A metabolomic study for chronic heart failure patients based on a dried blood spot mass spectrometry approach

 Gaowa Zhao,^{ab} Dong Cheng,^{ab} Yu Wang,^{ac} Yalan Cao,^{ad} Shuting Xiang^{ad}
 and Qin Yu *^a

Objective: a dried blood spot (DBS) method integrated with direct infusion mass spectrometry (MS) focused on a metabolomic analysis was applied to detect and compare the difference of metabolites between the heart failure (HF) patients and non-HF patients in order to facilitate the early detection of heart failures, provide targeted intervention and offer prognostic insights. **Methods:** the method we used was an untargeted metabolic approach. The dry blood spot mass spectrometry (DBS) was used to analyze 23 types of amino acids and 26 types of carnitine in blood samples. In the current study, 49 metabolites were selected to establish the PLS-DA model to compare the differences between the 117 HF patients and 118 non-HF patients, which inclined to detect the difference between the two groups. Multiple algorithms were run for selecting different metabolites as potential biomarkers. Ten-fold cross validation method was used to verify and evaluate the selected potential biomarkers. **Results:** through significant analysis of the microarrays (SAM) and analysis of 9 parameters, 8 metabolites showed significant discrepancies between the HF and non-HF groups. Among these metabolites, the levels of 5 metabolites were increased, and the other 3 metabolites were decreased in the HF group compared with the non-HF group. However, 7 metabolites including Asn, C0, C14, C4DC, C5-OH, C6 and Glu were selected to distinguish the HF group from the non-HF group with specificity and sensitivity of 0.8475 and 0.8974, respectively. **Conclusion:** metabolomic study for chronic heart failure (CHF) patients based on the dried blood spot mass spectrometry approach would be beneficial to understand the metabolic pathway of HF, and probably work as biomarkers to predict the prognosis of HF and provide the basis for an individualized treatment.

Introduction

Heart Failure (HF) is a global public health problem with high morbidity and mortality, involving 26 million worldwide population, particularly occupying approximately 1% to 2% of the adult population.^{1,2} From an epidemiological perspective, timely diagnosis and early interventions in HF probably have far-reaching impacts on the healthcare economics and public health. From a microscopic perspective, HF is a manifestation of metabolic derangements on the genetic, cellular, proteomic, and metabolic levels;^{3,4} however, the metabolomic mechanism of HF is not completely understood. According to statistics, more than 40 000 unique metabolites have been identified in the Human Metabolome Database.⁵ Therefore, exploring the specific metabolomics and related biomarkers in the HF

patients would be beneficial to early diagnosis, prediction, prognosis and individualized treatments.

Metabolomics is used to detect low-molecular metabolites produced during the cellular metabolism processes.⁶ MS could detect and quantify low-abundance metabolite sensitively.^{7,8} As an important metabolic analytical technology, mass spectrometry (MS) has been widely used in the field of HF including the detection of metabolic spectra, screening of biomarkers and exploring the metabolic changes both in human blood and urine samples.^{9–11} Furthermore, the direct infusion MS technology could meet the requirements of high-throughput and rapid collection of fragmentation data and it has been applied in the metabolomics studies of various diseases.^{12,13} Compared to the traditional venous blood sampling technology, a dried blood spot (DBS) sample technology was usually used to collect blood in new born screening (NS), which makes samples easy to be transported and stored.^{14,15} In the current study, we combined direct infusion MS with the DBS samples to compare the metabolomic profiles of HF and non-HF patients, which has potential in prevention, detection, evaluation, and management of HF in patients.

Materials and methods

Sample information

HF and non-HF patients were obtained from Affiliated Zhongshan Hospital of Dalian University. All the clinical parameters were obtained from the targeted population including age, height, weight, and blood pressure (BP) levels. In addition, the medical histories were collected. DBS samples were composed of 117 HF patients as the case group. In addition, 118 non-HF patients were taken into the control group without cardiovascular diseases. The HF patients enrolled in the study should meet the following inclusion criteria for the diagnosis of chronic heart failure (CHF), who should meet the Framingham heart failure diagnostic criteria; ESC (European society of Cardiology) guidelines for the diagnosis and treatment of HF 2016; New York Heart Association (NYHA) class II to IV. Exclusion criteria: patients with malignant hypertension, severe arrhythmia, acute myocardial infarction (<72 h), acute myocarditis, aortic dissection, hemodynamic instability, and malignant tumor combined with severe hepatorenal dysfunction; other specific oxidative stress related diseases. In the control group, patients with non-HF were excluded from diabetes, digestive diseases, chronic infectious diseases, hypertension, kidney diseases, autoimmune diseases, endocrine disorders and cancer. The average age of the case and control groups is 54 (23–91) years and 73 (26–96) years, respectively. The information for HF patients and non-HF patients are shown in Table 1. There was no age difference between the case and control groups ($p = 0.2975$, t -test). All the participants were used to build a training set for the prediction model. Ten-fold cross validation was executed to build the test set for checking the applicability of the prediction model. The study was approved by Affiliated Zhongshan Hospital of Dalian University. Also, all the participants have understood and signed the informed consent.

Chemicals

We acquired high-purity acetonitrile of high-performance liquid chromatography grade from Thermo Fisher (Waltham, MA), and obtained 1-butanol and acetyl chloride from Sigma-

Aldrich (St Louis, MO). Also, we utilized isotope-labeled internal standards, which were obtained from Cambridge Isotope Laboratories (Tewksbury, MA) for 12 amino acids (NSK-A) and 8 acyl carnitines (NSK-B) to make absolute quantification. We prepared these standards by dissolving in 2 ml pure methanol and storing them at 4 °C. Besides, we diluted the working solution 100-fold for metabolite extraction. We purchased the quality control (QC) standards for amino acids and carnitine from Chromsystems (Grafelfing, Germany) and injected the QC standards into the real sample analysis queue to ensure analysis stability.

Sample preparation

A DBS filter paper (equivalent to 3.2 μ l whole blood) was placed into a 96-well plate. This disc was transferred to a Millipore Multi Screen HV 96-well plate (Millipore, Billerica, MA, USA) for metabolite extraction. Briefly, 100 μ l of the working solution was dispensed into one well containing a DBS disc and gently shaken for 20 min at room temperature and centrifuged at 1500 $\times g$ for 2 min to collect the filtrate into a new flat bottom 96-well plate. The filtrate and QC solutions were subjected to drying by pure nitrogen gas at 50 °C. Each dried sample was derivatized in a 60 μ l butanol and acetyl chloride mixture (90 : 10, v/v) at 65 °C for 20 min. The derivatized solutions were dried by pure nitrogen gas at 50 °C again. Every 100 μ l mobile phase solution was added into each well prior to the metabolomics analysis.¹⁶

Metabolomic analysis

The direct injection MS metabolomic analysis was conducted using an AB Sciex 4000 QTrap system (AB Sciex, Framingham, MA, USA). The equipped ion source was an electrospray ionization source. All the analytes were scanned under a positive model.¹⁷ The positive model, we used, was linked with abundant detection of the metabolites, while use of a negative model could not detect the metabolites, so only “positive model” was used in the current study.

We injected 20 μ l sample for each run, and used the 80% acetonitrile aqueous solution as the mobile phase at an initial flow rate of 0.2 ml min⁻¹. The flow rate was subsequently decreased to 0.01 ml min⁻¹ within 0.08 min and remained for 0.5 min. We set an ion spray voltage at 4.5 kV, a curtain gas pressure to 20 psi, the pressure for ion source gas 1 and gas 2 to 35 psi, and an auxiliary gas temperature at 350 °C.

Analyst v1.6.0 software (AB Sciex) was used to execute the raw data collection and system control. Data preprocessing was achieved by the ChemoView 2.0.2 software (AB Sciex). Partial least squared discriminant analysis (PLS-DA) and principal component analysis (PCA) were used to distinguish the HF patients from non-HF individuals. In addition, importance in projection (VIP) was calculated by SIMCA-P v12.0 (Umetrics, Umea, Sweden). This variable represents the contribution of variables towards disease classification. Therefore, VIP values were used to select the variables. In order to check the rationality of the building model, a 200-time permutation test was used. The normality for all the variables in the HF and non-HF groups was inspected using the Shapiro–Wilk test. T -test was

^a The clinical indicators were compared between case and control groups. Continuous variables were analyzed by the unpaired t -test. Chi-squared test was used to count variables.

Fig. 1 Partial least-squared discriminant analysis (PLS-DA) for the metabolomic data of the heart failure and non-heart failure groups. (A) Score plot shows the discrepancy between the heart failure and non-heart failure groups. (B) The model is accessed via 200-time permutation test. A 200-time permutation test was used to assess the model. The y-axis intercepts are R2 (0, 0.0954) and Q2 (0, -0.116).

used to check the discrepancy between the HF and non-HF groups. For the non-parametric variables, the Mann-Whitney test was applied. In addition, for adjusting the p -values towards multiple hypothesis testing, a Benjamini Hochberg-based false discovery rate (FDR) was applied.¹⁸ For selecting variables, the VIP values ($VIP > 1$) and adjusted p -values (adjusted $p < 0.05$) were applied with targeted values over 1 and lower than 0.05, respectively. In addition, the significant analysis of microarrays (SAM) method was used, which could inspect the variables with significant difference between the HF and non-HF groups. For further selection of the parameters, stepwise selection methods were applied to select the final variables, and the selected variables could be used to build the prediction model. At last, the binary logistic regression method was used to build the HF prediction model. SAS software was used to conduct the statistical analysis.

Results

Metabolomic differences between HF and non-HF groups

In this study, 49 metabolites including 23 amino acids and 26 carnitines were used to build the PLD-DA model.¹⁹ This model

showed that the differences between the HF and non-HF groups were significant (Fig. 1A). A permutation test indicated that over-fitting was almost impossible to exist (Fig. 1B). R2 and Q2 values are given in the study: R2 = (0.0, 0.0954), Q2 = (0.0, -0.116). In addition, a PCA scatter plot for metabolomics data demonstrated that the heart failure group could be distinguished from the non-heart failure group (Fig. 2). However, from the analysis results, the difference between the two groups was not obvious.

Selecting differential metabolites

A PLS-DA model was applied to select the vital contribution variables to distinguish the HF from non-HF groups (Fig. 1A). A total of 16 parameters with $VIP > 1.0$ were selected for further analyses. Significant differences for all the variables were calculated using the Mann-Whitney test and t -test. In addition, false discovery rate was adjusted. There were altogether 20 variables retained. Together, a total of 9 metabolites were selected using the calculations of VIP and p -values (Fig. 3).

For further defining the biomarkers with significant discrepancies between the HF and non-HF groups, SAM was analyzed (Fig. 4). The results were shown in Fig. 4. For the selected 9 parameters, the differences for 8 metabolites between

Fig. 2 Principal component analysis (PCA) for the metabolomic data of the heart failure and non-heart failure groups.

Fig. 3 Scatter plot for the metabolomic data for VIP and adjusted p -values.

Fig. 4 Significant analysis of macroarrays for metabolomic data. The false discovery rate was zero.

the HF and non-HF groups were significant (Table 2). Among these, the levels of 5 metabolites were increased, and the levels of other 3 metabolites were decreased in the HF group compared with non-HF group.

Prediction regression model

A stepwise regression method was used to further select the variables. Finally, 7 biomarkers were selected to establish the binary logistic regression model, and these biomarkers were Asn, C0, C14, C4DC, C5-OH, C6 and Glu (Fig. 5). This model is adjusted by gender, age, body mass index (BMI), systolic blood pressure (SBP), and diastolic blood pressure (DBP) with the logic probability being given by (Logit probability = $0.3582 - 0.828 \times \text{gender} + 2.0622 \times \text{age} + 0.7273 \times \text{BMI} + 1.16 \times \text{SBP} - 0.2799 \times \text{DBP} - 0.3078 \times \text{Asn} + 0.4063 \times \text{C0} + 0.9498 \times \text{C14} - 0.3275 \times \text{C4DC} - 0.5561 \times \text{C5-OH} + 1.4037 \times \text{C6} + 0.2495 \times \text{Glu}$). The receiver operating characteristic (ROC) curve analysis was executed to assess the diagnosis potential of the 7 biomarkers, and an ROC curve is shown in Fig. 6. The AUC value for this ROC curve is 0.9549. The ROC curve displayed sensitivity of 0.8475 and specificity of 0.9487 for distinguishing HF from the non-HF groups. Ten-fold cross validation was applied to test the diagnostic potential for the 7 selected biomarkers. The AUC value for the ROC curve of the ten-fold cross validation

model was 0.9386. The sensitivity and specificity for this validation model were 0.8475 and 0.8974, respectively.

Discussion

HF is a global medical problem with poor prognosis. Although the HF treatment has been constantly updated with development in medicines and technology, the difference in metabolomics between HF and non-HF patients remains unclear. Metabolomic strategies could be used in probing the metabolic aspects of HF, which is beneficial to understand the altered metabolic pathways of HF. In the current study, the metabolites including amino acids, carnitine and acylcarnitines in the HF and non-HF groups were measured using the direct infusion MS detection method and DBS sample technology. After systematic selections, the differences for 8 metabolites between the HF and non-HF groups were significant. Ultimately, 7 metabolites as novel potential HF biomarkers taken from the stepwise regression process could be used in classification for non-HF patients.

There are many reasons for heart failure, and the common causes of heart failure are high blood pressure, coronary atherosclerotic disease, myocardial ischemia, myocardial infarction, hyperglycemia, impaired glucose tolerance, diabetes, obesity and so on. However, during the development of heart failure, a complex network of compensatory mechanisms is activated on macro and micro structural, cellular, and molecular levels to maintain the heart function.²⁰ The heart needs and consumes more energy than any other organ of the human body. To reach this enormous demand, the heart converts chemical energy stored in the fatty acids and glucose into mechanical energy. If these mechanisms do not reach the demand of the heart, cardiac malfunction, mechanical failure of the heart occurs. The “energy starvation” hypothesis subsumes the altered mechanisms of myocardial energetics, which leads to the energy depletion. From the perspective of metabolism, heart failure is the manifestation of an abnormal myocardial energy metabolism, including the metabolism of fatty acids, glucose, amino acids.

Amino acids are an important part of the human body and the basic components of structural and functional proteins.²¹ They are also used as substrates for generating energy.²² Previous metabolomics studies have shown HF to be associated

Fig. 5 Levels of seven metabolites were used for building binary the logistic regression model (A–G).

with abnormal amino acid metabolism.²³ In the study, Asn level was found to be decreased, whereas the Glu and Cit levels increased for HF patients, all of them being the non-essential amino acids. Asn can be used as a carrier of K^+ and Mg^{2+} to deliver the electrolytes to the myocardium. Previous studies have verified the process involved in improving the myocardial systolic function, reducing oxygen consumption and effecting

the myocardium protection when the coronary artery circulation is impaired by hypoxia. In addition, it is involved in the ornithine cycle, promoting the production of urea from oxygen and carbon dioxide and reducing the amount of nitrogen and carbon dioxide in the blood. It seems reasonable that the level of Asn is decreased in HF. Glu is the main component of protein and one of the basic amino acids for nitrogen metabolism in the

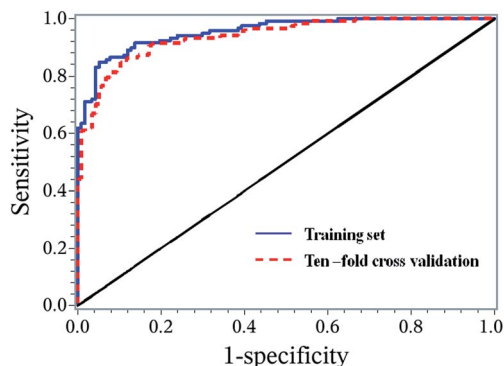

Fig. 6 ROC curves for the training set and ten-fold cross validation set based on the logistic regression model.

body, which has been demonstrated to have the effect on vasodilatation, promoting blood circulation and improving tissue energy metabolism. The previous study showed a decreased expression of the mitochondrial protein 9030617O03Rik in the heart failure mouse model.²⁴ The accumulation of glutamate in the heart of 9030617O03Rik-deficient mice suggests that glutamate is metabolized in the mammalian hearts. In our study, increased glutamate levels in the patients with HF may be associated with impaired myocardial cells and impaired glutamate metabolism.²⁵

Cit is produced in the body when NOS catalyzes arginase reactions through the arginine NO pathway to produce nitric oxide (NO).²¹ NO acts on the vascular endothelial cells to expand the peripheral blood vessels, and has a variety of effects such as reducing blood pressure, inhibiting platelet aggregation, and antioxidant. The activity of arginase was increased in the previous studies, leading to the decrease in the NO formation and increasing the production of reactive oxygen species. Therefore, the increased Cit level in HF may be due to the increased arginase activities, which leads to the increased ornithine level and thus the increased citrulline level.²⁶ So, the level of Cit could serve as a biomarker for the endothelial function.

Carnitine is a micronutrient that plays a key role in lipid metabolism.²⁷ Carnitine exists as both free carnitine and acylcarnitine in the human body and present in all body fluids, which is mainly in tissues with high energy demand, skeletal muscle and myocardium, and only a small part in liver, brain, kidney and extracellular fluid (such as plasma and urine). Carnitine and its acyl derivatives play an important role in the fatty acid oxidation. In the current study, the levels of two acylcarnitines, including C4DC and C5-OH were obviously decreased in the HF patients; however, the levels of three carnitine and acylcarnitines, including C14, C6 and C0, were significantly increased in the HF patients. C4DC and C5DC are belonging to short-chain acylcarnitines, which might promote the expression of gene and protein related to oxidative stress. Hence, the decrease in the short-chain acylcarnitine in the HF patients may be related to the regulation of oxidative stress factors.^{28,29} The long-chain acylcarnitine are closely related to fatty acid β -oxidation, which is an important source of energy for the body. The heart is the most metabolically active organ

in the body and primarily utilizes free fatty acids (FFAs) as energy substrates. Healthy myocardium primarily meets its requirements for energy through the oxidation of long-chain fatty acids (LCFA), where carnitine plays a key role as a carrier.³⁰ In the HF group, changes occur in myocardial mitochondrial functions that result in a shift towards the preferential use of glucose for metabolism rather than FFAs.³¹ LCFAs are activated by the esterification of CoA at the outer mitochondrial membrane. The inner mitochondrial membrane is impermeable to the acyl-CoA esters. The “carnitine shuttle” regulates the flux of acyl-CoA esters into the mitochondria. Many clinical and experimental studies have demonstrated that the failing heart undergoes metabolic remodeling and develops a metabolic inflexibility, switching to glucose utilization at the expense of fatty acid oxidation.³² These findings are consistent with the notion that the syndrome of HF may be characterized by a general state of metabolic inflexibility and mitochondrial inefficiency that leads to the accumulation of the metabolic intermediates of fatty acid oxidation such as the long-chain acylcarnitines.³³ C0 is an amino acid derivative, and is necessary for the entry of long-chain fatty acids into the mitochondria for β -oxidation and protects the myocardium against ischemic injury. When HF occurs, myocardial cells are damaged, accompanied with abnormal mitochondrial metabolism, long-chain fatty acids in the cytoplasm are difficult to enter the mitochondria for β -oxidation, myocardial energy is insufficient and lipid accumulation in the cytoplasm further damages the myocardial cells, forming a vicious cycle. The increased level of C0 in the plasma of HF patients might be associated with the leakage of C0 into plasma through damaged myocardial cells,³⁴ which might explain the difference between the HF and non-HF patients.

A binary logistic regression model was constructed to test if the significantly changed metabolites could be used in differentiating the HF patients from non-HF individuals. Seven metabolites (Asn, C0, C14, C4DC, C5-OH, C6, Glu) were used to build the regression model. The ROC curve based on the seven parameters showed significant classification between the HF patients and healthy subjects with the AUC value of 0.9386. The sensitivity and specificity for this validation model were 0.8475 and 0.8974, respectively (Fig. 5). This suggested that excellent performance of classification between the HF and non-HF groups could be realized *via* the seven decisive parameters.

Conclusion

In the current study, the direct infusion MS analysis combined with the DBS sample approach supply us a convenient, accurate and effective metabolomic technology to detect metabolite changes in HF. A binary logistic regression model was built based on seven decisive metabolites. It is indicated that this prediction model could be used as an alternative method for the screening of HF, which would be beneficial to understand the metabolic pathway of HF, finding out the biomarkers to predict the prognosis of HF and providing the basis for individualized treatments.

Abbreviations

DBS	Dried blood spot
HF	Heart failure
MS	Mass spectrometry
CHF	Chronic heart failure
Cit	Citrulline
Glu	Glutamic acid
Asn	Asparagine
C4DC	Succinyl/methylmalonylcarnitine
C5-OH	3-Hydroxyisovalerylcarnitine
C6	Hexanoylcarnitine
C14	Myristoyl-carnitine
C0	Free carnitine
BP	Blood pressure
PLS-DA	Partial least squared discriminant analysis
PCA	Principal component analysis
SAM	Significant analysis of microarrays
VIP	Variable importance in projection
NS	Newborn screening
FDR	False discovery rate
