface plasmon resonance (SPR) on the metal surface,<sup>120</sup> (2) charge transfer (CT) prompted by the interaction between the metal surface and adsorbed molecules.<sup>121</sup> The development of SERS is associated with progress of the fabrication of novel substrates. Thus, the manufacture of efficient SERS substrates becomes more vital in this study field. The “hot spots” existing in the nanogap between metal nanoparticles is considered to be a key issue to produce outstanding SERS substrates.<sup>122</sup> CDs without doping and modification were first regarded as SERS substrates by Shi and co-workers in 2012.<sup>123</sup> An electrophoresis deposition strategy was developed to assemble GQDs into nanotube arrays by using a nanoporous anodic aluminum oxide membrane as a template. By using Rhodamine 6G (R6G) molecules as probes, the highest 74-fold SERS enhancement could be obtained on the surface of GQDs nanotubes, which was much higher than those on the graphene substrate. The SERS spectra revealed that the detection limit could reach around 10<sup>−9</sup> M, demonstrating their high sensitivity. In addition to dye probes, this SERS substrate has also shown the capacity for 2,4-dinitrotoluene (2,4-DNT) detection. The SERS spectrum showed similar vibrational frequencies to those previously reported Au and Ag substrates. Similar to the graphene film, efficient CT between GQDs and target molecules should contribute to the excellent SERS property of the GQDs nanotubes. Furthermore, the unique porous structure of the GQDs nanotubes with a rough surface guaranteed the large specific surface area for target molecule adsorption as well as incident light capture, which is another key factor to generate unique SERS activity. This fact could be verified by the weak SERS signals on the surface of GQDs microbowls.

Recently, CDs have been reported to show strong catalysis to generate gold and silver nanomaterials as efficient SERS substrates for quantitative analysis.<sup>124–126</sup> In addition, CDs have also been used to support Au and Ag materials for efficient SERS substrates to enhance their SERS activity. For example, Qu and co-workers fabricated a honeycomb architecture composed of CQDs to support gold nanoparticles as a SERS substrate, exhibiting 8–11 times higher SERS activity than the traditional Au nanoparticle SERS substrate. It was speculated that the CQDs honeycomb structure and the uniformly distributed small Au particle size (<10 nm) contributed to the improved Raman response.<sup>127</sup> Recently, our group has synthesized Ag@CDs nanoparticles (NPs) with a core-shell structure serving as SERS substrates.<sup>128</sup> It was found that the Ag@CDs NPs could quench the fluorescence of CDs through the introduction of Ag, which was beneficial for the SERS enhancement. In addition, the superior adsorption of target molecules by Ag@CDs also contributed to their SERS enhancement. By using *p*-aminothiophenol (PATP) as target molecules, the typical  $a_1$  vibration mode at 1077  $\text{cm}^{-1}$  and  $b_2$  vibration modes at 1143, 1390, 1434, and 1570  $\text{cm}^{-1}$  were observed. The enhancement factor value was calculated to be about  $6.7 \times 10^5$  for the Ag@CDs NP substrate. Furthermore, the prepared Ag@CDs NPs showed a better SERS enhancement than individual Ag NPs, demonstrating the synergistic effect between Ag and CDs for the SERS activity. More interestingly, the core-shell Ag@CDs NPs also exhibited excellent enzymatic catalytic activity towards the oxidation of 3,3',5,5'-tetramethylbenzidine (TMB) in the presence of  $\text{H}_2\text{O}_2$  (Fig. 8a), plasmon driven *p*-nitrothiophenol (PNTP) dimerization into 4,4'-dimercaptoazobenzene (DMAB) (Fig. 8b), and the catalytic reduction of PNTP to PATP by  $\text{NaBH}_4$  (Fig. 8c). Similarly, we have also prepared a Ag NPs/CDs hybrid *via* a simple chemical coupling reaction strategy as a SERS substrate to study the enhancement mechanism.<sup>129</sup> Fig. 8d illustrates the relationship between the peak intensity ratio (1144 ( $b_2$ ), 1075 ( $a_1$ )  $\text{cm}^{-1}$ ) of PATP molecules and the excitation energy on the surface of Ag NPs/CDs and Ag NPs. It could be concluded that the SERS signal of Ag NPs was associated with the polarizability of the molecules and the change of the potential under higher excitation energy, which was consistent with a previous report.<sup>130</sup> The SERS signal of Ag NPs/CDs was related to the degree of CT. Meanwhile, the relationship between the relative intensity ( $b_2/a_1$ ) and the laser power of the two bands was investigated (Fig. 8e and f), from which it could be concluded that the SERS chemical enhancement mechanism was mainly controlled by the enhancement of the  $b_2$  band.

In addition to Au and Ag hybrids with CDs,<sup>131,132</sup> a Cu/CDs hybrid has also been prepared to be an efficient SERS substrate.<sup>133</sup> For example, Jiang and co-workers reported the fabrication of Cu/CDs assemblies with varied morphologies through an organic-inorganic interface interaction. Owing to the lattice-matching, CDs selectively deposited on the Cu{111} plane to form a unique Cu/CDs hybrid. Further, CDs in the Cu/CDs hybrid not only prevented Cu oxidation but also provided a unique interface for optical conversion and CT, contributing to the enhanced SERS effect. The SERS detection

(d) The Raman intensity of PATP molecules on Ag NPs/CDs versus time, (e) the SERS intensity ratio ( $I_{1144}/I_{1075}$ ) at different times with different powers, (f) the SERS intensity ratio ( $I_{1144}/I_{1075}$ ) versus power at 300 s.<sup>129</sup> (Reprinted with permission from Elsevier B.V. Copyright 2017.) (g) Schematic of a P-GQDs substrate for Raman measurement and (h) Raman mapping of the intensity of the G band and the characteristic peaks of R6G on P-GQDs. (i–n) Raman spectra of thermally evaporated Rhodamine 6G (R6G), copper phthalocyanine (CuPc) and Protoporphyrin IX (PPP) on  $\text{SiO}_2/\text{Si}$ , GQDs produced by solution processes (S-GQDs), highly oriented pyrolytic graphite (HOPG), transferred chemical vapor deposition (CVD) graphene and P-GQDs, respectively. (e–g) Relative intensity of the Raman signals of R6G, CuPc and PPP on different substrates, normalized to the signals on  $\text{SiO}_2/\text{Si}$ .<sup>134</sup> (Reprinted with permission from Nature Publishing Group, Copyright 2018.)

limit reached  $10^{-8}$  M by using PATP as target molecules. The SERS enhancement mechanism of GQDs using R6G molecules as probes has been investigated by an *ab initio* density functional theory (DFT) calculation approach.<sup>134</sup> The CT process between GQDs and R6G would occur when their HOMO levels were close, which contributed to the SERS signal. In addition, the authors also investigated the SERS substrate based on the quasi-equilibrium plasma-enhanced chemical vapor deposition GQDs (P-GQDs) grown on  $\text{SiO}_2/\text{Si}$  (Fig. 8g). P-GQDs as the SERS substrate was demonstrated to be reliable *via* analyzing the Raman spectra (Fig. 8i–k) and relative intensity (Fig. 8l–n) of R6G, copper phthalocyanine (CuPc) and Protoporphyrin IX (PPP) on different substrates, with an ultra-low detection concentration ( $1 \times 10^{-9}$  mol  $\text{L}^{-1}$ ) for R6G. The authors conjectured that the superior SERS activity could be attributed to the high-quality GQDs with atomically clean surfaces and a large number of edges, as well as the enhanced CT between molecules and GQDs with appropriate diameters due to the existence of Van Hove singularities in the electronic density of states.<sup>134</sup>

## 2.4 Phosphorescence

Phosphorescence refers to a radiative transition and spin-forbidden process from the triplet state ( $T_1$ ) to the singlet

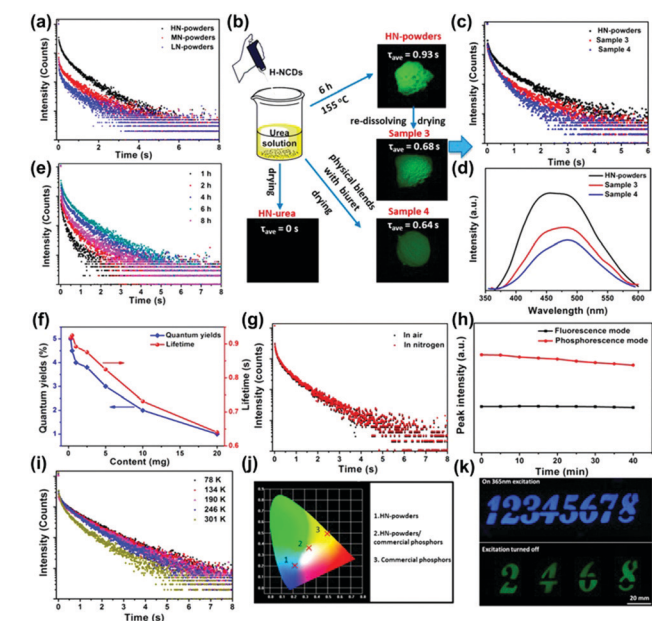

ground state ( $S_0$ ). The phosphorescence lifetime is longer than the fluorescence lifetime.<sup>135</sup> As an emerging optical response material, the room temperature phosphorescent properties of CDs have been investigated, which could be monitored by steady state PL spectroscopy and time-resolved phosphorescence spectroscopy. The first observation of phosphorescence from CDs in a polymer matrix was reported by Zhao and co-workers.<sup>136</sup> Yang and co-workers concluded that C=N bonds facilitate the production of triplet excitons (Fig. 9a).<sup>137</sup> Moreover, the complex matrix was a key factor in preventing the triplet state from a long lifetime quenched by inhibiting the nonradiative processes (Fig. 9b–e). It can be seen from the optical spectra of N doped CDs incorporated into biuret composite matrices that they possessed a good oxygen barrier performance and the hydrogen bonds were effective in suppressing vibrational dissipation at all temperatures (Fig. 9f–i). In addition, the N doped CDs-based composite with distinguishable lifetime codes was expected to be applied in data encryption (Fig. 9j and k). The steady-state PL and phosphorescence spectra presented the contributions of hydrogen bonding between N-doped CDs and biuret to the emissive triplet relaxation. The phosphorescence mechanism is ascribed to the generation of novel energy level structures from C=N bonds on the surface of the N-doped CDs. Moreover, an ultralong phosphorescence lifetime of 1.06 s was achieved for the prepared N-doped CDs encapsulated in biuret under 280 nm excitation.

Organic molecules have also been used to construct hydrogen-bonded networks with CDs by utilizing water molecules to promote phosphorescence emission.<sup>138</sup> The prepared CDs–cyanuric acid (CA) hybrid displayed a high phosphorescence lifetime of 687 ms, which was ascribed to the enhanced rigidity of the CDs after the introduction of CA. The enhancement mechanism for the phosphorescence emission of the CDs/CA system has also been investigated.<sup>139</sup> There were two main aspects that were involved in the reducing the surface defect and increasing the degree of conjugation between the carbon core and carboxyl groups. Zhou and co-workers proposed a strategy to effectively enhance phosphorescence signals by using water molecules to build hydrogen bond networks between cyanuric acid and CDs, which effectively stiffens the C=O bond of the CDs, as well as greatly increases the rigidity of the overall system.<sup>140</sup>

In the last few years, phosphorescence energy transfer systems between CDs and inorganic matrixes have attracted increasing attention for their promising applications for sensing and security applications. For example, phosphorescence energy transfer has been observed to take place between carbon nanotubes and Mn-doped ZnS quantum dots conjugated with capture ssDNA, which could be used for supersensitive detection of DNA.<sup>141</sup> Similarly, the phosphorescence efficiency of CDs has been enhanced by the introduction of an inorganic layered double hydroxide (LDH) matrix, which improved the rate of radiative attenuation from  $T_1$  to  $S_0$  and intersystem crossing (ISC) from  $S_1$  to  $T_1$ .<sup>142</sup> A molten salt (MS) strategy has been used to prepare CDs@MS, showing an excitation dependent phosphorescence property.<sup>143</sup> The phosphorescence generation could be related to the preservation of the triplet state of CDs by the rigid structure from the crystallization of MS. The high charge density of metal ions reduced the energy gap of CDs for the achievement of ISC. It is well known that boron is an electron withdrawing atom, which is able to reduce the energy gap between the singlet and triplet states. Therefore, the introduction of boric acid into CDs was beneficial for the ISC between  $S_1$  and  $T_1$ , which enhanced the triple excitons and the phosphorescence emission.<sup>144</sup> The prepared heteroatom-free-CDs/boric acid hybrid displayed a yellow-green phosphorescence and an ultrahigh lifetime of 1.6 s.

In addition to the polymers, organic molecules and functional inorganic matrixes, individual CDs have also been observed to show room temperature phosphorescence.<sup>145–149</sup> For example, Lin and co-workers proposed a self-immobilization strategy to prepare N and P doped fluorescence emissive CDs. After a further heating process, the product can convert fluorescence to ultralong phosphorescence.<sup>145</sup> An excitation-dependent phosphorescence spectrum of the CDs powder was achieved. The steady state fluorescence and afterglow decay spectra revealed an average lifetime of about 1.39 s. It could be concluded that the formed compact cores *via* a further heating step self-immobilize the excited triplet excitons due to the intraparticle hydrogen bonds. Furthermore, the N and P dopants are also beneficial to form an  $n \rightarrow \pi^*$  transition to improve the ISC process for populating triplet species. Similarly, a microwave irradiation approach has also been demonstrated to fabricate N and P doped-CDs,

displaying the longest phosphorescence lifetime and undergoing an  $n-p^*$  transition to effectively fill triplet excitons.<sup>146</sup> F and N co-doped CDs (FNCDs) have also been prepared to emit green self-protective phosphorescence with longevous triplet excited states.<sup>147</sup> The phosphorescence of the FNCDs results from the  $n-\pi^*$  electron transitions for  $C=N/C-N$  bonds as well as the reduction of the phosphorescence quenching to oxygen by the hydrogen bonds between F and N-H. Recently, Yang and co-workers demonstrated that a novel covalently crosslinked framework structure of the polymeric CDs could efficiently suppress the nonradiative transitions and the abundant energy levels of the polymeric CDs increased the ISC.<sup>148</sup> Therefore, a phosphorescence emission with a broad peak centering at 494 nm was observed for the prepared polymeric CDs. In addition, the lifetime of the obtained polymeric CDs was calculated to be about 0.03 s. The crosslink enhanced emission effect has been regarded as the key factor for the phosphorescence production.

## 2.5 CL

CL can be described as a process of emitting photons from the excited states to the ground states during a chemical reaction.<sup>150,151</sup> Most properties of CL are similar to fluorescence. The difference is that the excitation energy of fluorescence comes from the excitation of external light sources, while the excitation energy of CL is produced by self-chemical reactions. In a chemical reaction, a molecule or an atom is excited by absorbing the chemical energy generated during the reaction. The energy is released by means of optical radiation when the excited molecule or atom returns to the ground state. The remarkable property of CL usually shows a high sensitivity due to the absence of an external light source. At present, the work on CL analysis based on CDs is still in its infancy.

Lin and co-workers first studied the CL properties of CDs in a mixed solution of  $\text{NaNO}_2$  and  $\text{H}_2\text{O}_2$ , which were the main emitters in the CDs- $\text{NaNO}_2$ - $\text{H}_2\text{O}_2$  system.<sup>152</sup> The CL spectra showed that the systems of  $\text{NaNO}_2 + \text{H}_2\text{O}_2$  and CDs +  $\text{H}_2\text{O}_2$  only exhibited a weak CL emission, while the system of  $\text{NaNO}_2 + \text{H}_2\text{O}_2 + \text{CDs}$  produced a very strong CL. This result implied that the product (oxidant,  $\text{ONOOH}$  and  $\text{OH}_3$ ) during the reaction of nitrites and acidified  $\text{H}_2\text{O}_2$  could transform and inject small holes of the CDs. This process, accelerating the hole-injected annihilation and increasing the number of injected electrons, brought about the release of energy in the form of CL emissions.<sup>153-156</sup> Lin and co-workers also developed a CL platform based on N-doped CDs to improve the CL sensitivity in a  $\text{KIO}_4$ - $\text{H}_2\text{O}_2$  system in a basic medium (Fig. 10b).<sup>157</sup> As shown in Fig. 10a and c, the intensity (3) was much higher compared with (1) and (2) because of the decomposition of  $\text{H}_2\text{O}_2$  and energy transfer of  $^1\text{O}_2$  as emissive species. Dong and co-workers reported a CNDs/ $\text{K}_2\text{S}_2\text{O}_8$  system with enhanced CL efficiency induced by triethylamine (TEA) (Fig. 10f).<sup>158</sup> The CL spectrum showed that the CL intensity of the CDs/ $\text{K}_2\text{S}_2\text{O}_8$  system increased after the introduction of TEA (Fig. 10d). The enhanced CL emission could result from the reduction of CNDs by the TEA free radicals to generate excited CNDs. Furthermore, the addition of CNDs at the end is beneficial to increase the CL signal (Fig. 10e). Similar to the CNDs, Abdolmohammad-Zadeh and co-workers constructed

Fig. 10 (a) CL curves of a  $\text{KIO}_4$ - $\text{H}_2\text{O}_2$ -N-doped CDs system ((1)  $\text{H}_2\text{O}_2$  was added to the mixture of  $\text{KIO}_4$  and N-CDs, (2) N-CDs was added to the mixture of  $\text{KIO}_4$  and  $\text{H}_2\text{O}_2$ , (3)  $\text{KIO}_4$  was added to the mixture of  $\text{H}_2\text{O}_2$  and N-CDs). (b) The mechanism of enhancement of the CL of the  $\text{KIO}_4$ - $\text{H}_2\text{O}_2$  system by N-doped CDs in acidic (the decreasing effect) and basic (increasing effect) solutions. (c) CL spectra of the  $\text{KIO}_4$ - $\text{H}_2\text{O}_2$  system in the presence and absence of N-doped CDs and NaOH (a:  $\text{KIO}_4$ - $\text{H}_2\text{O}_2$ , b:  $\text{KIO}_4$ - $\text{H}_2\text{O}_2$ -N-doped CDs, c:  $\text{KIO}_4$ - $\text{H}_2\text{O}_2$ -N-doped CDs-NaOH).<sup>157</sup> (Reprinted with permission from the American Chemical Society, Copyright 2016.) (d) The CL spectrum of the CNDs/ $\text{K}_2\text{S}_2\text{O}_8$  system and the CNDs/TEA/ $\text{K}_2\text{S}_2\text{O}_8$  system. (e) CL spectrum of the CNDs/TEA/ $\text{K}_2\text{S}_2\text{O}_8$  system under different reagent mixing orders. (f) The scheme of the CL mechanism of the CNDs/ $\text{K}_2\text{S}_2\text{O}_8$ /TEA system.<sup>158</sup> (Reprinted with permission from the American Chemical Society, Copyright 2016.)

a graphitic carbon nitride quantum dots ( $g\text{-CNQDs}$ )- $\text{K}_3\text{Fe}(\text{CN})_6$  CL system to achieve enhanced CL emission.<sup>159</sup> After mixing the  $g\text{-CNQDs}$  and  $\text{K}_3\text{Fe}(\text{CN})_6$ , a wide peak centered at around 503 nm was observed, which was similar to but significantly higher than the fluorescence band of  $g\text{-CNQDs}$ , revealing the efficient CL property of the  $g\text{-CNQDs}$ - $\text{K}_3\text{Fe}(\text{CN})_6$  system. Due to CL quenching in the presence of  $\text{Hg}(\text{II})$  ions binding with the  $g\text{-CNQDs}$  and the CT process, this system could be used to detect  $\text{Hg}(\text{II})$  with a high sensitivity and excellent selectivity. Recently, Amjadi and co-workers prepared Si doped CDs (Si-CDs) to construct a novel Si-CDs- $\text{Fe}(\text{II})$ - $\text{K}_2\text{S}_2\text{O}_8$  CL system, showing a CL emission peak at around 500 nm.<sup>160</sup> During the reaction, Si-CDs were used as receptors and  $^1(\text{O}_2)_2^*$  was used as a donor, producing excited-state Si-CDs with CL emission. Besides, the group illuminated the CL system based on a  $\text{CNQDs}$ - $\text{Cu}(\text{II})$ - $\text{H}_2\text{O}_2$  system, which took place under the condition of electron and hole injection (oxygen radicals).<sup>161</sup> This CL reaction has been utilized for the sensitive detection of  $\text{H}_2\text{O}_2$  and glucose. Similarly,  $N$ -(amino-butyl)- $N$ -(ethylisoluminol)-GQDs- $\text{H}_2\text{O}_2$ ,<sup>162</sup>  $\text{Cu}^{2+}$ -CDs,<sup>163</sup> and  $\text{Cu}(\text{II})/\text{Cu}_2\text{O}$ /N-doped GQDs-luminol- $\text{H}_2\text{O}_2$  CL systems<sup>164</sup> have also been constructed to show superior CL properties for biosensing applications. It has been reported that the surface groups of the CDs play an important role in their CL properties. For instance, the CL intensity of CDs prepared in peroxyinitrite was related to the concentration of C-O group-related O-states, demonstrating that ample C-O functional groups in CDs with high O-states could promote the electron transfer.<sup>165</sup> A recent report showed that N-doped GQDs strongly strengthen the CL intensity of the permanganate-sulfite system. However, the enhancement mechanism for N-doped GQDs was not dependent on the particle size.<sup>166</sup> The CL spectra revealed that pyridinic N in N-GQDs acted as a catalytic active site to the amplified CL emission.

With the increment of the pyridinic N concentration, an enhanced CL intensity was obtained.

## 2.6 ECL

ECL is a phenomenon where chemical substances that are produced on the electrode surface go through electron transfer reactions to realize excited states to generate light emission.<sup>167,168</sup> ECL mechanisms are categorized as two types according to the source of free radicals, which are the annihilation pathway and the co-reaction pathway, respectively. ECL techniques based on the CDs materials are widely used because of their simple synthesis, low-cost equipment requirement, high sensitivity and a wide linear range. The first investigation of CDs on ECL properties was reported by Yang and co-workers in 2009.<sup>169</sup> The CNDs were prepared through a simple microwave reaction by using poly(ethylene glycol) (PEG-200) and saccharide as the carbon sources. The ECL spectrum of the CNDs showed a similar behavior to those of traditional CdSe, CdTe, and Si nanocrystals. The ECL mechanism should be ascribed to the transfer of the excited CNDs ( $R^*$ ) that are formed from the electron-transfer annihilation of the oxidized state ( $R^{\bullet+}$ ) and the reduced state ( $R^{\bullet-}$ ) under a potential cycle to the ground state *via* a radiative pathway, which efficiently emitted a photon. Similar to CNDs, GQDs have also been proved to be a brilliant ECL material.<sup>170</sup> It has been reported that greenish-yellow colored GQDs were prepared from a microwave reaction *via* cleaving GO by acids, exhibiting a maximum wavelength at around 512 nm in the ECL spectrum. Most importantly, the high content of  $sp^2$  carbon domains in GQDs provides their unique energy gap compared with graphene, which is beneficial for the electron transport during the ECL process. CQDs could also be assembled into nanospheres with the assistance of a surfactant (pluronic F127), showing an excellent ECL stimulus response in water, while a weak ECL signal in a nonpolar solvent.<sup>171</sup> This is because the nonpolar CQDs (NCQDs)/F127 hybrid possesses two secondary structures, *e.g.*, a hydrophobic layer from the polyoxypropylene (PPO) moiety of F127 and NCQDs, and a hydrophilic layer from the PPO moiety of F127. In aqueous solution, the hydrophilic layer could adsorb  $SO_4^{\bullet-}$  to excite nearby NCQDs, producing superior ECL emission. However, in a nonpolar solvent, the NCQDs are separated from F127, which are difficult to excite by the  $SO_4^{\bullet-}$ , generating weak ECL signals.

High conductive materials have been utilized to improve the ECL property as a conducting bridge for efficient electron transfer. For example, a hybrid made of sandwiched CDs labeled on secondary antibodies on a glass carbon electrode showed certain ECL signals.<sup>172</sup> After the introduction of graphene as a conducting bridge, about 30-fold ECL enhancement was achieved. In addition to graphene, Au nanoparticles have also been used as signal transduction units for ECL amplification. Qiu and co-workers proposed a dual-potential ECL ratiometric approach to produce ECL signals by using GQDs and luminol as cathodic and anodic ECL emitters, and Au NPs as signal transduction units.<sup>173</sup> The introduction of Au nanoparticles could both reduce the cathodic ECL of GQDs and increase

the anodic ECL of luminol, demonstrating a dual-potential ECL ratiometric strategy to monitor kinase activity.

The ECL technique based on CDs could be used for sensing applications with a high sensitivity. For example, Wang and co-workers reported a dual-peak ECL system to detect iron ions, showing a higher efficiency than single peak ECL.<sup>174</sup> In this system, the ECL system at  $-2.84$  V (ECL-1) was induced through an electron transfer reaction between the reduced nanoparticles and co-reactant, while the ECL system at  $-1.71$  V (ECL-2) resulted from the quenching process. In addition to iron ions, a sensitive ECL biosensor based on N-doped CDs-Pd@Au hexoctahedra has been constructed for the detection of intracellular  $Pb^{2+}$  with a detection limit of  $0.33$  ng mL<sup>-1</sup> and relative standard deviations (RSDs) of no more than 5%.<sup>175</sup> Recently, a solid-state ECL sensor (CDs-Fe(CN)<sub>6</sub><sup>3-/4-</sup>) with an excellent signal amplification has also been constructed, which could be used to detect glutathione with a low detection limit of 54.3 nM and excellent selectivity.<sup>176</sup> Another example of a silica-doped GQDs-based ECL system with fluorescence was reported to detect ochratoxin.<sup>177</sup> With the addition of concanavalin A (Con A), glucose oxidase (GO)<sub>x</sub>-CeO<sub>2</sub>@Ag-GQDs were also demonstrated to be used as an excellent material by further analyzing the construction of biosensors (Fig. 11a) and the ECL response of different biosensors (Fig. 11b-d) under the same conditions. This ECL system could be used to detect Con A with a high sensitivity.<sup>178</sup> Xia and co-workers amplified dual potential ECL signals of GQDs *via* coupled electrochemical and chemical reactions in the presence of two different reactants (K<sub>2</sub>S<sub>2</sub>O<sub>8</sub> and Na<sub>2</sub>SO<sub>3</sub>); then, CQDs immobilized on graphene showed a nearly 48-fold ECL amplification to detect chlorinated phenols (CPs) in water by using K<sub>2</sub>S<sub>2</sub>O<sub>8</sub> as a coreactant.<sup>179</sup> The superior detection ability results from the high yield of the excited CQDs ( $C^{\bullet+}$ ) (Fig. 11e).<sup>180</sup> The reaction mechanism diagram is shown in Fig. 11f and g. The ECL signal was decreased due to

**Fig. 11** (a) ECL response of different structures of biosensors; a–d in the inset figure stand for bare glassy carbon electrode (GCE), electrodeposited of gold layers (Dp Au)/GCE, GOx/Dp Au/GCE, bovine serum albumin (BSA)/GOx/Dp Au/GCE, Con A/BSA/GOx/Dp Au/GCE and (GOx-CeO<sub>2</sub>@Ag-GQDs/Con A/BSA/GOx/Dp Au/GCE). (b–d) The ECL responses of different biosensors' modified electrodes.<sup>178</sup> (Reprinted with permission from Elsevier B.V., Copyright 2019.) (e) ECL intensity signal of CQDs/graphene in S<sub>2</sub>O<sub>8</sub><sup>2-</sup> solution (pH 7) at gradient increasing concentrations of pentachlorophenol. pentachlorophenol (PCP) on the CQDs surface oxidized by  $C^{*+}$ . Single-cell analysis is very important in bioscience and biomedical technology. To realize this objective, Yang and co-workers established an ECL analysis platform based on solid-state zinc-coadsorbed CQDs hybrids for breast cancer cell detection.<sup>181</sup> Through such a strategy, the determination of MDA-MB-231 and MCF-7 single cells with linear ranges of 1–18 and 1–12 cells has been realized, respectively.

### 2.7 Chirality

Chirality is defined as a property of a molecule by which it possesses a structure that is non-superimposable on its mirror image, which is one of the most pivotal factors to affect the optical properties of photosensitizer molecules. Chirality is ubiquitous in nature, not only in natural amino acids and DNA, but also in synthesized materials such as CDs.

Herranz, Martin and co-workers first reported the preparation of chiral GQDs from acidic exfoliation and oxidation of graphite in the presence of (*R*) or (*S*)-2-phenyl-1-propanol.<sup>182</sup> Pyrene was introduced to interact with GQDs. The GQDs-(*S*)/pyrene aggregates represented a positive cotton effect, while the GQDs-E(*R*)/pyrene aggregates exhibited a negative cotton effect in the circular dichroism spectrum from 320 to 350 nm. This result clearly revealed that the (*R*) or (*S*) configuration of 2-phenyl-1-propanol has been introduced into the GQDs structure. Chiral CDs have also been synthesized by using *D*-/*L*-methionine, *D*-/*L*-glucose, and *D*-/*L*-glucosamine.<sup>183</sup> The circular dichroism spectrum displayed a peak at around 210 nm in the positive direction for GQDs synthesized from *D*-methionine, while a different behavior was observed for GQDs from *L*-methionine. More interestingly, it was found that the chiral GQDs could affect the optical properties of azobenzene. Under UV light, azobenzene can react differently with *D*- and *L*-GQDs. Liu and co-workers synthesized chiral emitting CDs through a pyrolytic route using citric acid and *D*-/*L*-penicillamine (*D*/*L*-Pen) (Fig. 12a).<sup>184</sup> The chirality of Pen precursors was transferred to the CDs *via* an active surface passivation procedure (Fig. 12b). Fig. 12c shows anisotropic *D*/*L*-Pen-CDs. Chiral CDs have been widely used for targeted therapy, modulating cellular functions, and photoluminescent enantioselective sensing. Similarly, chiral CDs have also been prepared by cyclic  $\alpha$ -amino acids (*D*- or *L*-enantiomer), and *D*-/*L*-lysine as capping agents.<sup>185,186</sup> Recently, the chirality mechanism of *D*-CQDs and *L*-CQDs has also been demonstrated (Fig. 12d).<sup>187</sup> The spectra of *D*/*L*-CQDs and *D*/*L*-tryptophan (Trp) were symmetrical in a certain range of wavelengths. Moreover, they were enantiomeric isomers (Fig. 12e and f). The chiral *D*-/*L*-CQDs were prepared using raw material *D*-/*L*-tryptophan as both carbon and chiral sources. A symmetrical and opposite CDs spectrum has been observed for the *L*- and *D*-CQDs, showing three typical bands at 220, 240 and 290 nm. The former 220 nm signal is attributed to the inheritance of *L*-/*D*-Trp, and the latter two peaks are related to the inducement of the chiral environment. In detail, the 240 nm signal is ascribed to the  $\pi$ - $\pi^*$  conjugation of the  $sp^2$  carbon skeleton in *L*- and *D*-CQDs, while the 290 nm signal is derived from the  $\pi$ - $\pi^*$  transition between the introduced

Fig. 12 (a) The schematic diagram of the formation of chiral light emitting CDs by citric acid and *D*/*L*-Pen as the carbon sources. (b) The circular dichroism spectra of the as-prepared CDs. (c) The corresponding anisotropy factors for all as-prepared CDs.<sup>184</sup> (Reprinted with permission from the Royal Society of Chemistry, Copyright 2017.) (d) Schematic for the synthesis of *L*-/*D*-CQDs. (e) The circular dichroism spectra of *L*-/*D*-Trp. indole. A clear understanding of the chiral mechanism provides great potential for their applications in chiral recognition and other fields.

## 3. Summary and outlook

This review provides an overview of the unique optical properties of CDs, including PL, NIR fluorescence, SERS, phosphorescence, CL, ECL, and chirality. As one of the emerging versatile materials, CDs with varied compositions and chemical structures provide tunable and unique optical properties. The distinguishable optical properties have been characterized by the corresponding spectroscopies. Despite realizing the outstanding optical properties of a large number of novel CDs, there are still some challenges to be addressed for guiding their further applications. In particular, more attention should be paid to improve the optical performance of the CDs.

Firstly, the synthesis of varied CDs with tunable compositions, sizes, shapes, crystallinity and electronic structures is essential to tailor their optical properties. Although many advances have been achieved to prepare multifunctional CDs, most reported strategies suffer from the shortcomings of time consuming, environmentally unfriendly and low quantity production. Therefore, it is urgent to develop an efficient, controllable and sustainable synthetic strategy to prepare CDs with high quality and a large volume.

Secondly, the PL properties especially with blue or green fluorescence have been broadly explored in most types of CDs. However, CDs with NIR fluorescence, phosphorescence, ECL, and SERS properties are rarely reported. CDs with these optical properties are more suitable for bio-imaging, light emitting and highly sensitive sensing applications. It is highly desirable to prepare unique CDs with such unique optical properties with a high efficiency for promising applications.

Thirdly, the elucidation of the mechanism of the optical properties is still not clear. Up to now, much work has focused on the investigation of the PL mechanism of CDs, which has been attributed to the edge and surface states as well as the quantum confinement effect of CDs. However, there is still no strong evidence to propose a more universally acceptable PL mechanism of the CDs. Most importantly, the mechanisms of the other optical properties of CDs are much less investigated. It is necessary to conduct more theoretical and experimental research to better understand the mechanism of optical properties of CDs.

Finally, the hybridization of CDs with other functional materials is an efficient strategy to enhance their optical properties. In this regard, the modulation of the surface functionalization and interfacial effect of CDs-based hybrids is very important. In addition, much more attention including theoretical calculations and modern characterization techniques should be paid to the investigation of the correlation between the optical properties and their interfacial interactions.

We believe that the deep understanding of the optical properties of CDs will promote their promising applications in a large variety of fields. Furthermore, CDs are considered to be one of the most safe and eco-environmental materials. This makes CDs potential candidates for optical and photoelectronic applications.
