rsc.li/materials-advancesAmplified spontaneous emission from
oligo(*p*-phenylenevinylene) derivatives†Masashi Mamada,^a Hajime Nakanotani^{ab} and Chihaya Adachi^{abc}

For an improved understanding of molecular design for efficient laser materials, we report structure–property relationships in a series of oligo(*p*-phenylenevinylene) derivatives. The π -extended phenylenevinylene systems have been studied less frequently than the well-known 1,4-distyrylbenzene framework, despite easy syntheses and great prospects for optoelectronic devices. Here, light amplification behaviours, with amplified spontaneous emission thresholds as low as $7.2 \mu\text{J cm}^{-2}$, were characterized for oligo(*p*-phenylenevinylene) crystals. Substitution with cyano groups significantly changes the crystal packing and emission properties, while also improves the lasing behaviour.

Introduction

Organic lasers have had a long history since the first demonstration of the dye laser in 1966.¹ Research and development has been extended to solid-state lasers, with the potential of innovative optoelectronic applications.^{2–4} Although organic semiconductor laser devices that enable light amplification under electrical pumping have been studied for several decades, they have not been realized until very recently.^{5,6}

The gain media for organic solid-state lasers can be classified into two main classes: amorphous films of small molecules and polymers, and organic crystals.^{7–14} Amorphous films are compatible with organic light-emitting diode (OLED) structures; therefore, they are important for the development of organic semiconductor laser diodes (OSLDs).⁵ Single crystals have several advantages, such as higher mobilities, light out-coupling, and better stabilities based on long-range molecular order. They can also be used in light-emitting field-effect transistors (LEFETs).⁶ For both classes, the molecular structures of the laser materials involve common basic π -electronic systems, such as simple oligo-aromatics and oligomeric

phenylenevinylenes.^{15–24} Therefore, fundamental knowledge of the relationship between basic structure and properties is necessary to develop a wide variety of laser materials.

Stilbene is an important moiety that is used in numerous solid-state laser materials. Stilbene derivatives with carbazole rings form amorphous films with excellent laser properties,^{25–28} which were key to the success of quasi-continuous-wave lasers and electrically pumped lasers.^{5,29,30} In addition, poly(*p*-phenylenevinylene) (PPV) is a notable backbone for deriving excellent laser materials.^{31–33} Meanwhile, high-quality single crystals can easily be made from 1,4-distyrylbenzene (DSB/2PV/P3V2, **1a** in Fig. 1).^{34–36} Thus, there have been many derivatives based on **1a** that have several substituents, such as cyano and alkoxy groups, which control crystal-packing structures.^{11,14} In particular, there are many reports on compounds having cyano groups on the vinyl groups (**1b** and **1c**).^{37–53} Both compounds exhibit polymorphism with blue and green emission. The blue phase of **1b** and **1c** has a herringbone packing structure similar to **1a**, which results in similar emission maxima in the blue region. These are also known to have lasing capabilities. On the other hand, the green phases have strong π -stacking structures that exhibit excimer-like emission. Therefore, they have high mobilities in single-crystal LEFETs but exhibit no light amplification. The relationship between laser properties and crystal-packing structures has been well-documented in review papers.^{12,14}

Compared with P3V2 derivatives, there is a very limited number of π -extended molecules except for PPV-based polymers.^{19,36,54–56} Because the net-gain cross-section for lasers is a function of the stimulated emission cross-section (σ_{em}) and the population inversion density (ΔN), a large transition dipole moment in a molecule can reduce the threshold energy for light amplification. A longer π -conjugation length increases the oscillator strength of an electronic transition, which is

Fig. 1 Chemical structures of phenylenevinylene small molecules.

proportional to the square of the transition dipole moment. Therefore, extended π -structures are an effective strategy to improve laser properties. Nevertheless, the π -conjugation length of **1a** is relatively short compared with those of excellent amorphous-type laser materials.²⁰

In this work, we investigated several oligo(*p*-phenylenevinylene) derivatives (Fig. 1). The laser properties are expected to be improved for the P5V2 and P4V3 series relative to those of the P3V2 derivatives since **3a** had a better amplified spontaneous emission (ASE) threshold than **1a**.³⁶ However, it is more difficult to predict packing structures that greatly affect laser properties. Although linear oligo-aromatics generally have a herringbone packing because of the low C/H ratio,⁵⁷ cyano-substituted compounds should have more complex intermolecular interactions that can form various arrangements, including π -stacking structures. Here, their crystal structures and photophysical properties are presented.

Results and discussion

The compounds **1d**, **2a**, **2d** and **3a** were synthesized with the Wittig–Horner reaction, and **1b**, **1c**, **2b**, **2c**, **3b** and **3c** were synthesized by the Knoevenagel reaction. Both reactions produced good yields (Methods S1 in the ESI†).⁵⁸ The compounds were purified by vacuum sublimation and their crystals were grown *via* sublimation under a nitrogen flow. The sublimation temperatures were 300–350 °C for the P5V2 series and 270–300 °C for the P4V3 series.

The absorption and photoluminescence (PL) spectra for these compounds in chloroform solutions and in the crystalline form are shown in Fig. 2. In general, because of extended π -conjugation, the P5V2 and P4V3 series spectra were at longer wavelengths than those of the P3V2 series. Although the absorption maxima of **1b**, **2b**, and **3b** in solution appear at shorter wavelengths relative to those of **1a**, **2a** and **3a**, respectively, the onset of absorption is in the order **a** < **b** < **c** < **d**. Hence, the optical energy gap ($E_{\text{g}}^{\text{opt}}$) decreases in order from **a** to **d**, which agrees well with the calculations (Methods S2 and Tables S1–S3 in the ESI†). The Stokes shifts for **1b**, **1c**, **2b**, and **2c** are larger than those for **1d** and **2d**, as indicated by the calculations (Table S3, ESI†), and the 0–0 peaks for **b** and **c** have a gentle slope relative to those for **a** and **d**. These results might be related to the high degree of rotational motion of the vinyl

groups that were substituted with cyano groups in **b** and **c**. Such compounds are known to exhibit aggregation-induced emission enhancement (AIEE) and crystallization-induced emission enhancement (CIEE).⁵⁹ Thus, the PL quantum yields (Φ_{PL}) in solution are very low for **b** and **c**, although **2c** was slightly emissive (Table 1). The radiative rate constant (k_{r}) values for **1a**, **2a**, and **3a** in solution are very high at 7.3×10^8 , 1.1×10^9 , and $7.7 \times 10^8 \text{ s}^{-1}$, respectively, which were consistent with the conjugation lengths and the calculated oscillator strengths.

The photophysical properties in the crystal are distinctively different from those in solution because the molecular geometries are fixed in the solid state and the intermolecular interactions greatly affect their electronic structures. Single-crystal X-ray structure analysis is thus the best way to understand the relationship between solid-state optoelectronic properties and structures. Crystal structures have been reported for **1a** (CCDC 1181381,³⁴ and 921998³⁵), the **1b** blue phase (CCDC 1247728,³⁷ 799014,³⁸ 892284,³⁹ and 1473570,⁴⁰ note that these structures are substantially the same), the **1b** green phase (CCDC 892287,³⁹ and 1473571⁴⁰), the **1c** blue phase (CCDC 815708),⁴⁶ the **1c** green phase polymorph 1 (CCDC 860278),⁴⁸ and the **1c** green phase polymorph 2 (CCDC 1542079).⁵² The crystal structure of **2a** was reported,⁵⁴ but no CCDC number is available. Hence, we solved the crystal structures for **1d**, **2b**, **2c**, **2d**, **3a**, **3b**, and **3c** (Fig. 3 and Tables S4–S10, ESI†). Judging from their emission spectra, the crystals for these compounds are unlikely to exhibit polymorphism. The emission properties of the crystals are also summarized in Table 1. Significant differences in the crystal structures of these compounds occur in the packing motifs, that is, herringbone or π -stacking. Note that crystals of these compounds are often referred to as H- and J-aggregates for the specific arrangement of two molecules in the stacking direction. However, the molecules have three-dimensional interactions, complicating the dipole couplings. The excitation spectra for these crystals (Fig. S1, ESI†) indicate that the classification is difficult because **1a**, which is often described as a H-aggregate with herringbone packing,¹² might exhibit a red-shifted absorption in the crystal compared with that in solution. Therefore, we avoid mentioning H- and J-aggregates for the new compounds. Further discussion should be reported in the future, with the combination of theoretical calculations and full experimental data, including optical spectra and crystal structures.

The compounds without cyano groups (**1a**, **2a**, and **3a**) had typical herringbone packing with nearly flat stilbene structures and similar k_{r} values ($> 2 \times 10^8 \text{ s}^{-1}$). Compounds **1b** and **1c**, both with polymorphisms, have blue-emissive herringbone packing and green-emissive π -stacking structures. The emission wavelengths of the blue phases are similar to those of **1a**, although **1b** and **1c** have twisted conformations. The large bathochromic shifts of the emission with broad spectral shapes observed for the π -stacking molecules are attributed to excimer-like features. The cyano-vinylene groups are overlapped with phenyl groups in the π -stacking, which enables intermolecular charge transfer (CT). For **1d**, the 1,4-dicyanobenzene apparently inhibited herringbone packing. Thus, the crystal packing is

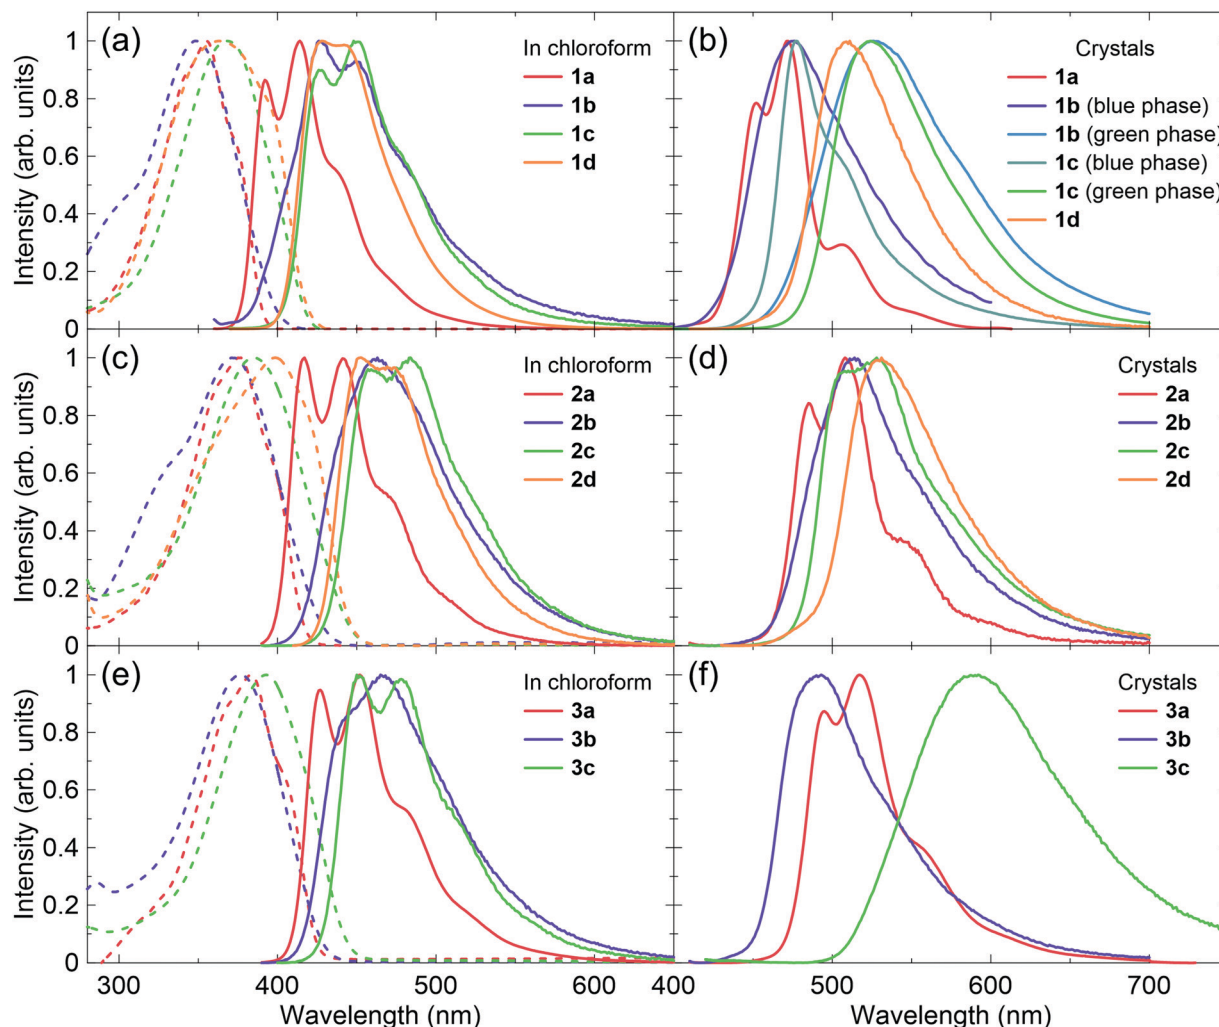

Fig. 2 Ultraviolet-visible absorption (dashed lines) and emission (solid lines) spectra for (a) **1a–1d** in chloroform, (b) crystalline **1a–1d**, (c) **2a–2d** in chloroform, (d) crystalline **2a–2d**, (e) **3a–3c** in chloroform, and (f) crystalline **3a–3c**.

relatively similar to the green phases of **1b** and **1c**, with strong π -stacking. The emission properties are also similar.

Compounds **2b** and **2c** have herringbone packing, but did not form π -stacking structures. This can be explained by the non-planar biphenyl rings, which prevent interactions between the cyano-vinylene groups and the phenyl rings, while still facilitating herringbone packing between the biphenyl rings. The emission wavelengths of **2b** and **2c** are not significantly red-shifted from those of **2a**. The values of Φ_{PL} and k_{r} are high and are expected to exhibit ASE. Similar to **1d**, the 1,4-dicyanobenzene structure in **2d** hinders the herringbone packing, while biphenyl rings also limit π -stacking. As a result, **2d** has a hybrid structure of herringbone and π -stacking. The excimer features are not strong because the 1,4-dicyanobenzene rings are mainly overlapped between themselves, which results in a small bathochromic shift compared with **2a–2c**. However, the emission decay lifetime is relatively long and k_{r} was less than $1 \times 10^8 \text{ s}^{-1}$.

Interestingly, compounds **3b** and **3c** had very different features. The **3b** emission was blue-shifted from that of **3a**,

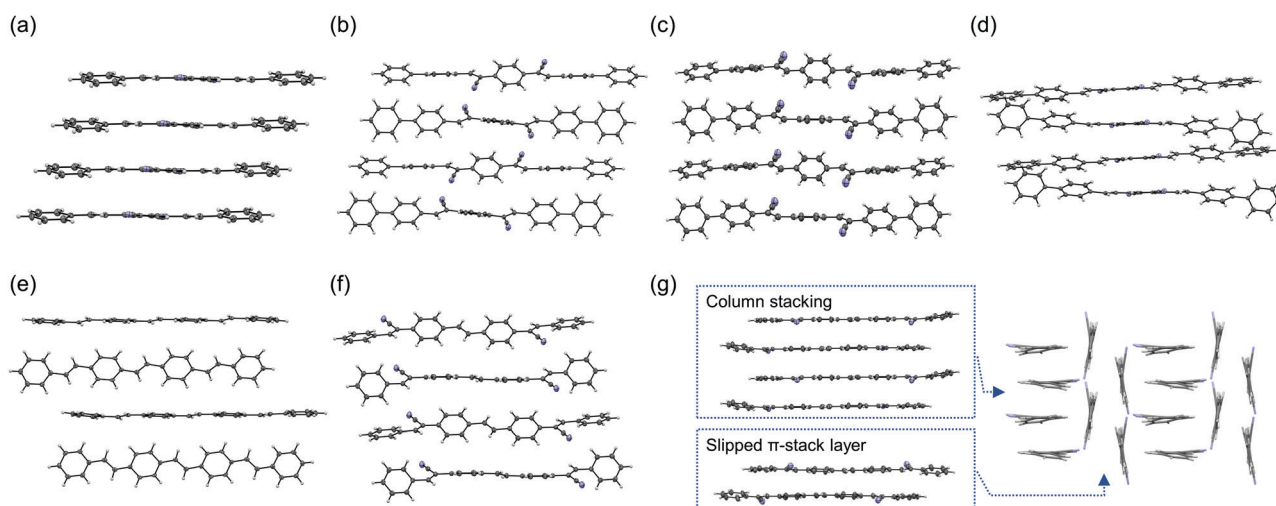

but the **3c** emission was largely red-shifted. The **3c** crystal included two types of π -stacking: single column stacking and two molecular layers with slipped π -stacking between the columns. The broad orange emission implies extensive excimer formation, probably in the molecules forming the column stacking. The Φ_{PL} of the **3b** crystal is relatively high and that of **3c** is moderate, although the fluorescence in solution was very weak for both compounds. Thus, these compounds are considered to be CIEE materials, such as **1b** and **1c**. The AIEE characteristics were also examined in mixed tetrahydrofuran (THF)/water solvents (Fig. 4). The suspension in solutions with higher water content includes various aggregated states, which may be different from the bulk crystals. Compound **3b** had AIEE characteristics, although the Φ_{PL} even in 90% water was lower than that in the crystals. The **3c** spectra were clearly shifted with increasing water content up to 70%. However, the Φ_{PL} were almost constant. Therefore, the highly ordered molecular arrangements are expected to be efficiently emissive. The values of k_{r} for the **3b** crystal was slightly higher than that of the blue-emissive **1b** crystal. This is attributed to the larger

oscillator strength. The value of k_f for the **3c** crystal was expected to be low because of its relatively long fluorescence lifetime based on excimer formation.

Fig. 5, 6 and Fig. S2 (ESI[†]) show ASE characteristics for these crystals. The blue-emissive crystals of **1b** and **1c** are reported to exhibit ASE with the extremely high thresholds of $1.8 \times 10^4 \mu\text{J cm}^{-2}$ and $360 \mu\text{J cm}^{-2}$, respectively.¹⁴ The thresholds are often increased in the low-quality crystals. In general, sublimation under a nitrogen flow forms better-quality crystals compared to solution-based techniques. The oligo(*p*-phenylenevinylene) derivatives tend to form large single crystals. In many cases, thin platelet crystals with

thicknesses ranging from several hundred nanometres to several micrometres are favourable for ASE measurements and LEFET fabrications. Fortunately, large enough crystals of blue-emissive **1b** could be obtained, although the larger green-emissive crystals were the main products. An ASE threshold as low as $18 \mu\text{J cm}^{-2}$ can be observed for the blue-phase crystal (Fig. S2, ESI[†] and Table 1). Meanwhile, the **1c** blue-emissive crystals were very small, which hindered the determination of a reliable ASE threshold with our apparatus. Note that the green-emissive crystals with π -stacking structures did not exhibit ASE for **1b** and **1c** up to $200 \mu\text{J cm}^{-2}$.

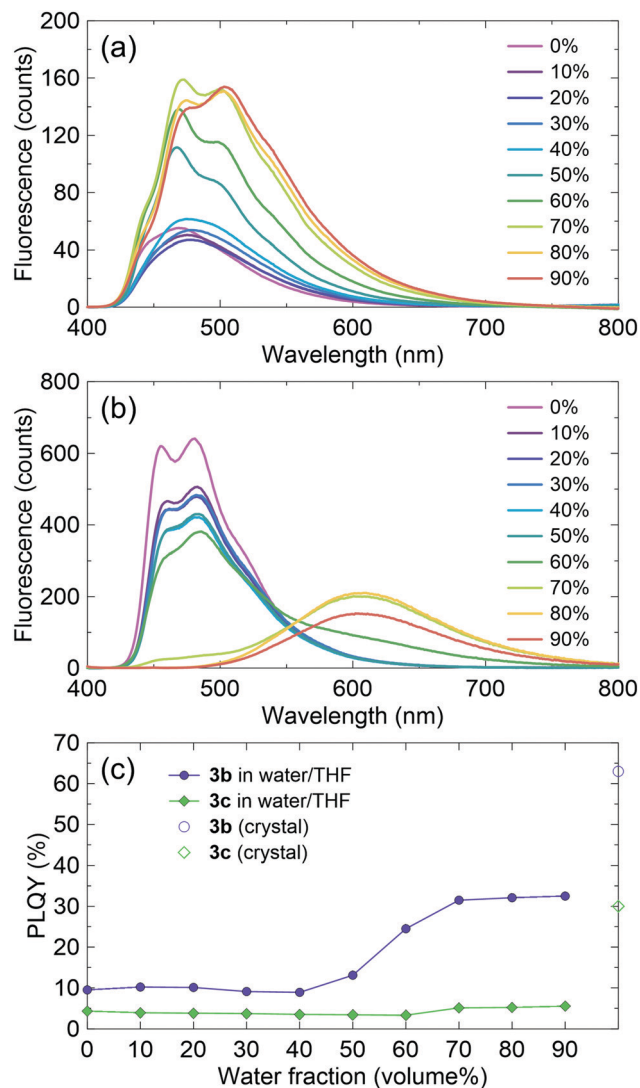

Fig. 4 Emission spectra of (a) **3b** and (b) **3c** in $x\%$ -water/(100 – $x\%$)-tetrahydrofuran (THF) mixed solvent. The concentration was fixed at 3.0×10^{-5} M. (c) Water fraction dependence of the Φ_{PL} and the Φ_{PL} in the crystal.

The ASE for **2a** and **2b** were observed at *ca.* 515 nm, which is nearly the same as the peaks of stimulated emission cross-section spectra (Fig. 5). The ASE thresholds of **2a** and **2b** were $18 \mu\text{J cm}^{-2}$ and $7.4 \mu\text{J cm}^{-2}$, respectively. Similarly, the thresholds for **3a** and **3b** were $11 \mu\text{J cm}^{-2}$ and $7.2 \mu\text{J cm}^{-2}$, respectively. The introduction of electron-withdrawing cyano groups into the compounds with donor units resulted in red-shifted emission, a decrease in k_{r} , and an increase in the ASE thresholds because of increased intramolecular CT character.²⁷ However, we have demonstrated improved ASE thresholds for cyano-substituted compounds without strong donor-acceptor interactions. These results indicated that cyano-substitution paves the way for improving the laser properties of *p*-phenylenevinylene derivatives, including polymers based on PPV.

The ASE of **2c** has two peaks that are apparently different from the others (Fig. 6), but more similar to that of methyl-substituted P3V2, 1,4-bis(4-methylstyryl)benzene.⁶⁰ The results seem to correlate with crystal thicknesses. The thicker crystals

(>1000 nm) had ASE mainly at the lower-energy sub-band at 531 nm (referred to the 0–2 transition, according to ref. 60). In contrast, the thinner crystals (~ 250 nm) had the ASE at the higher-energy sub-band at 504 nm (referred to the 0–1 transition, according to ref. 60). In addition, the two ASE peaks evolved simultaneously in the moderately thick crystals (300–1000 nm), where the peak at 531 nm first increased (number 1 in Fig. 6e), then the peak at 504 nm increased (number 2 in Fig. 6e), while the 531 nm peak then decreased (number 3 in Fig. 6e). Note that the out-of-plane X-ray diffractions for these crystals excluded polymorphism (Fig. S3, ESI†). The dual-wavelength ASE has been explained by re-absorption by molecules in the ground state or in excited states.^{61–63} The experimental results for **2c**, including the thickness dependence and the different energy behaviours of the two ASE peaks, suggest the same mechanism as that reported previously for the two-transition ASE origin. Because the optical amplifications at 504 nm and 531 nm are competitive processes, the 531 nm intensity decreased with increasing 504 nm intensity in Fig. 6e when the net gain at 504 nm became larger than that at 531 nm with intense excitation. The best thresholds were $12 \mu\text{J cm}^{-2}$ and $8.5 \mu\text{J cm}^{-2}$ for the 504 nm and 531 nm transitions, respectively.

As expected, the other compounds (**1d**, **2d**, and **3c**) with π -stacking structures did not exhibit ASE. These results also verified that solid-state interactions are very important when developing highly efficient laser materials.

Finally, charge transport properties for **2a** were evaluated and summarized in Table S11 (ESI†) since the reported mobilities were relatively low ($\mu_{\text{h}} = 1.6 \times 10^{-4} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$) compared with those of **1a** ($\mu_{\text{h}} = 0.12 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ and $\mu_{\text{e}} = 1.3 \times 10^{-2} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$) and **3a** ($\mu_{\text{h}} = 0.12 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ and $\mu_{\text{e}} = 0.11 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$).^{36,54} This is certainly attributed to the different types of active media and device configurations: thin-film *vs.* single-crystal and gold source-drain (S-D) electrodes *vs.* asymmetric gold-calcium S-D electrodes. The single-crystal transistors normally exhibited better performances because of their perfect molecular arrangements that were free of grain boundaries and had minimal defects.⁶⁴ The asymmetric electrodes with different work-functions (gold: 4.5–5.1 eV and calcium: 2.9–3.0 eV) ease the injection of both hole and electron carriers.⁶⁵ Therefore, we fabricated **2a**-based single-crystal transistors using gold-calcium electrodes. Both *p*- and *n*-type characteristics were clearly observed with saturated mobilities of $\mu_{\text{h}} = 0.05 \pm 0.01 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ and $\mu_{\text{e}} = 0.25 \pm 0.06 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ for three devices (Fig. 7). Although the hole mobility was slightly lower than those in **1a** and **3a**, it was significantly improved compared to those in the thin-film devices. In addition, high electron mobility was observed owing to effective carrier injection from the calcium electrode. These high mobilities suggest considerable potential of *p*-phenylenevinylene derivatives for electrically pumped lasers. Unfortunately, the devices of the cyano-derivatives such as **2d** and **3b** did not show improved performances. In addition, the **3c** crystals are needles, which differ from the thin-platelets of the other compounds; this makes device fabrication difficult.

Conclusions

In this study, we developed several π -extended stilbene derivatives to increase the understanding of structure–property relationships. The crystal structures were fully investigated and classified according to herringbone and π -stacking structures. The k_r values were strongly related to the packing motifs, and high values up to $3.7 \times 10^8 \text{ s}^{-1}$ were achieved for compounds with herringbone packing. Since the biphenyl groups prevent π -stacking, it would be useful to design the laser materials. On the other hand, it is more difficult to predict the crystal packing for the compounds with cyano groups on the vinyl groups. Compounds with π -stacking structures did not exhibit ASE, while clear ASE peaks were observed for those with herringbone packing. The ASE thresholds were mostly lower for the π -extended compounds and were as low as $7.2 \mu\text{J cm}^{-2}$ with cyano substitutions. These results give a systematic insight into light amplification in the single crystals.

Experimental section

General

Commercially available materials were used as received from the suppliers for the synthesis (Table S12, ESI†). Details of instruments and physical measurements are given in Table S13 (ESI†).

Materials synthesis and characterization

The synthesis procedures and characterization data of materials used in this study are described in the ESI† (Methods S1) and NMR spectra are given in Data S1.

Quantum calculations

Details of the calculations are described in the ESI† (Methods S2 and Tables S1–S3).

X-Ray structure analysis

Single crystals suitable for X-ray analysis were grown by slow sublimation under nitrogen flow. X-Ray diffraction data were collected on a Rigaku Saturn724 diffractometer with Mo-K α radiation ($\lambda = 0.71075 \text{ \AA}$) at 123 K for **2b**, **3b** and **3c**, a Rigaku

R-Axis RAPID diffractometer with Cu-K α radiation ($\lambda = 1.54187 \text{ \AA}$) at 183 K for **2c**, and a Rigaku AFC HyPix-6000 diffractometer with Mo-K α radiation at 100 K for **1d**, **3a**, and **2d**. All non-hydrogen atoms were refined anisotropically. The positions of all hydrogen atoms were calculated geometrically and refined as a riding model. CCDC 2034947–2034953.†

ASE measurements

The thin flexible crystals were grown by sublimation under nitrogen flow. The crystal samples were placed on the cleaned quartz substrate. ASE properties were characterized by optically pumping with a randomly polarized nitrogen gas laser (KEN2020, Usho Optical Systems Co., Ltd) at an excitation wavelength of 337 nm with a 0.8 ns pulse (operating frequency of 10 Hz). The input laser beam was focused into a stripe with dimensions of ca. 0.5 cm \times 0.1 cm using a cylindrical lens. Neutral density filters were used to adjust excitation intensity. ASE measurements were performed under a nitrogen atmosphere to prevent degradation. Output light emission from the edge of the sample was collected into an optical fiber connected to a spectrometer (Hamamatsu Photonics PMA-11). ASE thresholds were identified from the plot of output versus input intensity. The thresholds of absorbed energy density were not calculated because absorbance of a single crystal sample is difficult to measure. Reproducibility was confirmed by measuring at least five different samples.

Conflicts of interest

There are no conflicts to declare.
