Tuning the exposure of BiVO₄- $\{010\}$ facets to enhance the N₂ photofixation performance[†]

Honghao Chu,^a Shisheng Zheng,^a Yang Li,^a Kuanda Xu,^a Qingshui Hong,^b Tangyi Li,^a Wenju Ren,^c Shunning Li,^a Zongwei Mei^{*a} and Feng Pan^{®*ad}

Effective separation of photoexcited carriers and chemisorption of the N₂ molecule are two key issues to efficient nitrogen photofixation. The spatial charge separation of BiVO₄ with anisotropic exposed facets, namely the transfer of photoexcited electrons and holes to {010} and {110} facets, respectively, helps to enhance the separation ability of photogenerated carriers. Theoretical calculation results predict that a surface oxygen vacancy is easier to form on the (010) facet than on the (110) facet of BiVO₄.

Nitrogen fixation to NH₃ is an important artificial synthesis in the chemical industry.¹ Nowadays, NH₃ is commonly produced through the Haber-Bosch process, which requires high temperature (400-500 °C) and high pressure (15-25 MPa).² This process accounts for $\sim 2\%$ of the total global energy consumption and contributes ~1.6% of the total global emissions.³ With the growing energy needs and demand for cleaner environment, a more environmentally friendly method is needed for NH₃ manufacture. Photocatalytic N2 fixation, which employs solar energy and water to produce ammonium, is a promising sustainable and green strategy for NH3 synthesis compared with the traditional Haber-Bosch process.4-9 However, the photocatalytic performance of N2 fixation is far from satisfactory due to the inefficient separation of photogenerated carriers, the high activation energy barriers and hard cleavage of the strong N \equiv N triple bond energy (941 kJ mol⁻¹) of the N₂ molecule.¹⁰

Crystal facet engineering of semiconductors is a significant strategy for fine-tuning the charge separation of photocatalysts.¹¹ Facet engineering of anatase TiO_2 has been given considerable research attention for photocatalytic reaction by controlling the {001} exposure ratio.¹²⁻¹⁴ Recently, different research groups reported that the exposure of anisotropic facets of BiOX (X = Cl, Br, or I) enabled the directional transfer of photoexcited electrons and holes for spatial charge separation, accordingly improved the photocatalytic activities.¹⁵⁻¹⁷ Other semiconductors including SrTiO₃,¹⁸ LaNbON₂,¹⁹ and C₃N₄ (ref. 20) also demonstrated that the predominating anisotropic facet exposure could improve the separation of photogenerated carriers. Simultaneously, the spatial charge separation of BiVO₄ with anisotropic exposed facets has been observed by direct imaging²¹ and photo-reduction or photo-oxidation reactions on {010} or {110} facets, respectively.²²⁻²⁴ These results indicated that the photoexcited electrons (e⁻) and holes (h⁺) would transfer to the {010} and {110} facets, respectively. Based on the special property of BiVO₄, photocatalytic water splitting for O₂ evolution has been greatly improved.²⁵ However, a few researches on BiVO₄ with anisotropic exposed facets have been reported for photocatalytic N₂ fixation.

It is commonly understood that surface vacancies with abundant localized electrons play a critical role in N2 photofixation by capturing and activating the inert N2 molecule.26,27 Efficient transfer of the photogenerated electrons to the inert N₂ molecule is also a key step for the effective photocatalytic N₂ fixation.28 Considerable research results have revealed that surface oxygen vacancies could activate the N2 molecule by chemisorption, and act as the transfer bridge of photoexcited electrons from photocatalysts to the activated N2 molecule. For example, Pan et al. reported that the bond length of N=N was elongated by the interaction with the surface O_{VS} on MoO_{3-r} nanobelts or W18O49 nanowires, and the photocatalytic activities for the N_2 fixation were directly related to the surface O_{VS} concentration.^{29,30} The critical role of O_{VS} in the photofixation of N2 was also revealed by other semiconductors including TiO2,10,31-33 BiOCl,34 BiO quantum dots,35 ultrafine Cu2O,8 and amorphous CeO_x.³⁶ However, the surface O_{VS} on BiVO₄ for N₂ photofixation has been rarely studied.

Theoretical calculation results predicted that the formation energy (E_f) of an O_V on the surface of the representative (010)

Paper

facet was lower than that on the surface of the typical (110) facet, accordingly there were more Ovs on the surface of the (010) facet. Together with the spatial charge separation property, anisotropic exposed BiVO4 was believed to exhibit a good N_2 photofixation performance. In this study, BiVO₄ with anisotropic {010} and {110} facets were synthesized by a solidliquid state reaction.37 It was first found that the as-prepared $BiVO_4$ with higher percentage of exposed {010} facets exhibited better performance for N2 photofixation without any sacrificial reagent and cocatalyst under ambient conditions. The easier formation of a surface oxygen vacancy (O_v) on the (010) facet was experimentally proved by the enhanced chemisorption of the N₂ molecule based on the temperature programmed desorption (TPD) characterization. The enhanced separation of photogenerated carriers and more surface oxygen vacancies (O_{VS}) made BiVO₄ with a higher exposed ratio of $\{010\}$ facets to be more efficient for photocatalytic N₂ fixation.

The primitive unit cell consists of four units as shown by the side and top view of the optimized BiVO₄ (Fig. 1a and b), and the optimized lattice parameters are as follows: a = 7.33 Å, b = 11.77 Å, c = 5.18 Å, and $\beta = 134.92^{\circ}$. They are in good agreement with the experimental values: a = 7.25 Å, b = 11.70 Å, c = 5.09 Å, and $\beta = 134.225^{\circ}$. The formation energy of the oxygen vacancy (*E*_f) on the surface of (010) and (110) facets were calculated by following equation:

$$E_{\rm f} = E_{\rm O_v} + E_{\frac{1}{2}\rm O_2} - E_{\rm surface}$$

Fig. 1 The side view (a) and top view (b) of optimized monoclinic BiVO₄. The purple, blue and red atom indicates Bi, V and O, respectively; (c) the optimized structure of the (010) surface and (010) surface with one vacancy. (d) The optimized structure of the (110) surface and (110) surface with one vacancy.

where E_{0_v} , $E_{\frac{1}{2}O_2}$, and E_{surface} represent the total energy of surface with one oxygen vacancy, the half of total energy of oxygen and the total energy of surface without oxygen vacancy. The calculated formation energies of an oxygen vacancy were 2.91 eV and 4.93 eV on (010) and (110) surface, respectively. It means that the formation of a surface oxygen vacancy on the (010) facet was more energetically favorable than that on the (110) facet.

Based on the theoretical calculation result, BiVO₄ with different exposure ratios of {010} facets was fabricated by tuning the nitric concentration in the reaction solution according to a previous report (see ESI[†]). The as-synthesized BiVO₄-0.50, BiVO₄-0.75, and BiVO₄-1.0 can be indexed to the monoclinic crystal structure (PDF# 14-0688) (Fig. 2a and S1[†]). However, the BiVO₄-0.25 sample in Fig. S1[†] consists of a hybrid monoclinic structure (PDF# 14-0688) and a tetragonal crystal phase (PDF# 14-0133), probably due to the low concentration of the HNO3 solution. Furthermore, the (020) peak of BiVO₄-0.50 appears around 15° of 2θ (Fig. 2a). The as-synthesized BiVO₄ in different concentrations of HNO₃ shows different facet exposure ratios of $\{010\}$ to $\{110\}$, and BiVO₄-0.50 exhibits the largest exposure ratio (Fig. 2b and S2⁺), which is consistent with the previous report.37 The largest exposure of {010} facets must cause the appearance of the (020) peak in Fig. 2a. The typical TEM image shows the regular shape of BiVO₄-0.50 (Fig. 2c). The HRTEM interplanar spacing is 0.47 nm, corresponding to the value of (110) facet (Fig. 2d). The selected area electron diffraction (SAED) rings in the inset of Fig. 2d corresponds to the (110) and (040) crystal facets of monoclinic BiVO₄.

Fig. 3 exhibits the temperature programmed desorption (TPD) characterization of the N₂ molecule. A single peak centering at 220 °C is observed, which is ascribed to the desorption of the chemisorbed N₂, and BiVO₄-0.50 exhibits the strongest chemisorption of the N₂ molecule. It is consistent with the theoretical calculation result shown in Fig. 1.

For the general photocatalytic N_2 photofixation process in pure water, the photoexcited electrons are injected into the

Fig. 2 Typical XRD pattern (a), SEM image (b), TEM image (c), and HRTEM image (d) of the as-synthesized $BiVO_4$ -0.50. Inset in (d) SAED pattern.

chemisorbed N2 molecule via oxygen vacancy, and then the activated N₂ molecule combines with H⁺ from water to form NH₃. Simultaneously, the photogenerated holes oxidize the OH^- from water to produce O_2 . The standard curve from the different concentrations of NH₄⁺ is shown in Fig. S4.[†] Photocatalytic performance test indicates that BiVO₄-0.50 exhibits the best activity for N₂ fixation among these four samples (Fig. 4a). The average ${\rm NH_4^{\ +}}$ evolution rate is about 15.5 $\mu mol~g^{-1}~L^{-1}~h^{-1}$ for BiVO₄-0.50 during a 6 h test. The average NH₄⁺ evolution rates decrease to 13.1, 5.35, and 5.3 μ mol g⁻¹ L⁻¹ h⁻¹ for BiVO₄-0.75, BiVO₄-1.00, and BiVO₄-0.25, respectively (Fig. 4a). The Brunauer-Emmett-Teller (BET) measurements indicate that the surface areas are 2.9 $m^2\,g^{-1},$ 2.0 $m^2\,g^{-1},$ 1.8 $m^2\,g^{-1},$ and 1.5 $m^2\,g^{-1}$ for BiVO_4-0.25, BiVO₄-0.50, BiVO₄-0.75, and BiVO₄-1.00, respectively. The corresponding ratios of the average NH_4^+ evolution rate to surface area are 4.5 $\mu mol~L^{-1}~h^{-1}~m^{-2}$, 7.8 $\mu mol~L^{-1}~h^{-1}~m^{-2}$, 3.0 $\mu mol \ L^{-1} \ h^{-1} \ m^{-2},$ and 3.5 $\mu mol \ L^{-1} \ h^{-1} \ m^{-2}.$ It is obvious that the surface area is not the determining factor of the photocatalytic activity. In order to confirm the origination of the nitrogen element in NH4⁺, Ar gas was bubbled and the aqueous suspension of the BiVO₄-0.50 sample was irradiated by a 300 W xenon lamp during the test time. It is found that there is no detectable NH_4^+ (Fig. 4a), and it can be concluded

Fig. 4 (a) Photocatalytic nitrogen fixation performance of $BiVO_4$ samples synthesized with different concentrations of nitric acid (light source: 300 W xenon lamp; photocatalyst: 0.05 g; reaction solution: 100 ml of pure water). (b) Nitrogen fixation performance of $BiVO_4$ -0.50 illuminated by LED with different wavelengths (365 nm, 384 nm, 400 nm, 470 nm, 498 nm, 515 nm, and 590 nm).

Fig. 5 Photocatalytic stability test for $BiVO_4$ -0.50 (light source: 300 W xenon lamp; photocatalyst: 0.05 g; reaction solution: 100 ml of pure water).

that the detected NH_4^+ did not originate from environmental contamination, but from the photofixation reaction of N_2 molecule by the BiVO₄ photocatalyst. Fig. 4b shows the lightwavelength-dependent photofixation activity of BiVO₄-0.50. The photocatalytic performance decreases from 365 nm and exhibits almost no NH_4^+ from 515 nm, and no NH_4^+ is detected at 590 nm due to the light absorption range (Fig. S3†). The photocatalyst possessed photoexcited electrons with higher energy under the irradiation of the shorter wavelength light, and the photofixation of N_2 was more easy to occur. However, the photofixation reaction of N_2 molecule could not occur when the longer wavelength light was unable to excite the BiVO₄ photocatalyst. This result further confirmed the photofixation of N_2 in our study. The calculated value of quantum efficiency (QE) at 365 nm was about 0.003%.

In order to evaluate the stability of $BiVO_4$ -0.50 for N_2 photofixation, three cycle tests were carried out, as exhibited in Fig. 5. After each cycle, the photocatalyst was washed by vacuum filtration with pure water for several times and dried in a vacuum oven. The photocatalytic activity gradually decreased probably due to the loss of photocatalyst during the wash process.

In summary, BiVO₄ with exposed anisotropic {010} and {110} facets was synthesized, and studied for the first time for ammonia production by photocatalytic N₂ fixation from pure water. It was found that the sample with the high facet exposure ratio of {010} to {110} exhibited a better photocatalytic performance for N₂ fixation, which resulted from the better separation ability of the photoexcited carriers and more surface O_{VS} on the {010} facet. The photoexcited electrons more effectively transferred to the more surface O_{VS} on the typical (010) facet, where the N₂ molecule can be activated, and accordingly benefited to the enhancement of the photocatalytic performance. Our study provides a good strategy to improve the photocatalytic activity for N₂ fixation.
