# P(VDF-TrFE) nanofibers: structure of the ferroelectric and paraelectric phases through IR and Raman spectroscopies†

Alessia Arrigoni,<sup>ID a</sup> Luigi Brambilla,<sup>ID a</sup> Chiara Bertarelli,<sup>ID ab</sup> Gianluca Serra,<sup>ID a</sup> Matteo Tommasini<sup>ID a</sup> and Chiara Castiglioni<sup>ID \*a</sup>

This study elucidates the complex morphology and the related spectroscopic response of poly(vinylidene fluoride-co-trifluoroethylene) copolymer, with 80% molar VDF content, namely P(VDF-TrFE) (80/20). We investigate the molecular structure, the morphology and the thermal behaviour of P(VDF-TrFE) samples obtained as electrospun nanofibers; we discuss their thermal evolution crossing the Curie temperature and the structure resulting after annealing, giving a comparison with P(VDF-TrFE) films. The new experimental data here obtained, combined with previous spectroscopic studies carried out on piezoelectric fluorinated polymers and copolymers, allow identifying spectroscopic markers sensitive to the molecular structure, the molecular orientation, the conformational defects and the kind of crystalline phase. We assign the vibrational modes localized on TrFE units by combining experimental observation and density functional calculations carried out on suitable molecular models. This work provides a sound set of diagnostic tools, which can be exploited for the assessment of structure/property relationships aimed at clarifying the molecular mechanisms leading to the piezoelectric performance of fluorinated copolymers.

## 1. Introduction

Thanks to their ability to transduce mechanical work into electrical energy and *vice versa*, piezoelectric materials have generated a lot of interest in different fields such as energy harvesting devices, sensors and actuators.<sup>1–7</sup> Typically, piezoelectric ceramics – such as lead zirconate titanate (PZT), zinc oxide (ZnO) and barium titanate (BaTiO<sub>3</sub>) – show excellent piezoelectric properties but are intrinsically brittle and usually require very high temperatures of processing ( $T > 600$  °C), thus limiting their application.<sup>3,8–10</sup> Electroactive polymers offer an interesting alternative to these materials, overcoming their mechanical and temperature limits. Polymer-based piezoelectrics are also open to a wide range of innovative solutions, such as flexible electronic devices, biocompatible sensors and others.<sup>3–5,11</sup>

Among piezoelectric polymers, polyvinylidene fluoride (PVDF) and its copolymers are the most studied and applied.<sup>3,12,13</sup> Fluorine-based polymers possess piezoelectric characteristics due to their peculiar molecular structure, showing a net molecular dipole (perpendicular to the chain axis) when the polymer chains assume the *trans*-planar conformation. A peculiar chain packing in the crystal may result in polar crystallites, where polymer chains align with parallel dipole moments.

PVDF is a semi-crystalline polymer showing four crystalline phases:  $\alpha$  (non-polar),  $\beta$  (polar),  $\gamma$  (polar), and  $\delta$  (polar).<sup>14–22</sup> For the thermodynamic point of view, the  $\alpha$  phase (with  $(TGTG')_n$  chain conformation) is the most stable phase. Therefore, the polymer crystallizes from the melt preferentially in  $\alpha$  phase. The  $\beta$  phase has an *all-trans* planar-zigzag chain conformation  $(T)_n$  – see sketch in Table 1 – with an orthorhombic unit cell, in which the chains are aligned along the *b* axis.<sup>22</sup> This polymer conformation is the one leading to highly polar crystals, with permanent dipoles that can orient within macroscopic domains, therefore it is the conformation of interest when piezoelectric properties are desired.

To overcome the issues related with the poor control on PVDF crystallization, poly(vinylidene fluoride-co-trifluoroethylene) random copolymers with different co-monomer ratios – denoted as P(VDF-TrFE) – have been developed and have gained a lot of attention since the eighties.<sup>23–28</sup> Based on experimental evidence, it is believed that the copolymer has the

**Table 1** Band assignment of PVDF and P(VDF-TrFE) spectra in the range 700–1500  $\text{cm}^{-1}$ , see Fig. 1. The assignment is based on DFT (PBE0/pob-TZVP) calculations for PVDF in the two  $\beta$  and  $\alpha$  phases.<sup>22</sup> The computed wavenumbers are scaled by the empirical factor 0.978, which allows obtaining a good agreement between theoretical and experimental wavenumbers. Calculated IR absorption intensities (2<sup>nd</sup> and 4<sup>th</sup> columns) allow identifying strong and weak transitions (the latter are highlighted with a grey background). The experimental wavenumbers of the peaks of PVDF and P(VDF-TrFE) are taken from spectrum c and a, respectively (see Fig. 1). The last three columns refer to the  $\beta$  phase and report the phonon symmetry, the direction of the transition dipole, the band polarization (the parallel direction corresponds to the direction of the chain axis of the polymer) and a description of the vibrational eigenvector based on group internal coordinates. The labels of the symmetry species for the  $\beta$  crystal follow the choice of the Cartesian reference illustrated in the sketch

tendency to preferentially form a crystalline phase similar to the ferroelectric *all-trans*  $\beta$  phase of PVDF.<sup>28–30</sup> Remarkably, no evidence of the formation of non-polar crystalline phases (e.g.,  $\alpha$  phase) has been reported so far for P(VDF-TrFE).<sup>12,31</sup>

Compared to the homopolymer PVDF, the copolymer P(VDF-TrFE) shows a reduced degree of crystallinity due to the intrinsic presence of chemical defects – i.e., the TrFE units, randomly distributed among PVDF sequences.<sup>12,31,32</sup> However, the enhanced stabilization of the  $\beta$  phase in the copolymers grants a better stability of the piezoelectric phase, thus bypassing the mechanical/electrical pre-treatments usually required in PVDF to increase the  $\beta$  phase content. At difference from PVDF, a Curie temperature has been identified in P(VDF-TrFE), which corresponds to a change of the polymer morphology which accompanies the transition between the ferroelectric (FE) and the paraelectric phase (PE).<sup>27,30,33–36</sup>

PVDF and P(VDF-TrFE) membranes are often subjected to uniaxial or biaxial stretching to (i) promote the macroscopic orientation of polymers chains in the amorphous phase and of the crystallites and (ii) enhance the degree of crystallinity thanks to the stretching of the chains in the amorphous phase forming new crystalline domains. The preferential orientation of the polymer chains makes the material macroscopically anisotropic and allows optimizing the piezoelectric response associated to electrical or mechanical stimuli in a given direction.<sup>11,37–39</sup>

In this framework, vibrational spectroscopy – particularly IR spectroscopy – is widely used to study molecular structure, crystal phases and chains orientation.<sup>22,30,33,34,40–56</sup> Several papers dealt with the IR spectra of PVDF and P(VDF-TrFE) samples, some of which concerning the identification of the marker bands of the different crystalline phases, to evidence correlations between the IR spectral pattern and the corresponding piezoelectric response of samples treated in different conditions.<sup>13,27,30,33,34,39–50,52–54</sup>

At difference from IR, relatively few Raman studies of P(VDF-TrFE) have been reported in the literature. For instance, J. S. Green *et al.*<sup>55</sup> presented a detailed analysis of the evolution of the Raman spectra of a 60/40 random copolymer, aiming at the description of chain conformation at  $T_c$ , whereas K. Tashiro *et al.*<sup>56</sup> analysed the temperature dependence of the Raman spectra of different P(VDF-TrFE) copolymers.

Despite the abundant literature dealing with structural characterization of P(VDF-TrFE) copolymers, well established criteria to obtain unique, reliable information regarding complex, sample-dependent morphology are still required. A case concerns electrospun piezoelectric polymers nanofibers, where the analysis of the vibrational spectra of P(VDF-TrFE) fibres is often carried out on the basis of correlative criteria, which derive from spectra analysis of related materials prepared with different methods. Most likely, this is the reason why the conclusions concerning structure–property or structure–treatment correlations are sometimes contradictory.

The main goal of the analysis here reported is to set up a sound method for the structural analysis of the P(VDF-TrFE) (80/20) copolymer, based on the joint use of IR and Raman spectroscopies, and supported by results from theoretical modelling. This work aims to highlight the spectroscopic evidence related with the different phases/molecular structures

occurring in a given sample. The comparison between samples prepared with different methods (i.e., polymer films and electrospun nanofibers) allows identifying subtle but well-defined spectroscopic markers associated to different chain structures or crystalline domains. Therefore, we provide the reader with a systematic analysis and summary of the available spectroscopic evidence on P(VDF-TrFE) copolymers, setting up grounds for the interpretation of their relevant spectral features.

The study of the effect of thermal treatments on the IR and Raman responses will provide an excellent test for the assessment of the diagnostic tools here proposed. Moreover, it highlights a peculiar behaviour of fibres not observed so far and different from findings in the case of films or powder samples.

The major steps followed in this paper are:

(1) We compare the experimental IR and Raman spectra of P(VDF-TrFE) with those of PVDF, and we discuss the assignment of the observed vibrational peaks. Among the first-principles predictions available for PVDF,<sup>57,58</sup> we will exploit the careful vibrational assignment for the different crystalline phases of PVDF of ref. 22, based on Density Functional Theory (DFT) calculations.

(2) We carry out DFT calculations on selected molecular models aimed at mimicking P(VDF-TrFE) segments, so to thoroughly discuss the spectroscopic markers of the TrFE units.

(3) We analyze P(VDF-TrFE) electrospun nanofibers by IR spectroscopy and we compare them with P(VDF-TrFE) films; this allows introducing a reliable and simple method to assess the molecular orientation in nanofibers.

(4) We highlight by IR and Raman spectroscopies the changes in material morphology and chain orientation during thermal treatments.

We would like to highlight two important aspects which show the relevance of the detailed analysis herein reported. On the one hand, P(VDF-TrFE) is a complex material formed by different phases where the macromolecules experience different intermolecular environments. It follows that IR and Raman bands are often broad and structured, thus revealing the presence of different contributions from differently arranged materials. This peculiarity has to be carefully considered for a sound interpretation and it is very informative, if properly analysed. On the other hand, the IR and Raman spectra of P(VDF-TrFE) are complementary under different respects. In addition to the trivial advantage to collect data for the whole set of vibrational transitions, we obtained evidence that the two techniques have a different sensitivity to the different phases present in the P(VDF-TrFE) samples. Hence IR and Raman spectroscopies can provide unique information about phase occurrence and evolution with sample treatments, based on the changes observed in the intensity pattern/band shapes in the two complementary spectra.

We also think that the approach presented here, in conjunction with a characterization of the piezoelectric/ferroelectric performance, may contribute to the knowledge of the molecular mechanisms responsible for the piezoelectric/ferroelectric behaviour of P(VDF-TrFE), a topic widely discussed in the literature, but still lacking of unambiguous interpretation. Finally, the setup of well-established

experimental methods for monitoring structural properties – e.g., degree of crystallinity, kind of crystalline phases, chain conformations, and molecular orientation – could provide powerful tools for the control over the processing required to obtain optimized P(VDF-TrFE) materials for specific technological applications.

## 2. Materials and methods

### 2.1 Materials

**Solution preparation.** All the materials have been purchased from Sigma Aldrich and used without further treatments. Solvane® 200/P400, namely poly(vinylidene fluoride-trifluoroethylene) P(VDF-TrFE) (80/20) in powder form ( $M_w = 400\,000\text{ g mol}^{-1}$ ), was dissolved in a (4 : 6) volume ratio of *N,N*-dimethylformamide/acetone (DMF, anhydrous (99.8%)/acetone (99.9%)) at a polymer/solvent concentration of 20% w/v. The solution was mixed using a magnetic stirrer at room temperature for about 1 h until a uniform and clear solution was obtained. The same conditions have been kept also for the preparation of polyvinylidene fluoride (PVDF) solutions, starting from PVDF in powder form with  $M_w = 534\,000\text{ g mol}^{-1}$ .

**Films.** Films have been prepared by drop-casting, homogeneously spreading the solution (see above) on the substrate, and evaporating completely the solvent by keeping the film 1 h under dynamic vacuum condition. The same procedure was followed for both P(VDF-TrFE) and PVDF, allowing for the direct comparison between the corresponding spectra.

**Nanofibers webs.** P(VDF-TrFE) nanofibers webs were prepared by electrospinning. We adopted a horizontal electrospinning setup, with voltage applied using a Spellman SL-150 High Voltage Power Supply. The prepared polymer solution (see above) was loaded into a 1 ml glass syringe (Hamilton Gastight, model 1002 TLL) with a stainless-steel needle (inner diameter = 22 gauge). The syringe was mounted on a mobile infusion pump (KDS Scientific, model series 200) which allowed to set the flow rate. Randomly aligned nanofibers were collected on a rectangular static collector, electrically grounded and wrapped with aluminium foil. For the deposition of aligned nanofibers, a cylindrical rotating collector was used. All the samples were processed using the following parameters: distance between the needle and the collector of 20 cm, applied voltage of 17 kV, and solution flow rate of  $0.05\text{ mL h}^{-1}$ .

**Substrates.** The nanofibers were deposited on glass slides for preliminary optical inspection. For SEM analysis we used Si substrates. For FT-IR characterization we used a ZnSe substrate because it is transparent to IR radiation and compatible with the temperature conditions selected for the thermal cycles. We used sapphire substrates for the Raman spectroscopy of powders. During the Raman experiments in the heating cell, we held the samples in aluminium crucibles usually employed for DSC analysis.

### 2.2 Samples characterization

**FT-IR.** The IR absorption spectra were recorded using a Thermo Nicolet NEXUS FT-IR spectrometer ( $4\text{ cm}^{-1}$  resolution, 128 scans) equipped with a ThermoElectro Continuum FT-

IR Microscope ( $4\text{ cm}^{-1}$  resolution, 128 scans). The spectra were recorded in transmission mode. For phase transition studies the samples were mounted in a Linkam heating cell (FT-IR 600) operated in nitrogen atmosphere. In this case, the FT-IR analysis was carried out in transmission mode using zinc selenide (ZnSe) substrates. With the same FT-IR setup, we used a ZnSe wire grid IR polarizer for the dichroism analysis of the aligned nanofibers.

**Raman.** The Raman spectra of P(VDF-TrFE) powders and nanofibers were recorded with a Jobin Yvon Labram HR800 Raman spectrometer coupled to an Olympus BX41 microscope using a  $50\times$  objective. The excitation line of a diode-pumped solid-state laser (532 nm) was used with a power of 30 mW. Each spectrum was obtained as the average of 3 acquisitions of 40 s. For phase transitions studies the Linkam heating cell (FT-IR 600) was placed under the Raman microscope equipped with a ULWD  $50\times$  objective.

**Scanning electron microscopy.** SEM images were taken by means of a JEOL scanning electron microscope (mod. JSM-6010LV), applying a potential of 3 kV. The measurement of the fibres' diameters was carried out by processing the SEM images with the software ImageJ (Rasband, W.S., ImageJ, U. S. National Institutes of Health, Bethesda, Maryland, USA, <http://imagej.nih.gov/ij/>, 1997–2016). The statistical analysis of the diameter distribution has been carried out with Origin software (ver. 8) considering for each sample 100 independent measurements of the fibre diameter. Random and aligned mats are characterized by defect-free homogeneous fibres with a mean diameter of 600 nm and 628 nm, respectively, with narrow size distribution (see Fig. SI1–SI4†).

### 2.3 Theoretical modelling

The assignment of the crystallinity bands of PVDF (Table 1) is based on previous DFT calculations, carried out in a work<sup>22</sup> co-authored by one of the authors (CC) of the present paper. Ref. 22 determines the structure and the vibrational properties of PVDF in different crystal phases and it makes use of the CRYSTAL code,<sup>59</sup> within periodic boundary conditions (full details about the computational set-up adopted are thoroughly described in ref. 22).

The marker bands of the P(VDF-TrFE) copolymer have been investigated in this work by means of DFT calculations suitably carried out, considering a molecular model composed by one TrFE unit surrounded by four VDF units on one side and five VDF units on the other side. The two ends of this oligomer are terminated by one  $\text{CH}_3$  and one  $\text{CF}_3$  unit (see ESI†). In this model, the conformational degrees of freedom were constrained as to obtain the *all-trans* conformation expected in the crystal phase of the copolymer. To carry out the B3LYP/6-31G(d,p) DFT calculations on such model we used the Gaussian software.<sup>60</sup>

## 3. Infrared spectra of P(VDF-TrFE)

A thorough interpretation of the vibrational spectra of a semi-crystalline polymer requires the knowledge of its molecular

structure and, possibly, of the crystal structure. We analyse here a P(VDF-TrFE) (80/20) random copolymer. The relatively small hindrance of the fluorine atoms may allow the accommodation of isolated TrFE units in crystalline domains, while longer sequences of TrFE units are supposed to segregate in the amorphous phase. For these reasons, as a starting point for the analysis of the spectra of P(VDF-TrFE), we will refer to the previous vibrational assignment done for PVDF.<sup>22</sup>

In the next sections, we will discuss in detail the IR spectra of different samples of P(VDF-TrFE), namely films cast from solutions at room temperature and after thermal treatments, and we will compare such spectra with those of PVDF films.

### 3.1 P(VDF-TrFE) films at room temperature

We begin the assignment of the observed IR transitions, by considering film samples of both the homopolymer and the copolymer at room temperature. The close correlation between the structures of P(VDF-TrFE) and PVDF is corroborated by the direct comparison (Fig. 1) of the IR spectrum of P(VDF-TrFE) (Fig. 1(a)) with the spectra of two different thin films of PVDF, characterized by a different relative amount of  $\beta$  and  $\alpha$  phases (Fig. 1(b and c)). Fig. 1 clearly shows that some characteristic IR bands of PVDF nicely correspond to IR bands of the copolymer.

In Table 1 we report the wavenumbers of the  $\Gamma$  point phonons computed by DFT (ref. 22) for the  $\alpha$  and  $\beta$  phases of PVDF ( $\beta$  phase markers are typed in blue, and  $\alpha$  phase markers are typed in red). We also report in Table 1 the wavenumbers of the main peaks of spectrum c of PVDF, which show a good match with the computed wavenumbers of transitions with non-negligible IR intensity. The rows of Table 1 that correspond to bands with very small IR intensities are highlighted with a grey background. Because of the very weak intensities, such

computed transitions can be hardly recognized among the experimental features present in the IR spectra.

Both the  $\beta$  and  $\alpha$  phase contribute to the spectrum c, where several markers appear, namely:

- $\beta$  phase: 840, 1073 and 1277  $\text{cm}^{-1}$
- $\alpha$  phase: 762, 976 and 1207  $\text{cm}^{-1}$

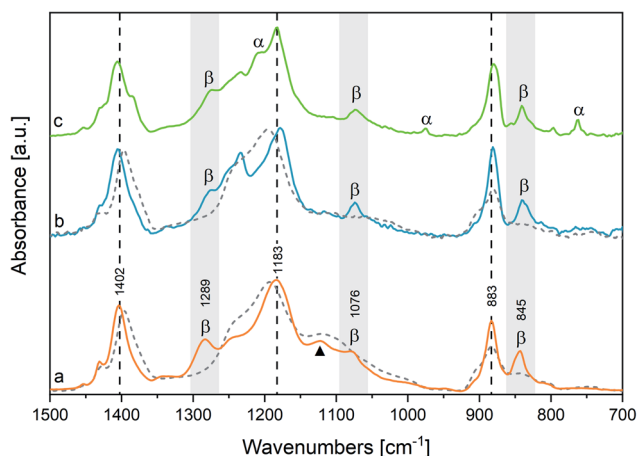

Remarkably, in the spectrum b of PVDF the  $\alpha$  phase markers practically disappear, which indicates that this sample mainly contains the  $\beta$  phase. Other strong features of spectra b and c can be put in correspondence with wavenumbers computed for both  $\alpha$  and  $\beta$  phase PVDF crystals. Indeed, DFT calculations predict that some strong IR transitions are close in frequency (within 20  $\text{cm}^{-1}$ ) for the two crystal polymorphs: the data associated to such bands are listed in Table 1 in the same row and are typed in black. We conclude that the corresponding experimental features, namely the bands at 880, 1183 and 1406  $\text{cm}^{-1}$  in the spectrum c – only slightly shifted in the spectrum b – are scarcely sensitive to chain conformation, and both the  $\alpha$  and  $\beta$  phase concur to the total intensity of such features. Furthermore, to such three bands are expected to contribute also the IR absorptions from the amorphous phase (*i.e.*, loosely packed chains with disordered conformations) and the IR absorptions from defective chains belonging to crystalline domains (or lying on lamellae surfaces). Thus, their observed peak wavenumber is determined by the convolution of several contributions, slightly shifted in wavenumber.

Considering now the spectrum of the copolymer (spectrum a), we notice that several strong absorptions can be put in correspondence with those assigned to the  $\beta$  form of PVDF. In particular, we identify the two markers of the  $\beta$  phase at 845 and 1076  $\text{cm}^{-1}$ , which display a little shift with respect to the corresponding bands of PVDF. A more pronounced upshift ( $\sim 20 \text{ cm}^{-1}$ ) is found for the band of the copolymer at 1289  $\text{cm}^{-1}$ , which may be correlated to the third marker of  $\beta$ -PVDF (1277  $\text{cm}^{-1}$ ).

Furthermore, the three strong transitions peaked at 883, 1183 and 1402  $\text{cm}^{-1}$  in the spectrum of the copolymer find a nice correspondence with the main bands at 880/883, 1183/1178 and 1406/1402  $\text{cm}^{-1}$  of PVDF (spectra c/b).

Despite that P(VDF-TrFE) is known to crystallize only in the same  $\beta$  phase of PVDF, its main “crystallinity” bands are characterized by large FWHM (full width at half maximum), ranging from 40 and 20  $\text{cm}^{-1}$  (Table S1†). This is suggestive that a variety of crystalline domains, with different size and degree of perfection, contribute to the IR transitions.‡

Among the main absorption peaks of P(VDF-TrFE) in the analysed spectral range, only the band at 1124  $\text{cm}^{-1}$  (marked with a triangle in Fig. 1) could not find any correspondence in the spectra of PVDF. This strongly suggests that this band is

**Fig. 1** IR spectra of a P(VDF-TrFE) film (a) and of two different PVDF films (b and c). The grey background highlights the  $\beta$  phase markers. The  $\alpha$  phase markers are indicated in spectrum c. The vertical dashed lines mark strong infrared absorptions scarcely affected by the kind of crystalline phase. The black triangle indicates the marker band of TrFE units. The IR spectra of melt PVDF and P(VDF-TrFE) at 170 °C, are plotted as dashed curves superimposed to the corresponding solid-state spectra. The IR spectra have been normalized with respect to the 1183  $\text{cm}^{-1}$  peaks.

‡ In particular, several factors can in principle affect the vibrational frequency and transition dipole, namely: (i) the length of the *trans*-planar P(VDF-TrFE) sequences; (ii) the length of the VDF sequences spanning between TrFE defects; (iii) electrostatic inter-chain interactions in highly polar crystals, which can be modulated while approaching the surface of the crystal domain. For such reasons one can correlate the observed changes in band shapes, and the wavenumber shifts, to different material morphologies.

related to vibrational modes localized on the TrFE units. Therefore, the  $1124\text{ cm}^{-1}$  band can be useful to diagnose the copolymer composition.

Moreover, we clearly detect two weak features ( $1333$ ,  $1345\text{ cm}^{-1}$ ) in the spectrum of P(VDF-TrFE), which correspond to the broad and weak band of PVDF ( $1333\text{ cm}^{-1}$ ), and which cannot be related to any transition of PVDF crystals computed by DFT. We also observe in the absorption spectrum of P(VDF-TrFE) a broad feature centred at about  $950\text{ cm}^{-1}$ , at the same wavenumber of the crystallinity band of the  $\alpha$  phase of PVDF. According to ref. 41 the PVDF feature at  $1333\text{ cm}^{-1}$  is a crystallinity band of  $B_1$  symmetry, tentatively assigned to a combination transition involving the excitation of one  $B_2$  and one  $A_2$  phonon; the  $1345\text{ cm}^{-1}$  component, characteristic of the copolymer, could be ascribed to a local mode on TrFE units.

All the spectra reported in Fig. 1 show weak absorptions in the range of  $1220\text{--}1250\text{ cm}^{-1}$  and an asymmetric tail on the high-wavenumber side of the  $\sim 880\text{ cm}^{-1}$  peak. We ascribe such features to contributions from disordered domains, as described in the literature<sup>34</sup> and confirmed here by the thermal evolution of the spectra (see below).

### 3.2 DFT models of the markers of the TrFE units

We illustrate here some results from DFT calculations (B3LYP/6-31G(d,p)) of the vibrational spectra of two simplified molecular

models, describing a sequence of P(VDF-TrFE) units in the characteristic *trans*-planar conformation of the  $\beta$  phase. Such models are sketched in Fig. S16.† The model 10VDF is an oligomer containing 10 VDF repeating units; the model 9VDF-TrFE is the derivative of 10VDF with the central VDF unit replaced by the TrFE monomer. The IR spectra simulated from the results of DFT calculations are compared with the experimental spectra in Fig. S17,† to support the identification of vibrational modes and related IR markers characteristic of the presence of dilute TrFE units (*i.e.*, CFHCF<sub>2</sub>) in P(VDF-TrFE).

Regardless of the possible predictive limitations of gas-phase molecular models applied to experiments in the condensed phase, focusing on normal modes localized on the chemical defect it is possible to establish a correlation between calculations and experiment, supported by the analysis of the vibrational eigenvectors. In particular, the band observed at  $1124\text{ cm}^{-1}$ , previously assigned to markers of the TrFE units, finds a nice correspondence with some localized modes of 9VDF-TrFE, whose computed wavenumbers after scaling are  $1102\text{ cm}^{-1}$  and  $1113\text{ cm}^{-1}$ . Such modes originate vibrational absorptions that are absent in the simulated spectrum of 10VDF. The corresponding normal modes show a large content of CF stretching vibrations localized on the CHF group of the central TrFE unit (see nuclear displacements in Fig. S19†).

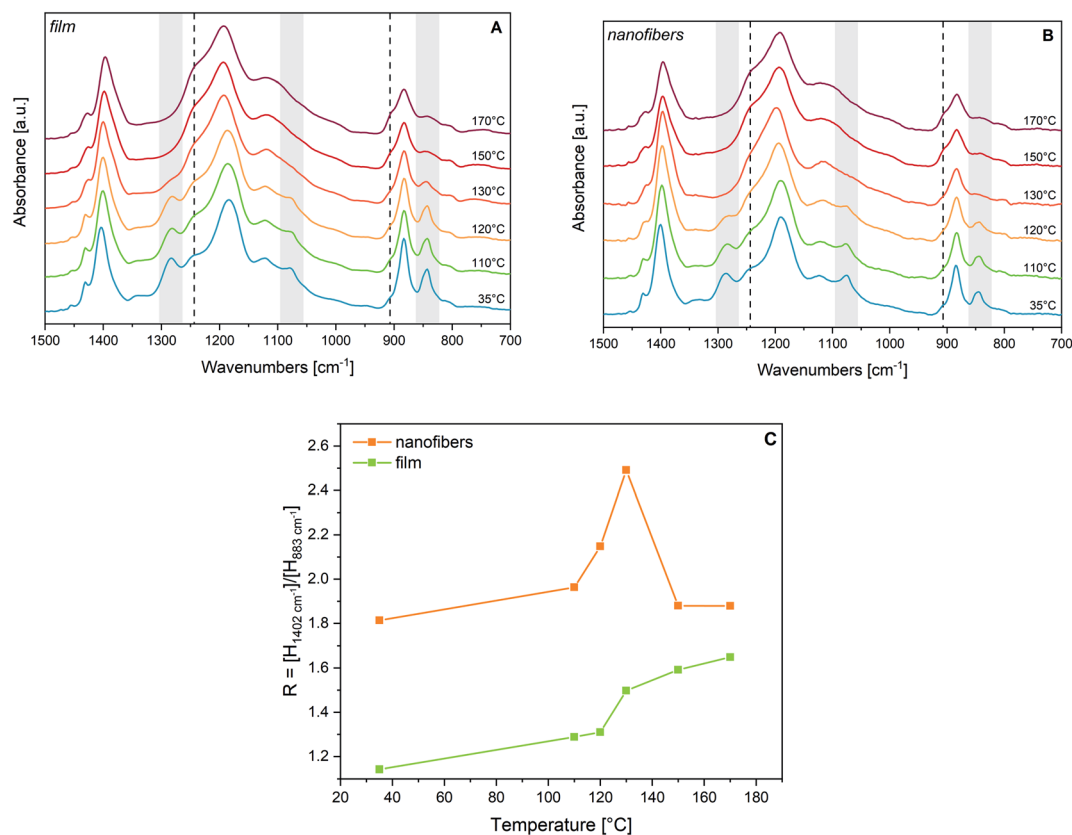

Fig. 2 Panel A: IR spectra of a P(VDF-TrFE) film at increasing temperatures. Panel B: IR spectra of P(VDF-TrFE) nanofibers at increasing temperatures. Dashed lines indicate shoulders growing with heating. Markers of the crystalline  $\beta$  phase are highlighted in grey. Panel C: Peak height ratio between the two infrared bands at  $1402\text{ cm}^{-1}$  and  $883\text{ cm}^{-1}$ : evolution with temperature for a P(VDF-TrFE) film (green line) and a fibres sample (orange line). All spectra are normalized on the central  $1183\text{ cm}^{-1}$  peaks.

Based on experimental evidence, we guessed to find contributions from modes related to the TrFE unit also in the 1300–1350  $\text{cm}^{-1}$  region. No strong new absorption of 9VDF-TrFE shows-up in this region; however, a careful analysis of the normal modes allows identifying two modes at 1341 and 1366  $\text{cm}^{-1}$ , which involve large contributions from CH bending vibrations mainly localized on the CHF unit (Fig. SI9†). Such modes can be related to the observed 1345  $\text{cm}^{-1}$  feature. DFT calculations on models of P(VDF-TrFE) described as 1-D crystal confirm such assignments (see ref. 61).

### 3.3 P(VDF-TrFE) and PVDF after melting

Fig. 1 also illustrates the effect of the melting on the spectra of PVDF and P(VDF-TrFE). The spectra of the two melts (dashed curves) show three main bands at 881/883, 1196/1193, and 1397/1397  $\text{cm}^{-1}$ , which are found at about the same wavenumber for PVDF and P(VDF-TrFE) respectively. Such features are very close to the strong bands of solid PVDF and P(VDF-TrFE) (observed at 880/883, 1183/1178 and 1406/1402  $\text{cm}^{-1}$ ), which are scarcely sensitive to the kind of crystal phase. However, on such three absorption features the melting induces remarkable broadening and wavenumber shift.

In the melt, the two bands of P(VDF-TrFE) at 883  $\text{cm}^{-1}$  and 1193  $\text{cm}^{-1}$  show the appearance of pronounced shoulders in their higher wavenumber side. Such behaviour – also observed in PVDF – confirms that these are markers of conformational disorder. This is proven by the remarkable monotonic increase of their intensity with increasing temperature, clearly shown in Fig. 2.

Remarkably, the feature at 1235  $\text{cm}^{-1}$  (the shoulder of the main peak at 1195  $\text{cm}^{-1}$ ) is clearly detected also in solid samples at room temperature: on such basis, it is considered a marker of conformational disorder in solid semi-crystalline samples.

The three  $\beta$  phase markers disappear after melting, which provides further validation of their assignment. Notably, the P(VDF-TrFE) band at 1289  $\text{cm}^{-1}$ , so far assigned to the  $\beta$  phase by exclusion (see Section 3.1), shows the behaviour expected upon melting for a “crystallinity” band.

The characteristic peak of P(VDF-TrFE) at 1124  $\text{cm}^{-1}$  originates upon melting a broader absorption band. It is the only feature that allows to discriminate between PVDF and P(VDF-TrFE) at high temperature, thus confirming that it is associated with the presence of the TrFE units.

### 3.4 Structural changes of P(VDF-TrFE) film at $T_c$ and annealing

We have followed by IR spectroscopy the heating of a P(VDF-TrFE) film (Fig. 2, panel A). The two spectra at 120 °C and 130 °C correspond to temperature conditions which are approximately 5 °C below and 5 °C above the Curie temperature. Passing through this phase transition, we observe a remarkable broadening and shift of the “crystallinity” bands of the  $\beta$  phase (highlighted in grey in Fig. 2(A)). According to previous works,<sup>30,33–35,62</sup> the disappearance of such bands proves that the polymer chains assume a different packing motif, with a drastic

reduction of the *trans*-planar conformational order. Because of the thermal expansion of the lattice, intense rotational/torsional motions of the chains are expected to take place. Based on XRD experiments at  $T_c$ , the structure of the lattice corresponds to the hexagonal packing of the chains,<sup>30,33,54–56</sup> which gives rise to non-polar para-electric domains; some authors<sup>29,52</sup> describe this phase as the analogue of the  $\alpha$  phase of PVDF, with chains adopting a regular *GTG'* conformation. Looking at Fig. 2(A), we observe that, while approaching  $T_c$ , there is a clear, continuous evolution of the two shoulders at about 1235  $\text{cm}^{-1}$  and 905  $\text{cm}^{-1}$ , which reach their maximum intensity in the melt. Accordingly, we conclude that conformational defects (*gauche* defects) are promoted by thermal energy supply. However, from spectra analysis, we do not find evidence of the formation of the  $\alpha$ -like phase: the characteristic conformation-sensitive  $\alpha$ -markers of PVDF (762, 976 and 1207  $\text{cm}^{-1}$ ) do not show up as new absorption features above the Curie temperature (Fig. 2(A)). Such observation agrees with ref. 30, 55 and 56.

The inexact interpretation of the transition of P(VDF-TrFE) to the  $\alpha$  phase at  $T_c$ , sometimes reported in the literature,<sup>29,52</sup> can be justified by considering that the only one conformational defect (kink) that can be easily hosted in a crystal made of fully *trans*-planar chains is indeed the *GTG'* sequence, which does not alter the overall direction of the polymer chain. Indeed, the same sequence of torsional angles occurs in PVDF chains belonging to the  $\alpha$  crystals, which show a regular conformation made by the repetition of the  $(TGTG')_n$  sequence. Indeed, normal modes localized on *GTG'* defects embedded in a fully *trans* chain can occur close to some vibrational frequencies of the  $\alpha$  crystal. However, crystallinity bands associated with collective phonons of the  $\alpha$  form, cannot show-up in the presence of randomly distributed *GTG'* defects that are expected in P(VDF-TrFE) at  $T_c$ . Remarkably, the presence of a hexagonal pre-melting phase was observed several years ago in *n*-alkanes<sup>63</sup> and was widely investigated by means of vibrational spectroscopy.<sup>64</sup> Also in such circumstances, *GTG'* defects can develop inside the crystal, which under this respect show intriguing analogies with the transition at  $T_c$  of P(VDF-TrFE).<sup>30,41,55,56</sup>

We compare in Fig. 3(a) the spectrum of a P(VDF-TrFE) film annealed above  $T_c$  with its spectrum before the thermal treatment. Interestingly, the features at 1235  $\text{cm}^{-1}$  and 905  $\text{cm}^{-1}$  weaken after annealing, suggesting that such thermal stimulus allows chain rearrangements with a decrease of the conformation defects. This phenomenon should increase the amount of *all-trans* sequences, fostering molecular packing in new (or less defective)  $\beta$  domains. This is supported by the intensification of the crystallinity bands at 845, 1076 and 1289  $\text{cm}^{-1}$ . Moreover, some absorption features become less broad, particularly in the 1000–1150  $\text{cm}^{-1}$  region. For instance, the FWHM of the 1183  $\text{cm}^{-1}$  band reduces from 74  $\text{cm}^{-1}$  to 58  $\text{cm}^{-1}$  upon annealing (see also Table SI1†).

In Fig. 3(a) a further experimental observation deserves a comment: upon annealing the strong absorption at 1402  $\text{cm}^{-1}$  significantly intensifies. As it will be better clarified later (discussing the IR spectra of electrospun nanofibers), this band is a sensitive probe of the orientation of polymer chains.

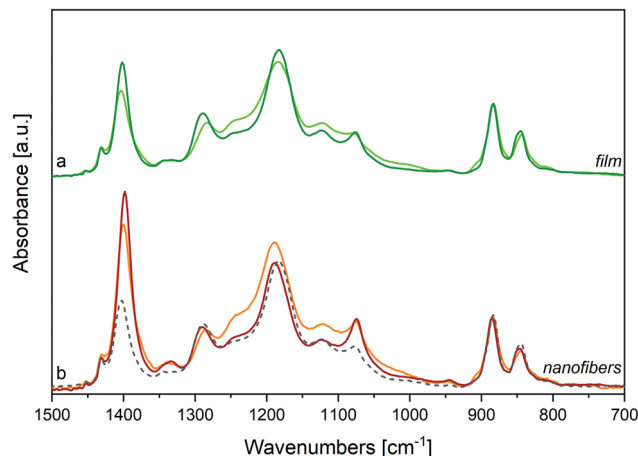

Fig. 3 (a) IR spectra of a P(VDF-TrFE) film at room temperature, before (light green line) and after annealing at  $T = 135\text{ }^{\circ}\text{C}$  (deep green line). (b) IR spectra of electrospun P(VDF-TrFE) nanofibers at room temperature, before (orange line) and after annealing at  $T = 125\text{ }^{\circ}\text{C}$  (red line), and of the same sample cooled at room temperature after melting (dashed line). Spectra normalized on  $883\text{ cm}^{-1}$  peaks.

Therefore, such intensity change observed for the band at  $1402\text{ cm}^{-1}$  can be ascribed to a modification of the film morphology upon annealing, accompanied by a preferential orientation of the crystal lamellae with respect to the plane of the slide onto which the film is deposited.

In the hypothesis that the annealing-induced changes in the spectrum are mainly due to a crystallinity increase (*i.e.*,  $\beta$  phase increase), we inferred the spectrum of the pure  $\beta$  phase by spectra subtraction. We subtract from the spectrum after annealing (Ann) – which is more abundant in  $\beta$  phase – the spectrum obtained before annealing (*i.e.*, the spectrum of the pristine film, Pr) (Fig. 4, panel A). As expected, the difference of the spectra, Ann – Pr, shows a different intensity pattern with respect to the spectrum before subtraction, with a clear change of the intensity ratios among the marker bands of the  $\beta$  phase and the three bands independent from chain conformation, whose intensity is affected by contributions from the amorphous phase in the spectrum before subtraction (Ann). We report in panel A of Fig. 4 also the difference of the spectra Pr – Ann, which is representative of the disordered material that undergoes structural rearrangement upon annealing. It shows features similar to those of the melt, but it also displays interesting differences. The main peaks, and in particular the strong band at about  $1195\text{ cm}^{-1}$ , are shifted. As expected, the bands assigned to conformational defects ( $905$  and  $1235\text{ cm}^{-1}$ ) are present both in the difference spectrum (Pr – Ann) and in the spectrum of the melt. Moreover, close to the markers of the  $\beta$  phase, the difference of the spectra Pr – Ann shows also some absorptions ( $840$  and  $1275\text{ cm}^{-1}$ ) that are completely absent for the melt. Such features might be ascribed to *trans*-planar sequences in a different environment from that of the bulk  $\beta$  phase. For instance, this could happen for very short *trans*-planar polymer sequences, for *trans*-planar sequences not arranged in a crystalline domain, or for chains belonging to very defective crystals, or belonging to crystal surfaces.

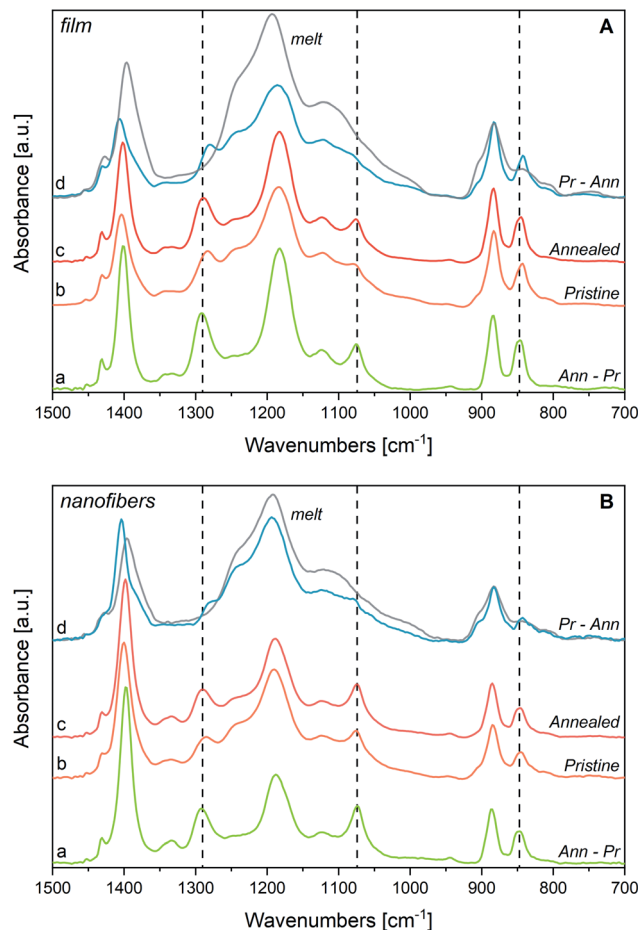

Fig. 4 Panel A: P(VDF-TrFE) film, (a) spectrum obtained as the difference between the IR spectrum after annealing (annealed, c) and that of the same sample before annealing (pristine, b); (d) difference between the IR spectrum before annealing (pristine, b) and that of the sample after annealing (annealed, c). On spectrum (d) is also reported in grey the spectrum of the melt. Panel B: same difference spectra (a), (d) for P(VDF-TrFE) nanofibers. Spectra of the samples at room temperature, pristine (b) and annealed (c) and of the melt (d, grey) are reported for sake of comparison. Spectra normalized on  $883\text{ cm}^{-1}$  peaks.

Interestingly, the two features at  $1333$  and  $1345\text{ cm}^{-1}$ , previously mentioned as characteristic absorptions of P(VDF-TrFE), are clearly evident in the spectrum inferred for the pure  $\beta$  phase (Ann – Pr), while just the component at  $1345\text{ cm}^{-1}$  survives in the spectrum (Pr – Ann) that represents the disordered component. This is a further indication that the band at  $1333\text{ cm}^{-1}$  is typical of the  $\beta$  phase, whereas the component at  $1345\text{ cm}^{-1}$  is a local mode of the TrFE unit. In a similar way, the marker band at  $1124\text{ cm}^{-1}$  – assigned to vibrations localized on TrFE units – shows contributions in both difference spectra, as expected for a defect mode scarcely sensitive to the morphology of the environment.

The analysis discussed above is compared with the results obtained by the principal component analysis (PCA) of the IR spectra,<sup>30</sup> from which the authors inferred the reference spectra ascribed to the crystalline and to the amorphous phase of

a VDF-TrFE (75/25) copolymer. Such PCA-derived spectra<sup>30</sup> show a very impressive similarity with those empirically obtained in this work, even to some minor details.

In conclusion, the analysis of the IR spectra of P(VDF-TrFE) in comparison with the spectra of PVDF films, and the results of DFT calculations allow stating that:

(1) The crystalline phase of P(VDF-TrFE) is similar to the  $\beta$  phase of PVDF, with marker bands at 845, 1076, and 1289  $\text{cm}^{-1}$ . Such markers are sensitive to the chain conformation and prove that the chains in the crystalline domains are *trans*-planar. The difference spectra between samples that are more crystalline (annealed P(VDF-TrFE) film) and more disordered (pristine P(VDF-TrFE) film), suggest that *fully trans* sequences can be found both in crystal domains and in disordered environments. Indeed, the crystallinity bands shadow non-negligible contributions (slightly displaced at lower wavenumbers) from *trans*-planar sequences not fully packed in a crystal.

(2) The band at 1124  $\text{cm}^{-1}$  and the weak features at 1345  $\text{cm}^{-1}$  are markers of TrFE units.

(3) The weak band at 1333  $\text{cm}^{-1}$  behaves with temperature as a “crystallinity band”: for this reason, it should be assigned to the crystalline domains. Being absent in DFT calculations within the harmonic approximation, such band could be tentatively ascribed to a second-order transition, in analogy with the assignment proposed for the corresponding feature of PVDF.<sup>41</sup>

(4) The features at 1235  $\text{cm}^{-1}$  and the high-frequency shoulder of the 883  $\text{cm}^{-1}$  band observed at 905  $\text{cm}^{-1}$  are markers of conformational defects; these are already present in the solid phase (amorphous component) and their contribution increases with temperature.

### 3.5 P(VDF-TrFE) nanofibers: structural characterization from IR spectra

Electrospinning not only represents an effective method to improve the  $\beta$  phase content in fluorinated polymers and copolymers, but it also opens to a wide range of nanostructure-based devices. PVDF<sup>65–72</sup> and P(VDF-TrFE)<sup>9,11,34,37–39,52,53,73–78</sup> nanofibers also offer the advantages of electrospinning to develop materials with a macroscopic orientation of the polymer chains.

Here, the rationale coming from the spectroscopic evidence on P(VDF-TrFE) obtained before allows for the interpretation of the peculiar structural properties of P(VDF-TrFE) electrospun nanofibers. Before assessing the effect of thermal treatments on the nanofibers, it is necessary to compare the IR spectra of nanofibers and films. In Fig. 5 we compare the IR spectra of three samples: a P(VDF-TrFE) film, a mat obtained by deposition of electrospun nanofibers and a sample of macroscopically aligned electrospun nanofibers, analysed in polarized light (Fig. 5(b)). We can make several observations:

(i) The main peaks of the films coincide with those of the fibres: notably, the  $\beta$  phase markers are present in both samples, which proves that the electrospinning does not prevent the formation of  $\beta$  phase crystals;

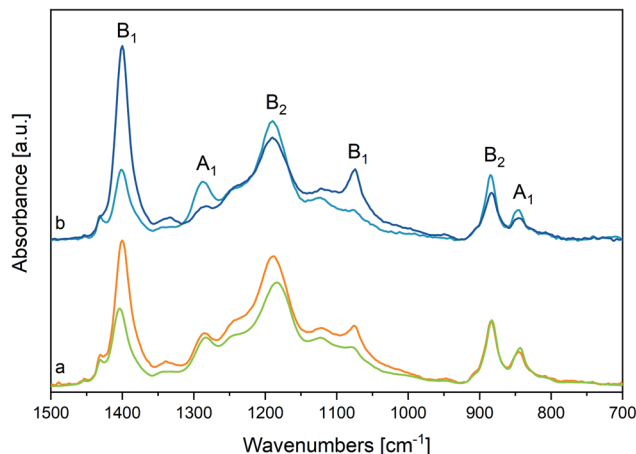

Fig. 5 (a) Comparison between the IR spectrum of a P(VDF-TrFE) film at room temperature (green line) and that of an electrospun nanofibers random mat (orange line). Spectra normalized on 883  $\text{cm}^{-1}$  peaks. (b) IR spectra of a nanofibers sample showing macroscopic orientation of the fibre axes. The spectra are recorded in polarized light in the direction parallel (deep blue line) and perpendicular (light blue line) to the fibres' axis.

(ii) The bands at 1183 and 1402  $\text{cm}^{-1}$  show a non-negligible peak shift towards higher and lower wavenumbers, respectively. Because these bands shadow the contribution of domains characterized by different morphologies (see discussion, Section 3.1), this behaviour indicates that contribution from the pure  $\beta$  phase and from the disordered phases are different in fibres and film samples (see Section 3.1);

(iii) For the fibres mat, a remarkable intensity increase is observed for the two  $B_1$  bands at 1402  $\text{cm}^{-1}$  and 1076  $\text{cm}^{-1}$ ;

(iv) The weak band at 1333  $\text{cm}^{-1}$  is more pronounced for fibres;

(v) The feature ascribed to conformational defects at 905 and 1235  $\text{cm}^{-1}$  are slightly stronger for fibres;

(vi) The intensity ratio between the crystallinity band at 845  $\text{cm}^{-1}$  and the band at 883  $\text{cm}^{-1}$  slightly decreases in the case of fibres;

(vii) Aligned nanofibers (Fig. 5(b)) show a clear parallel polarization of the  $B_1$  bands, while  $A_1$  and  $B_2$  bands have perpendicular polarization. Remarkably, the weak band at 1333  $\text{cm}^{-1}$  exhibits parallel polarization.

Observations (ii), (v), (vi) suggest that the  $\beta$  phase amount in the fibres mat is lower than in the film, because of the quick solidification induced by rapid solvent evaporation occurring during electrospinning.<sup>52,53</sup>

Observation (iii) and (iv) can be rationalized considering anisotropy in molecular orientation induced by electrospinning. Because of the  $B_1$  symmetry of the associated phonons, the two bands at 1183 and 1402  $\text{cm}^{-1}$  exhibit a dipole moment vector variation directed along the polymer chain axis. The parallel polarization behaviour of such two bands in aligned nanofibers (point vii, see Fig. 5(b)) indicates that in nanofibers the polymer chains are mainly directed parallel to the fibre axis. Based on this evidence, the behaviour of the IR intensity of the fibres mat (point iii) can be easily rationalized,

considering that the long axis of the fibres runs parallel to the substrate surface as shown by SEM images (Fig. S11 and S13†). A detailed discussion of the intensity pattern of the IR spectrum of fibres, based on symmetry analysis,<sup>79</sup> is reported in ESI.† The relevant result is that the intensity behaviour observed for the fibres mat can be definitely taken as the proof that the polymer chain axes are mostly oriented along the fibre axis, while drop cast films can be described as made by an isotropic distribution of crystallites.

Furthermore, based on the above discussion of the annealing of a P(VDF-TrFE) film, we explain the observed intensification of  $B_1$  absorptions of the P(VDF-TrFE) film after annealing as the evidence of some re-arrangement of the crystallites with their  $c$  axis parallel to the substrate. Remarkably, the existence of preferential chains orientation in P(VDF-TrFE) films has been already pointed out in the literature.<sup>7,80,81</sup>

### 3.6 Thermal treatment of electrospun P(VDF-TrFE) nanofibers

Thermal treatments of fluorinated piezoelectric polymers and copolymers are often carried out to optimize their morphology.<sup>29,31,34,52,53,82,83</sup> In particular, in the case of electrospun nanofibers, an increased piezoelectricity is expected after annealing above the Curie temperature, which can promote the epitaxial growth of new crystalline lamellae with polymer chains aligned to the pre-existing fibre core formed by stretch oriented, extended polymer chains. Indeed, chains belonging to the amorphous phase are already partially aligned after electrospinning, but a sudden loss of mobility due to fast evaporation of the solvent during the process may partially prevent crystallization. Moreover, the secondary crystallization occurring after annealing should guarantee the alignment of the new crystallites of the fibre core, possibly easing dipole orientation mechanisms.<sup>52,53</sup>

In Fig. 3(b) we show the result of the annealing at 125 °C of a sample made by nanofibers (the temperature was set on the basis of DSC thermograms – see Fig. S15†).

The comparison with the spectra obtained after annealing of the film shows that the thermal treatment induces similar modifications in samples with different morphology, promoting in both cases the reduction of conformational defects and a general increase of crystallinity. Moreover, the crystallinity bands sharpen. This is proved by the FWHM of the 1183  $\text{cm}^{-1}$  band, which upon annealing reduces from 74  $\text{cm}^{-1}$  to 58  $\text{cm}^{-1}$ . Interestingly, the annealing process, which exploits the increased mobility of the chains at high temperature, probably reinforces the original polymer chain orientation, mainly directed along the fibres. This is proven by the intensity pattern after annealing, which shows intensification of bands assigned to  $B_1$  phonons. Similar observations were done in ref. 50, considering the behaviour in polarized light of stretch oriented samples heated above  $T_c$ .

The above conclusion is further supported by the observed evolution of the IR spectra during thermal treatment of a fibres sample (Fig. 2, panel B). The changes of the IR pattern parallel what is observed in the case of the film, showing the loss of the

$\beta$  phase markers at the Curie transition, and a monotonic increase with the temperature of the bands associated to *gauche* defects. The trend of the absorption intensity of the  $B_1$  band at 1402  $\text{cm}^{-1}$  (Fig. 2, panel C) is very interesting. For increasing temperatures below  $T_c$  the peak height ratio  $R$  of the 1402  $\text{cm}^{-1}$  band to the 883  $\text{cm}^{-1}$  band increases, in a parallel way, for both the film and the fibres. After melting the value of  $R$  tends to a common value. The trend of  $R$  from room temperature to  $T_c$  can be mainly ascribed to a remarkable broadening of the 883  $\text{cm}^{-1}$  band. However, in fibres samples, the preferential molecular orientation with the polymer axis oriented along the fibre axis is kept up to  $T_c$ , as shown by the high  $R$  value, always larger than the  $R$ -value of the film by a factor of about 1.6.

By heating the sample up to melting and then cooling it back, crystallinity slightly increases, but chains are no more parallel to the substrate plane, as demonstrated by the weakening of the 1076  $\text{cm}^{-1}$  and 1402  $\text{cm}^{-1}$  peaks, giving rise to an intensity pattern very close to that of the cast film (Fig. 3(b), dashed line).

In conclusion, the annealing of a fibres mat at  $T_c < T < T_m$  allows to increase the crystallinity ( $\beta$  phase), with no loss of the planar orientation of the polymer chains, whereas heating at  $T > T_m$  followed by a slow cooling allows improving the crystal morphology, but results in an isotropic material.

Finally, we report in Fig. 4 (panel B) the spectra obtained as difference between the spectra of the fibres sample before and after annealing. Interestingly, the spectrum of the crystal phase (Ann – Pr) obtained for fibres shows a pattern very similar to that of the subtraction spectrum obtained for the film, with the notable exception of the intensity ratios between  $B_1$  and  $A_1$  (or  $B_2$ ) bands. In other words, the difference spectra coincide, except for the intensity behaviour of the  $B_1$  bands, which has been already rationalized as due to orientation phenomena that are pronounced for fibres.

Instead, the spectra (Pr – Ann), which were attributed to the disordered material which undergoes transformation upon annealing, are different in the two cases:

(i) The remarkably higher intensity shown by the fibres sample in the region 1100–1300  $\text{cm}^{-1}$  indicates that before annealing the degree of crystallinity is lower in the fibres sample;

(ii) The relatively high intensity of the band at about 1400  $\text{cm}^{-1}$  tells us that in the case of fibres the polymer segments lie in the substrate plane, although they do not belong to the crystalline phase;

(iii) The maximum of the band at about 1180  $\text{cm}^{-1}$  is slightly displaced in the two samples, thus suggesting that the disordered phase of the film and of the fibres samples consists of a mixture of polymer chains with different structural characteristics, which are present in different amounts in the two samples.

## 4. Raman spectra of P(VDF-TrFE)

### 4.1 Vibrational assignment

We report in Table 2 the assignment of the Raman bands of P(VDF-TrFE) (crystalline  $\beta$  phase), as obtained by theoretical

calculations on PVDF.<sup>22</sup> Due to the  $C_{2v}$  symmetry, the IR-active normal modes are also Raman-active. Moreover, also the IR-inactive  $A_2$  modes are expected to show up in the Raman spectrum. In Table 2, we highlight with bold-italics characters the wavenumbers of the  $\beta$  phase markers, which were obtained through the analysis of the Raman spectrum of PVDF.<sup>57</sup>

The strongest Raman transitions observed in Fig. 6 find a nice counterpart in the Raman data predicted by DFT (ref. 22) (Table 2). The experimental Raman spectrum of the  $\beta$  phase rich sample (Fig. 6(b)) is dominated by the sharp peak at  $841\text{ cm}^{-1}$ , which is assigned to the symmetric CF stretching “crystallinity” band of  $A_1$  symmetry. This line presents an intriguing behaviour: at difference from other Raman lines that show a good correspondence in position with their IR counterparts, the  $841\text{ cm}^{-1}$  Raman line is shifted by about  $5\text{ cm}^{-1}$  with respect to the IR band observed at  $845\text{ cm}^{-1}$ . This finding confirms a peculiarity already derived from IR experiments, through the analysis of difference spectra. Indeed, the vibrational bands of P(VDF-TrFE) usually considered as  $\beta$  phase markers, should be viewed as the convolution of several contributions, arising from a variety of crystalline domains with chains in *fully trans* conformation, and possibly from *trans-planar* polymer segments not fully packed in the crystal. Accordingly, the different position of the  $845/840\text{ cm}^{-1}$  band in IR and Raman spectrum can be rationalized by considering that Raman and IR intensities are affected in different ways by the environmental effects felt by the *trans-planar* polymer chains (*i.e.*, surroundings characterized by different polarity and crystal morphologies). This kind of phenomenology closely resembles the non-coincidence effect observed in polar liquids for Raman active bands corresponding to intense infrared absorptions.<sup>84,85</sup>

Interestingly, the  $A_2$  band computed by DFT at  $1188\text{ cm}^{-1}$  for the  $\beta$  phase of PVDF shows a discrepancy with the experimental

spectrum. Despite the sizeable computed Raman intensity, such  $A_2$  transition does not find any clear correspondence in the experimental Raman spectrum, which however shows several very broad and weak bands in the region  $1100\text{--}1250\text{ cm}^{-1}$ . This feature is a characteristic of the experimental spectrum of P(VDF-TrFE) copolymers, which parallels a similar behaviour of the  $\beta$  phase of PVDF. Instead of one only strong collective phonon of  $A_2$  symmetry, DFT calculations on models of a PTFE polymer containing chemical defects (*i.e.*, TrFE units),<sup>61</sup> display the appearance of several transitions involving  $\text{CH}_2$  twisting vibrations of the PVDF sequences variously coupled with vibrational displacements of the TrFE units (Fig. SI8†). This observation suggests that the presence of structural and/or chemical defects could result in the activation of several  $q \neq 0$  phonons characterized by different wavenumbers, as it happens for phonons belonging to rather steep dispersion branches, which span a wide wavenumbers range.

Other Raman features cannot be related to the transitions of an ideal  $\beta$  crystal, namely:

- (i) The two weak features at  $1345$  and  $1363\text{ cm}^{-1}$ . The band at lower wavenumber possibly corresponds to the broad weak IR absorption at  $1345\text{ cm}^{-1}$ , assigned to modes involving (TrFE) units (see above); the higher wavenumber component does not find any corresponding feature in the IR spectrum, possibly because it is hidden by the strong and wide IR band at  $1402\text{ cm}^{-1}$ ;
- (ii) A peak at  $939\text{ cm}^{-1}$ , which shows a possible counterpart in the weak broad IR feature observed at  $950\text{ cm}^{-1}$ ;
- (iii) A strong broad band at  $805\text{ cm}^{-1}$ ;
- (iv) The broad bands at  $601$  and  $642\text{ cm}^{-1}$ , and a pair of weak features at  $364$  and  $308\text{ cm}^{-1}$ ;
- (v) The peak at  $482\text{ cm}^{-1}$ .

**Table 2** Raman transitions of PVDF and P(VDF-TrFE) in the range  $250\text{--}1500\text{ cm}^{-1}$  (see Fig. 6). The assignment is based on DFT calculations of PVDF in  $\beta$  phase.<sup>22</sup> Calculated wavenumbers are scaled by the empirical factor 0.978, which allows obtaining a good agreement between theoretical and experimental wavenumbers. Data relative to the markers of the  $\beta$  phase are typed in bold-italics. Calculated Raman intensities (3<sup>rd</sup> column) allow identifying strong and weak transitions. The calculated IR intensities are also reported (2<sup>nd</sup> column). The wavenumbers of the experimental peaks of P(VDF-TrFE) are taken from the Raman spectrum of a powder sample (Fig. 6(d)) and are compared with the wavenumbers associated to the same phonons, as obtained from the experimental IR spectrum. The last column reports the phonon symmetry species

$\beta$ -Theory			P(VDF-TrFE) 80–20 exp	P(VDF-TrFE) 80–20 exp	Symmetry species
Wavenumbers [ $\text{cm}^{-1}$ ]	IR intensity [ $\text{km mol}^{-1}$ ]	Relative Raman intensity	IR-wavenumbers [ $\text{cm}^{-1}$ ]	Raman-wavenumbers [ $\text{cm}^{-1}$ ]

1408	139	0	1402	—	$B_1$
1443	11	88	1431	1433	$A_1$

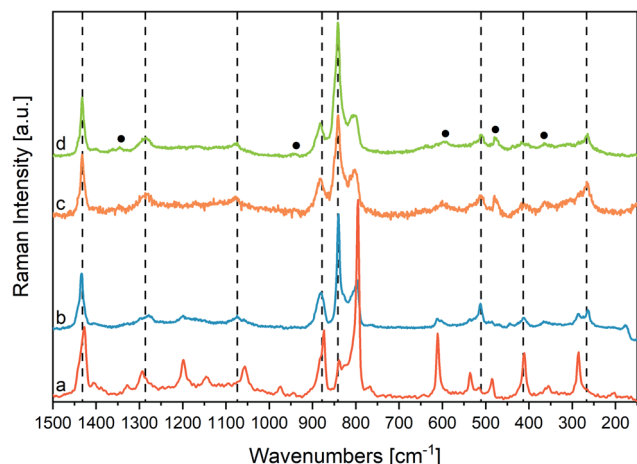

Fig. 6 (a) and (b) Raman spectra of PVDF samples with different amounts of  $\alpha$  and  $\beta$  phases (the (b) sample is richer in  $\beta$  phase than the (a) sample), (c) Raman spectra of P(VDF-TrFE) nanofibers (orange line), (d) P(VDF-TrFE) powder (green line); the dashed lines indicate fundamental transitions of the crystalline  $\beta$  phase; the black circles indicate extra-features, which can be ascribed to conformational or chemical defects. The Raman spectra have been normalized with respect to the  $1433\text{ cm}^{-1}$  peaks.

Features (iii) and (iv) can be tentatively assigned to disordered phases, containing *gauche* (*G*) defects; they are indeed rather close to features typical of the  $\alpha$  phase of PVDF, which is characterized by the presence of *G* dihedral angles. This educated guess will be confirmed later based on the evolution of the spectra during heating. DFT calculations suggest that the features at  $482\text{ cm}^{-1}$  and  $1345\text{ cm}^{-1}$  are associated to modes involving the chemical defect (TrFE). See also ESI (Fig. SI8, SI9 and Table SI2†).

#### 4.2 Effect of the annealing

In Fig. 7, we report the Raman spectra of a nanofibers mat (a) and of a powder sample (b), before and after annealing above

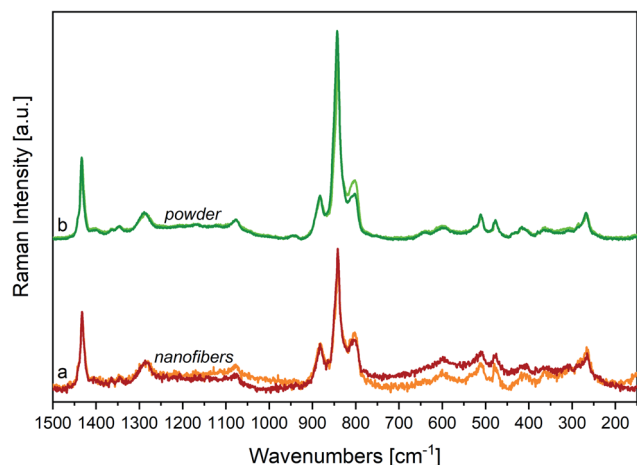

Fig. 7 (a) Raman spectra of P(VDF-TrFE) nanofibers sample before (orange line) and after (red line) annealing at  $T = 130\text{ }^{\circ}\text{C}$ ; (b) Raman spectra of P(VDF-TrFE) powder sample before (light green line) and after (deep green line) annealing at  $T = 132\text{ }^{\circ}\text{C}$ . Raman spectra have been normalized on  $1433\text{ cm}^{-1}$  peaks.

their Curie temperature ( $T_c < T_{\text{ann}} < T_m$ ). The comparison of the Raman spectra before and after annealing shows small shifts of the main peaks, accompanied by a clear weakening of the most important features we ascribed to a disordered phase, namely the signal at  $805\text{ cm}^{-1}$ .

By a closer look at the strong features in the  $900\text{--}800\text{ cm}^{-1}$  region, and by the analysis of difference Raman spectra (Fig. 8, panel B) we highlight some interesting phenomena:

(i) The peak position and the band shape of the “crystallinity” band at about  $841\text{ cm}^{-1}$  is modulated by the thermal history of the sample, proving that such band is a convolution of contributions from matter showing a different spectroscopic response. In particular, a lower wavenumber component

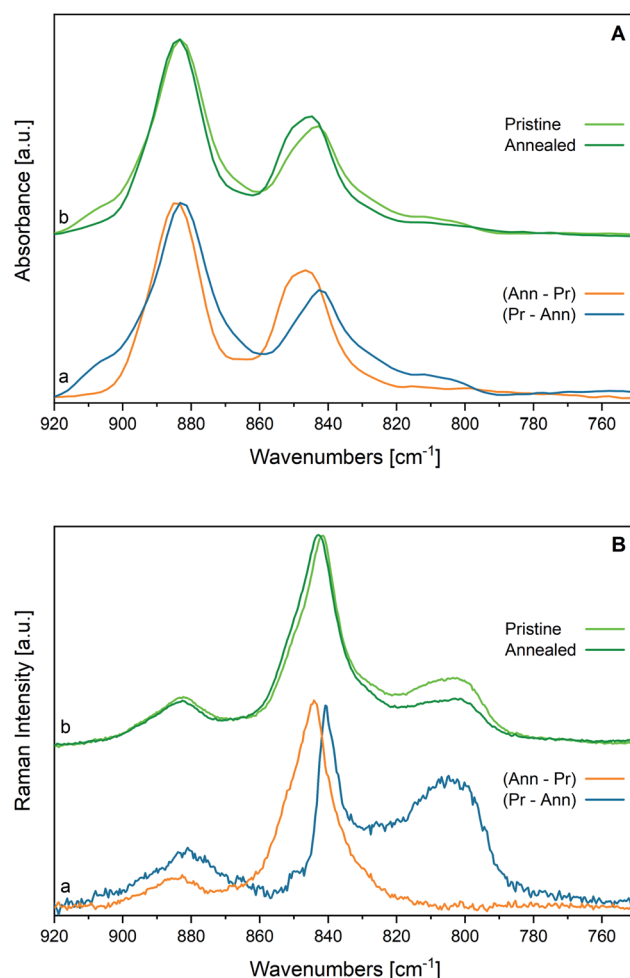

Fig. 8 IR and Raman spectra of P(VDF-TrFE) samples in the  $920\text{--}750\text{ cm}^{-1}$  region. Panel A: (a) Spectra obtained as subtraction of the IR spectrum at room temperature of a P(VDF-TrFE) film before annealing (pristine) from that obtained after annealing (annealed) (blue line) and vice versa (orange line); (b) IR spectra of P(VDF-TrFE) film at room temperature before (light green line) and after (dark green line) annealing. Panel B: (a) Spectra obtained as subtraction of Raman spectra at room temperature of the P(VDF-TrFE) powder before annealing (pristine) from that obtained after annealing (annealed) (blue line) and vice versa (orange line). (b) Raman spectra at room temperature of P(VDF-TrFE) powder before (light green line) and after (dark green line) annealing.

dominates in the spectrum of more disordered matter, which undergoes modification upon annealing (see the difference spectrum (Pr – Ann) drawn in blue). The spectrum of the more ordered phase (see the difference spectrum (Ann – Pr) drawn in orange) shows instead an impressive displacement of the “crystallinity” band at  $845\text{ cm}^{-1}$ , which is indeed the peak frequency observed in the IR;

(ii) As expected, the difference spectrum associated to the more ordered phase (Ann – Pr) does not show the broad features ascribed to conformational disorder;

(iii) Also, the band at  $880\text{ cm}^{-1}$  shows a slightly different peak wavenumber in the two difference spectra.

Consistently, the IR “crystallinity” band at  $845\text{ cm}^{-1}$  is the convolution of at least two different contributions with maximum at  $845$  and  $841\text{ cm}^{-1}$  (see Fig. 8, panel A). Before any subtraction, in the IR spectra, this peak is very close to that of the higher wavenumber component, whereas in the Raman it is the opposite and the lower wavenumber component dominates in the spectra of the pristine material. Therefore, we can argue that the polymer segments organized in well-packed polar  $\beta$  crystals exhibit remarkably larger dipole derivatives – and consequently stronger IR intensities – than the *all-trans* chains belonging to a more disordered phase; however, the effect of a polar environment is not so remarkable for the Raman polarizability tensors. Such interpretation is nicely supported by DFT calculations of the spectra of PVDF crystals and isolated chains.<sup>22,61</sup> This interesting spectroscopic behaviour certainly deserves further studies to unravel how the intermolecular interactions between polar bonds of  $\text{CH}_2\text{CF}_2$  units in different relative geometries may affect the electron density and the spectroscopic response.<sup>61</sup>

### 4.3 Temperature dependence of the Raman spectra

Fig. 9 illustrates the temperature dependence of the Raman spectra of the powder (panel A) and of the fibres (panel B). For the powder, the crystallinity markers of the  $\beta$  phase broaden or practically disappear above the Curie temperature. As expected, after the Curie transition, we observe a remarkable intensity increase of the Raman features at  $805$  and  $601\text{ cm}^{-1}$  ascribed to structural disorder (*G* defects). At  $T_c$  the  $805\text{ cm}^{-1}$  band dominates the spectrum and it further grows during melting.

Consistently with IR, the Raman spectrum above  $T_c$  indicates that the Curie transition gives rise to a disordered crystalline phase, where several *G* defects are present; there is no evidence of the existence of conformationally ordered chains as those belonging to the  $\alpha$  phase of PVDF. Indeed, the several Raman markers of the  $\alpha$  phase are absent. For this reason, the appearance of a strong line at  $805\text{ cm}^{-1}$  cannot be taken as a crystallinity marker, even if a marker of the  $\alpha$  phase of PVDF has nearly the same frequency.

In the case of fibres, we find a peculiar behaviour at  $132^\circ\text{C}$ , a temperature slightly above  $T_c$ : in this case, the crystallinity bands of the  $\beta$  form weaken, but are still clearly recognizable. In particular, the strong peak of the  $\beta$  phase at  $840\text{ cm}^{-1}$  dominates the spectrum. Indeed, this spectrum can be described as due to the superposition of the spectrum of several *trans*-planar

Fig. 9 Panel A: Raman spectra of P(VDF-TrFE) powder at different temperatures. Panel B: Raman spectra of P(VDF-TrFE) fibres at different temperatures. Raman spectra have been normalized on  $1433\text{ cm}^{-1}$  peaks.

chains with the spectrum of domains that undergo the Curie transition, giving rise to the so-called *gauche*, paraelectric phase. Kobayashi<sup>56</sup> describes a similar behaviour for copolymers with high TrFE content. This is the first time that this behaviour is observed for a given morphology, *i.e.*, for nanofibers. Interestingly, this phenomenon is not evidenced by the temperature dependent IR spectra of the same samples. We propose a possible explanation of the different behaviours of films and fibres with temperature by considering that electrospun fibres often exhibit a core formed by *fully extended chains*, produced by the high elongational stress occurring during electrospinning. The formation of *gauche* defects at  $T_c$  could be partially hindered in bundles of *fully extended chains*, because of their peculiar morphology. The formation of *GTG'* sequences above the Curie transition, causes a shortening of the chain segments belonging to the crystal, with a consequent decrease of the lamellar thickness. This change of the crystal shape can be easily accommodated by thin lamellae embedded in the amorphous phase, but in a long, highly oriented, fibre domain it could require additional energy supply.

The  $1364\text{ cm}^{-1}$  line is still present at  $T_c$  and in the melt, so it can be confidently considered a marker of TrFE units. Other weaker features possibly associated with TrFE are buried under an increasingly strong and broad background. Interestingly, the feature at  $601\text{ cm}^{-1}$  continuously grows while increasing temperature and evolves in a broad, strong band at the melting temperature.

We finally mention that the working hypothesis that the Raman intensity of *trans*-planar chains not well packed in the  $\beta$  crystal is intrinsically high, nicely explains why at  $T_c$  the fibres sample clearly shows the persistence of a fraction of chains in *all-trans* conformation. On the opposite, since the IR response of these chains should be rather low compared to that of chains well packed in the polar  $\beta$  crystals, such persistence is not observed through IR experiments above  $T_c$ , where the  $841\text{ cm}^{-1}$  band practically disappears.

## 5. Conclusions

The study of the IR and Raman spectra of a variety of samples of a P(VDF-TrFE) copolymer (80% VDF molar content), allows for the detailed description of the changes in polymer structure and morphology based on (i) sample preparation procedure (film casting and electrospinning); (ii) heating up to melting, and (iii) annealing treatments. The analysis presented explicitly takes into account the complex structure of these materials, where different phases can coexist, resulting in a complex morphology consisting of a variable relative amount of amorphous phases made by chains showing more or less ordered conformations, and of crystalline domains (with different degree of perfection and size). The relevant achievements are the following:

(1) We clearly identified IR and Raman “crystallinity” marker bands of the piezoelectric  $\beta$  phase through the comparison of the IR spectra of a P(VDF-TrFE) film with the spectra simulated by DFT<sup>22</sup> and the spectra of PVDF films characterized by different  $\beta$  phase contents; the proposed vibrational assignment validates previous vibrational analyses.<sup>30,33,56</sup>

(2) Three strong and structured IR bands ( $883$ ,  $1183$  and  $1402\text{ cm}^{-1}$ ) are ascribed to the contributions from different phases in the polymer samples. We clearly show here for the first time that the effect of the relative abundance of different crystalline phases (for PVDF) and the amount of conformational disorder/amorphous phases (for PVDF and P(VDF-TrFE)) determine intensity and band shape of such bands and minor shifts of their main peaks.

(3) DFT calculations carried out in this work on suitable model molecules, unveil the spectroscopic markers of the TrFE units. They are observed in the IR ( $1124\text{ cm}^{-1}$ , and the weak feature at  $1345\text{ cm}^{-1}$ ) and in the Raman spectrum ( $1345$ – $1364\text{ cm}^{-1}$ ). The observed persistence of such peaks in the vibrational spectra of the melt further validates this assignment.

(4) The availability of samples in the form of fibres mats, allowed to observe that the IR active  $B_1$  bands are remarkably stronger than in the spectra of the films. We have demonstrated that this finding is evidence of the orientation of the polymer

chains along the fibre axis; moreover, it confirms that we deposited fibres mats where the fibres mostly run along the plane of the substrate.

We studied the changes of the polymer morphology with temperature, by simultaneously monitoring the IR and Raman spectra of samples in the form of films, fibres and powders. Not only this comparative analysis allows to validate previous results or to settle contradictory conclusions reached by different authors<sup>29,52</sup> but also highlights unprecedented phenomena (points iii and iv below):

(i) The temperature dependence of the IR and Raman spectra allows identifying the bands associated with the conformational defects, which are already present in the room temperature phase.

(ii) Both the IR and the Raman spectra confirmed that the crystalline phase at  $T_c$  can be described as a disordered crystalline phase, where the polymer chains host *G* defects (*gauche* phase). Remarkably, statistically distributed *GTG'* sequences, surrounded by *all-trans* segments are conformational defects easily hosted in the crystal because they do not modify the chain axis direction. This fact also explains why the polymer chain orientation in nanofibers is not lost after annealing at a temperature  $T_c < T < T_m$ . In such temperature conditions, we do not observe spectroscopic markers testifying a phase transition toward a crystalline phase similar to the  $\alpha$  phase of PVDF.

(iii) Difference spectra obtained by subtraction of the spectra of annealed and pristine samples of P(VDF-TrFE) unveil the spectroscopic pattern of the crystalline  $\beta$  phase and that of the disordered phase, which undergoes structural rearrangement upon annealing. Interestingly, this analysis put into light the presence in P(VDF-TrFE) of “isolated” *all-trans* polymer segments and/or *trans*-planar chains packed in a structure different from that of the regular 3D crystal domains.

(iv) For the first time, we obtained experimental evidence of the occurrence of a peculiar phase in the case of nanofibers. Indeed, the thermal evolution of the Raman spectra just above  $T_c$  clearly shows the existence, presumably within the fibre core, of domains made by fully extended *trans*-planar chains not packed in  $\beta$  crystal lamellae. They do not show the conformational change expected at  $T_c$  (*i.e.*, the transition to the disordered *gauche* phase), which instead is complete in the case of powder sample or films.

The body of evidence here summarized provides the framework for the interpretation of the spectral response of several piezoelectric fluorinated polymers, for their thorough structural diagnosis. A detailed description of the material structure is useful toward the development of procedures aimed at the optimization of the piezoelectric performance (*e.g.*, copolymers formulation, sample preparation, mechanical and thermal treatments, poling). We have shown that also small variations in the vibrational spectra can be correlated to morphological changes of the sample. This is of utmost importance in the development of structure/property and process/structure relationships for this kind of polymeric materials.
