Rapid wet-chemical oxidative activation of graphite felt electrodes for vanadium redox flow batteries†

 Brian Shanahan,^{‡a} Khaled Seteiz,^{‡a} Philipp A. Heizmann,^{‡ab} Susanne Koch,^{‡ac} Jan Büttner,^{bde} Siham Ouardi,^f Severin Vierrath,^{‡abc} Anna Fischer^{‡bdeg} and Matthias Breitwieser^{*ac}

To boost the performance of vanadium redox flow batteries, modification of the classically used felt electrodes is required to enable higher cycling performance and longer life cycles. Alternative approaches to the standard thermal oxidation procedure such as wet chemical oxidation are promising to reduce the thermal budget and thus the cost of the activation procedure. In this work we report a rapid 1 hour activation procedure in an acidified KMnO_4 solution. We show that the reported modification process of the felt electrodes results in an increase in surface area, density of oxygenated surface functionalities as well as electrolyte wettability, as demonstrated by N_2 -physisorption, XPS, Raman spectroscopy as well as contact angle measurements. The activation process enables battery cycling at remarkably high current densities up to 400 mA cm^{-2} . Stable cycling at 400 mA cm^{-2} over 30 cycles confirms promising stability of the reported activation procedure.

Introduction

Clean energy generation requires development of clean energy storage such as hydrogen for mobility and batteries for stationary storage. Future smart grid infrastructure will require more integrated stationary energy storage solutions. Redox flow batteries (RFB) are considered an important energy storage system with the vanadium redox flow battery (VRFB) getting most attention due to its simple design, minimal upkeep costs and long operational life.^{1–5} One of the most important components in a VRFB is the electrodes. The role of the electrodes is to ensure efficient electron charge transfer and to facilitate the vanadium redox reactions on their surface.⁶ The most common electrode type used in VRFBs is a soft graphite felt produced from polyacrylonitrile (PAN). Graphite felts are

cheap to produce, chemically stable, have low electrical resistance and once activated, assume the role of catalyst reaction site for the vanadium redox reactions due to the incorporation of surface-based oxygen functional groups and defect sites.^{7–10} Rayon, which is based on a cellulose precursor, is another material commonly used to produce graphite felts which has different physical and chemical characteristics than PAN based felts such as lower electrical conductivity, bundle fibre morphology resulting in increased surface roughness and increased tendency for formation of surface oxygen functionality during activation.^{11–14} The use of strong oxidizing compounds has been shown to be a very promising activation method of Rayon based electrodes leading to both significant oxygen-based surface functionality^{15,16} and increased surface area through thermochemical decomposition.^{17–19} Deng *et al.* demonstrated a reduced graphene oxide graphite felt (rGO-GF) with high electrocatalytic redox reversibility towards $\text{V}^{2+}/\text{V}^{3+}$ and $\text{VO}^{2+}/\text{VO}_2^+$ redox couples.²⁰ The rGO-GF composite electrode contained abundant oxygen functional groups resulting in high electron conductivity and outstanding stability compared to the pristine graphite felt electrode. At current densities of 300 mA cm^{-2} they obtained an energy efficiency (EE) of 60%. Furthermore, Chen *et al.*, prepared a surface-wrinkle-modified GF with high oxygen and nitrogen functionalities prepared by a hydrothermal method followed by calcination resulting in stable average EE of 78% at 150 mA cm^{-2} (ref. 21) It should be noted that at a high current density of 300 mA cm^{-2} the EE was also 60%. Wang *et al.* reported a three-dimensional network in the GF electrode.²² This network with abundant oxygen functional groups exhibited improved performance compared to the

untreated GF. Jiang *et al.* recently reported a room temperature procedure to activate rayon-based graphite felt electrodes for VRFB applications *via* treatment in an aqueous potassium permanganate (KMnO₄) solution.²³ The authors demonstrated that immersing electrodes for up to five days in aqueous potassium permanganate solutions with concentrations between 0.1–0.3 M was sufficient to generate a porous and catalytically active electrode surface that was capable of facilitating both the positive and negative vanadium redox couples. In this work, we utilize an acidified KMnO₄ solution that results in a significantly faster activation process (1 hour *vs.* 5 days for the work of Jiang *et al.*) and results in an electrode with improved hydrophilic properties, higher active surface areas, no residual Mn based deposits and improved kinetics for the four vanadium redox reactions. Due to these improvements, stable single cell battery cycling up to 400 mA cm⁻² could be demonstrated.

Methods

Materials used

The electrolyte, activation and neutralization solutions were prepared using the following reagents: VOSO₄ (99.9% abcr GmbH), KMnO₄ (99% Grüssing GmbH), H₂SO₄ (96% Sigma Aldrich), H₂O₂ (30% Carl Roth), HNO₃ (65% Sigma Aldrich) and H₃PO₄ (85% Sigma Aldrich). Electrodes used for this study are SGL Sigracell GFA6-EA Rayon-based graphite felt electrodes. The electrodes were received from SGL carbon without any additional pre-activation and/or purification steps. For all single cell electrochemical testing, a Nafion® 212 membrane (Ion Power GmbH) was used.

Electrode preparation

Electrodes were cut from a pristine Sigracell GFA6-EA electrode sheet using a hole punch. Subsequently, these pristine electrode samples were cut into two equal pieces along their cross section to yield two 3 mm thick electrodes denoted as P-GF electrodes. Thermally activated graphite felt electrodes (T-GF) were prepared by treating P-GF electrodes in a tube furnace (OTF-1200X-S, MTI Corporation, USA) at 400 °C under an air atmosphere with a heating rate of 5 °C min⁻¹ and a holding time of 6 h. KMnO₄ activated graphite felts (K-GF) are fabricated in a two-step process. The first step involves reacting the pristine graphite electrode (P-GF) surface with acidified potassium permanganate (KMnO₄) activation solution which results in the electrode surface becoming decorated with MnO_x layers. The KMnO₄ stock solutions were prepared by dissolving KMnO₄ in deionized water (DI water). The activation solutions were prepared by mixing 19 mL of the appropriate KMnO₄ stock solution with 1 mL acid (for concentrations of KMnO₄ solutions and the type of acid used, see Table 1). The second step is removal of the MnO_x layers by immersion of the electrodes in 30 mL of neutralization solution at room temperature (1 : 1 ratio 2 M H₂SO₄ with 100 mM H₃PO₄ : 3% H₂O₂ solution) followed by washing in DI water for 1 minute with stirring. The neutralization solution and DI water washing steps were

repeated three times to ensure completed removal of all MnO_x layers on the electrodes surface. The resulting K-GF electrode was then dried overnight in an oven at 80 °C. To optimize the fabrication process of K-GF electrodes, essential parameters such as KMnO₄ concentration, solution temperature, immersion time and acid type on the performance of the modified felt electrodes were assessed by cyclic voltammetry (CV) in 80 mL of 1 : 1 ratio 0.1 M VO₂²⁺ : VO₂⁺ in 2 M H₂SO₄ with 100 mM H₃PO₄ solution. All half-cell electrochemical measurements were performed three times to ensure reproducibility across all samples. Testing variations are listed in Table 1.

Material characterization

Scanning electron microscopy (SEM) images were acquired using a FEG-SEM Amber X (Tescan) equipped with a secondary electron in-lens detector and an Everhart–Thornley detector. All images were acquired with a working distance of 3 mm applying an acceleration voltage of 2 kV and a beam current of 100 pA. The pore size distribution (PSD) and specific surface area were determined by isothermal nitrogen physisorption with an Autosorb-1 (Quantachrome), by applying a quenched solid density functional theory (QSDFT) model and the Brunauer–Emmett–Teller (BET)-model, respectively, to the adsorption desorption isotherms. For the PSD both adsorption and desorption branches were evaluated, whereas the appropriate range for the BET-analysis was chosen by 2 criteria: first a positive C constant (y-intercept of the BET-plot) and second an evaluation of the adsorption branch according to the criteria proposed by Rouquerol *et al.*²⁴ The composition and the chemical state of the surface was analysed by means of X-ray photoelectron spectroscopy (XPS) measurements using an EnviroESCA laboratory system (SPECS Surface Nano Analysis, GmbH, Germany). A monochromatized Al K_α X-ray source with an excitation energy of 1486.6 eV and a spot size of 300 μm diameter was used. All samples were measured at room

temperature under a pressure of *ca.* 10^{-7} mbar. Micro X-ray fluorescence (μ XRF) was conducted using a Bruker M4 TORNADO. An element mapping was acquired under vacuum conditions using a spot size (SS) of 20 μ m with a spot separation of 80 μ m. A scan rate of 15 ms per point was used with a source current of 600 μ A with a beam incidence angle of 50°. The detector energy resolution was set to 40 eV and an input count rate of 130 kcps. Raman spectra of the D and G bands, associated with sp^2 and sp^3 hybridized carbons,⁸ were obtained using a WITec alpha 300 confocal Raman microscope with a 532 nm laser operated at 10 ± 1 mW as the excitation source. Average spectra for the P-GF, T-GF and K-GF electrodes were produced by averaging five single spectra from each respective electrode. All single spectra were integrated for 0.5 s and accumulated ten times. The ratio of the D band and G band intensities (I_D/I_G) were obtained by dividing the amplitude of the D-band by the amplitude of G-band after applying a Lorentz fit. The respective error of I_D/I_G was calculated by error propagation with the obtained values from the Lorentz fit. Background subtraction and fitting was done using WITec project. Contact angle measurements of electrodes were obtained using a Dataphysics OCA 15 plus. Samples used were 1 cm² in size and the volume of each water droplet applied to the surface was 5 μ L.

Electrochemical measurements

Half-cell cyclic voltammetry (CV) was performed using a three-electrode setup consisting of a Pt mesh counter electrode, a saturated calomel reference electrode (SCE) and a glassy carbon rod working electrode which was inserted inside the GF electrodes to make electrical contact and keep the sample stable for the test duration. All positive electrode samples were tested in a positive electrolyte solution with the composition of 1 : 1 ratio of 0.1 M VO_2^+ : VO_2^+ in 2 M H_2SO_4 with 100 mM H_3PO_4 solution in a voltage window of 0.5 V to 1.2 V vs. SCE. Negative electrode samples are tested in a 1 : 1 ratio 0.1 M V^{2+} : V^{3+} in 2 M H_2SO_4 with 100 mM H_3PO_4 solution with a voltage window of 0 V to -0.9 V vs. SCE. All testing solutions were purged of dissolved/environmental O_2 with N_2 bubbling for 5 minutes prior and in between testing. All tests were conducted at room temperature (RT) using a CH Instruments 660 E workstation. Electrochemical double-layer capacitance (EDLC) measurements of the GF electrodes were performed in 2 M H_2SO_4 . The potential window of 0.4–0.9 V vs. SCE was used at different scan rates (200, 150, 100, 50, 20, 10, 5 mV s⁻¹). Single cell electrochemical testing was conducted using a Scribner 857 Redox Flow Cell Test System (Scribner Associates Inc, USA). P-GF, K-GF and T-GF electrodes of 3 mm thickness (uncompressed) with geometric area of 4 cm² were used for both the positive and negative electrodes. A Nafion 212 membrane was immersed in a 2 M H_2SO_4 solution for 24 hours prior to cell testing. PTFE hard stop gaskets were used to adjust the electrode compression to 60%. All tests were performed at 25 °C \pm 1 °C with a flow rate of 40 mL min⁻¹. An electrolyte precursor solution of 1.6 M VO_2^+ in 2 M H_2SO_4 with 100 mM H_3PO_4 was prepared. The inclusion of small quantities of H_3PO_4 to the electrolyte, has been reported to provide improved thermal stabilization of the

vanadium electrolyte^{25,26} and reduced polarization resistance of the negative electrode.²⁷ To generate the appropriate vanadium oxidation states on each side of the cell, 60 mL of precursor solution was added to the positive tank and 30 mL to the negative tank. A constant voltage of 1.65 V was applied which converts the precursor in the positive tank from VO_2^+ to VO_2^{2+} and the precursor in the negative tank from VO_2^+ to V^{3+} and finally to V^{2+} . Once the current dropped below 4 mA cm⁻², the charging step was considered complete and 30 mL of VO_2^+ was removed from the positive tank to ensure equal volumes of electrolyte on both sides of the cell. Electrochemical impedance spectroscopy (EIS) was performed potentiostatically in the frequency range of 10^{-1} to 10^4 Hz with an amplitude of ± 10 mV at open circuit voltage (OCV). OCV was obtained by charging the electrolyte to 100% state of charge (SOC) and applying zero current for five minutes. Cycling experiments were conducted at multiple current densities with five cycles at each current density. Upper and lower cell voltage limits of 1.6 V and 0.8 V were used for all cycling experiments. *In situ* HFR measurements are obtained from the Scribner 857's built in impedance analyser at a frequency of 10 kHz. R_{CT} values of T-GF and K-GF were extracted from the EIS data by the use on an equivalent circuit (Fig. S9†), which was adopted from literature.²⁸

Results & discussion

Preparation of $KMnO_4$ activated graphite felts (K-GF) was conducted in a two-step process as illustrated in Fig. 1. The first step involves reacting P-GF electrodes with acidified $KMnO_4$ solutions, of varying concentrations in order to create abundant surface oxygen functional groups ($-COOH$, $-C=O$, $-COH$) *via* chemical oxidation of the graphite surface. The addition of an acid to the $KMnO_4$ solution increases the aggressiveness of the reaction on the surface of the P-GF electrode and the reaction takes place as described in eqn (1).²³

After step 1, the electrode surface is decorated with various MnO_x layers as evidenced by SEM-EDX (Fig. S1†) and XRF (Fig. S2†). In contrast to the depicted simplified reaction scheme of eqn (1), the overall reaction is much more complicated. The reaction reportedly forms birnessite structures as opposed to just MnO_2 (ref. 29) and the liberation of CO_2 gas is occasionally not observable on graphite felt electrodes. Instead, the formation of surface based oxygen functional groups ($C-OH$, $C=O$ and $COOH$) are more common.^{30–32} The MnO_4^- anion oxidizes $C=C$ bonds throughout the graphite structure, yielding oxygen functional groups. The type of oxygen group yielded depends on the specific location of the $C=C$ bond. For example, double bonds located within the graphite structure tend to form carbonyl ($C=O$) functional groups while those located close to the edge tend to form carboxylic acids ($COOH$).³² While MnO_x coated electrodes are interesting electrodes which have been studied recently,^{31,33–35} all MnO_x deposits in this study were removed prior to electrochemical

Fig. 1 Schematic diagram of the K-GF fabrication process. Step 1 involves the deposition of MnO_x layers onto the P-GF electrode surface using acidified KMnO_4 solutions. Step 2 involves the removal of MnO_x layers using an acidified H_2O_2 solution to produce the K-GF electrode. SEM images depict the fibre morphology during each stage of the fabrication process. The scale bars in each SEM image represent 50 μm .

testing. Therefore, no analysis on the exact oxidation number of Mn in the MnO_x deposits was performed. The second step is a cleaning process where the MnO_x layers, on the electrode surface, are removed with a neutralization solution and washed with DI water. The final result is an electrode that has no detectable Mn based deposits on its surface (Fig. S2†).

As shown in Fig. 2a, increasing the concentration of KMnO_4 from 0.1 M to 0.3 M results in increased peak separations and decreased peak currents. Based upon a previous publication by Jiang *et al.*, in an aqueous KMnO_4 solution, a concentration of 0.1 M KMnO_4 was found to be optimal as higher concentrations of KMnO_4 increase the rate of MnO_x deposit formation. As these MnO_x deposits grow in size and number, they inhibit further

Fig. 2 Mass normalized cyclic voltammograms of K-GF electrodes in 1 : 1 ratio $0.1 \text{ M VO}_2^+ : \text{VO}_2^+$ in 2 M H_2SO_4 with 100 mM H_3PO_4 solution. CV was conducted at 5 mV s^{-1} scan rate at room temperature. (a) Variation of KMnO_4 concentration. (b) Variation of immersion time. (c) Variation of solution temperature. (d) Variation of supporting acid. Exact testing conditions of all electrode samples are stated in Table 1.

reactions on the electrode surface.²³ Consequently, 0.1 M KMnO_4 was chosen as the standard concentration for all activation procedures in this work. Immersion time and solution temperature were also assessed in Fig. 2b and c. We found that 1 hour was the optimal time for electrode activation as both longer and short time frames resulted in increased peak separation in the order of 1 hour < 30 minutes < 2 hours < 3 hours < 4 hours. Increasing solution temperature from 50 °C to 80 °C also influences the peak separation in the order 70 °C < 60 °C < 80 °C < 50 °C. As seen in Fig. 2d, the type of acid used, also impacts the peak separation of the redox reactions, more so the VO_2^{2+} oxidation peak than the VO_2^+ reduction peak. Consequently, from the data in Fig. 2 and Table S1,[†] the optimized parameters for the activation of GFs in this work is immersion for 1 hour at 70 °C in a 0.1 M KMnO_4 solution with H_2SO_4 supporting acid.

To verify if the MnO_x deposition process and subsequent cleaning steps occurred as expected, SEM-EDX and XRF analysis were conducted after each step. Results are depicted in the ESI (Fig. S1 and S2[†]). SEM images of the P-GF, T-GF and K-GF electrodes are shown in Fig. 3. The P-GF image shows a very smooth surface with very few open pores. After thermal activation, the T-GF electrodes surface is free from debris but does not appear to have undergone obvious surface structural changes, at least at the examined length scale. The K-GF electrode undergoes a strong structural change compared to the other felts. It features numerous pores and defects on the surface, which are expected to be beneficial for the catalytic activity towards the vanadium redox couples.^{7,8} The mass of the K-GF electrode decreased by 5.65% (decay from 99.1 mg to 93.5 mg) after treatment while the mass of the T-GF decreased by 3.23% (decay from 99 mg to 95.8 mg). It should be noted that both the T-GF and K-GF electrodes feature similar flexibility as the P-GF electrode, confirming mechanical integrity after treatment (Fig. S3[†]). The P-GF electrodes specific surface area is $0.74 \text{ m}^2 \text{ g}^{-1}$ which is comparable to the manufacturers reported BET value of $0.8 \text{ m}^2 \text{ g}^{-1}$.³⁶ The BET measurements of the K-GF electrode indicate a specific surface area of $9.93 \text{ m}^2 \text{ g}^{-1}$, which is an increase of over 13 times compared to the P-GF electrode. The T-GF electrode has a specific surface area of $1.11 \text{ m}^2 \text{ g}^{-1}$. For comparison, the aqueous KMnO_4 solution reported by Jiang *et al.*, increased the specific surface area of the pristine sample from $2.5 \text{ m}^2 \text{ g}^{-1}$ to $5.5 \text{ m}^2 \text{ g}^{-1}$.²³ The average pore radius for the P-GF, T-GF and K-GF electrodes were measured as 52 nm, 37 nm and 2 nm, respectively.

To understand the hydrophobic/hydrophilic nature of the various electrodes, water contact angles were measured for the P-GF, T-GF and K-GF electrodes. The hydrophobicity of the untreated P-GF is clearly evidenced with the high-water contact angle of 157° (Fig. S4[†]). Both the T-GF and K-GF exhibit significantly improved wettability after treatment, as the contact angle was not measurable due to the immediate absorbance of the liquid into the GF structures. Raman spectroscopy was conducted to identify potential changes in graphitic structure of the various GFs after treatment. Raman analysis of carbonaceous materials is a complex field as depending on the form of carbon material under investigation, a wide range of peaks from 1000 cm^{-1} to 3000 cm^{-1} are identifiable.^{37,38} Typically for VRFB

Fig. 3 SEM images displaying the surface morphology of (a) P-GF electrode, (b) T-GF electrode and (c) K-GF electrode.

electrode analysis, most focus is given to the two peaks located between $1200\text{--}1600 \text{ cm}^{-1}$ which correspond to the G-band (1580 cm^{-1}) and D-band (1350 cm^{-1}).^{14,39–41} The D-band originates in breathing modes of sp^2 -atoms in rings and its occurrence signals imperfect graphitic order. The G-band reflects bond stretching or pairs of sp^2 hybridized atoms in rings and chains and therefore indicates conjugated sp^2 hybridized systems, including graphitic domains.^{8,42} The I_D/I_G ratio is used as an indicator for graphitic disorder. The Raman spectra shows that the activated electrodes possess a ratio of 1.24 ± 0.07 and 1.20 ± 0.12 for the K-GF and T-GF respectively, whereas the ratio for the P-GF is 0.92 ± 0.13 (Fig. 4). This indicates that the treated electrodes contain more structural disorder and defects due to the activation process. The increased intensity of the D band with respect to the G-band plus the broadening of both

Fig. 4 Average Raman spectra indicating the D-band and G-band of P-GF, T-GF and K-GF electrodes. The average spectra are composed of five individual spectra which were fitted and smoothed using WITec Project.

Table 2 Elemental composition (at%) on the surface of P-GF and K-GF electrodes determined by XPS analysis

| Element | C [%] | N [%] | O [%] | S [%] | Si [%] |
|---------|-------|-------|-------|-------|--------|
| P-GF | 91.9 | 1.4 | 5.6 | 0.6 | 0.5 |
| K-GF | 68.3 | 1.8 | 25.0 | 3.0 | 1.9 |

bands in the T-GF and K-GF electrodes correlates to increased structural defects.⁴³

X-Ray photoelectron spectroscopy (XPS) analysis was used to investigate the composition of the surface as well as the chemical states of the elements on the surface. To ensure the homogeneity of the samples, survey spectra are measured at two different positions with a distance of a few mm. Fig. S5a and c,† show the survey spectra of the P-GF and K-GF electrodes, respectively, and each sample is measured at two different positions. The spectra in both positions are identical. Fig. S5b and d,† show semicore states up to 350 eV. Besides the elements C, O, and N, small fractions of the elements S and Si are also present on the surface of both samples. For the P-GF electrode this can be attributed to contamination from the manufacturing process as no additional processing was performed on this sample before conducting XPS analysis.

Important is, that after the activation, no trace of Mn or K is observed on the surface of the K-GF electrode. However, the amounts of both elements S and Si increase after the oxidative

activation with KMnO_4 solution. The increase in S content can be attributed to adsorbed H_2SO_4 on the fibre surface as a result of the cleaning step to remove the MnO_x deposits. The presence of Si must be linked to the felts manufacturing process as P-GF samples were not exposed to any chemical environment prior to XPS analysis. A possible reason for the increase in Si content is that more Si is exposed in the surface-sensitive XPS measurement in the significantly rougher fibre morphology of the K-GF sample. Table 2 summarized the elemental composition on the surface of P-GF and K-GF as determined from XPS survey spectra.

The K-GF sample exhibits the highest amount of O on the surface with 25% compared to the P-GF sample with 5.6%. This result improves the hydrophilic behaviour of the K-GF electrode, as seen in water contact angle measurements. The deconvolution of C 1s core states (Fig. S6a, b,† and Table 3) show a decrease in graphitic carbon from 48.2% for P-GF to 31.4% for K-GF electrode and marginal increases in all other non-graphitic carbon peaks, indicating the formation of defects in the graphitic structure which is consistent with our observations from Raman spectroscopy. To determine the chemical states of O on the surface, a peak fitting of the high resolution O 1s core state was carried out and shown in Fig. S6c, d,† and the results are summarized in Table 3. The amount of oxygen in different chemical states on the K-GF electrode is changing compared to the P-GF electrode. A relative increase in carbonyl groups ($\text{R}-\text{C}=\text{O}-\text{R}$) from 13.7% to 14.9% and carboxyl groups (COOH) from 23.7% to 44.7% and a large relative decrease in hydroxyl ($\text{C}-\text{OH}$) groups from 62.6% to 40.4% are observed. EDLC measurements are a useful method to assess the electrode–electrolyte interface as changes to both the wettability and porosity of the electrodes will have an influence on electrode performance and are shown in Fig. S7.† EDLC values were measured as 36 mF g^{-1} for the P-GF, 234 mF g^{-1} for the T-GF and 1006 mF g^{-1} for the K-GF. Reported EDLC values for pristine graphite felt electrode are in the similar range.⁴⁴ The low EDLC value for the P-GF electrodes are attributed to its hydrophobicity. Since the aqueous electrolyte ($2 \text{ M H}_2\text{SO}_4$) has difficulties accessing the entire electrode structure, only a small percentage of the electrode is wetted by the electrolyte and therefore contributes less to the EDLC measurement. The substantial rise in EDLC observed in the K-GF electrodes is the result of the increased electrode wettability and porosity leading to a substantial increase in electrode–electrolyte interactions.

CV was conducted in the positive and negative electrolytes to evaluate the electrochemical activity of all GF electrodes for the

Electrolyte composition for the negative electrolyte is 1 : 1 ratio $0.1 \text{ M V}^{3+} : \text{V}^{2+}$ in $2 \text{ M H}_2\text{SO}_4$ with $100 \text{ mM H}_3\text{PO}_4$.

$\text{VO}_2^+/\text{VO}_2^{2+}$ and $\text{V}^{2+}/\text{V}^{3+}$ redox couples. As shown in Fig. 5a, the P-GF electrode shows a VO_2^+ oxidation peak at about 1.1 V but almost no VO_2^+ reduction peak in the positive electrolyte. This means, the felt does not efficiently facilitate the conversion of VO_2^+ to VO_2^{2+} and has therefore poor electrochemical reversibility. The normalized peak currents for the oxidation and reduction peaks of the K-GF electrode are significantly higher than the T-GF electrode due to the higher active surface area as measured with BET and EDLC measurements. CV measurements in the negative electrolyte (Fig. 5b) show the same trend with smaller peak to peak separation in the order $\text{P-GF} > \text{T-GF} > \text{K-GF}$. The P-GF electrode is inactive in the negative electrolyte with no oxidation and reduction peaks. The hydrogen evolution reaction (HER) dominates the reduction reaction of the T-GF electrode in the negative side. However, the K-GF electrode shows a separate reduction peak at -0.7 V before the HER

dominates at -0.8 V . Normalized peak currents are higher for the K-GF electrode than the T-GF electrode.

Electrochemical impedance spectroscopy (EIS) was performed to assess the impact of the electrode treatments on the kinetic behaviour in a single cell environment. The resulting Nyquist plots are shown in Fig. S8.† The charge transfer resistance (R_{CT}) is calculated as the difference between the high frequency resistance (HFR) and low frequency resistance (LFR) of the equivalent circuit model in Fig. S9.† and extracted values are shown in Table S2.† For the P-GF electrode, R_{CT} is determined to be $90.50 \Omega \text{ cm}^2$. For the T-GF electrode significantly reduced values of $0.88 \Omega \text{ cm}^2$ are obtained. The large R_{CT} value for the P-GF electrode indicates a substantial kinetic resistance which would prevent this electrode from functioning efficiently inside the battery. The T-GF demonstrates a substantial improvement in R_{CT} compared to the P-GF electrode, but it is not comparable to the K-GF electrode which exhibits the lowest R_{CT} value of $0.53 \Omega \text{ cm}^2$.

Fig. 6 (a) CE, EE and VE values of the T-GF and K-GF electrodes after cycling at multiple current densities from $100\text{--}400 \text{ mA cm}^{-2}$ in 1.6 M vanadium with $2 \text{ M H}_2\text{SO}_4$ and $100 \text{ mM H}_3\text{PO}_4$. The P-GF electrode was unable to cycle at current densities higher than 40 mA cm^{-2} and was therefore not included in this figure. (b) Voltage–capacity plot of the first cycle at each current density for the K-GF (solid) and T-GF (dashed) electrodes.

Cycling results are shown in Fig. 6. The battery was cycled at multiple current densities to assess the performance of all three electrodes under different loads. The P-GF sample was not capable of completing any cycling experiments with current densities greater than 40 mA cm^{-2} , which is due to its poor half-cell electrochemical performance (Fig. 5), its hydrophobic behaviour during contact angle analysis (Fig. S4†) and its large R_{CT} value obtained by EIS (Fig. S8†). The T-GF electrode was capable of a maximum cycling rate of 200 mA cm^{-2} . Coulombic efficiency (CE) values of $>97\%$ were obtained for all current densities tested. Energy efficiency (EE) values show instability during cycling with on average 5% decay in EE at each current density tested. The T-GF electrode started with low EE values (70%) for the lowest current density tested (100 mA cm^{-2}). This poor performance continues to decline as the current density increased, with EE values decreasing below 60% during cycling at 200 mA cm^{-2} . Voltage efficiency (VE) values mirror the behaviour seen in the EE. The K-GF electrode achieved a very high cycling current density of 400 mA cm^{-2} . For all current densities tested, the CE remained $>97\%$ with values $>98\%$ while cycling higher than 300 mA cm^{-2} . At 100 mA cm^{-2} EE values are stable at 85%, at 200 mA cm^{-2} EE values are 77% and at 400 mA cm^{-2} the K-GF electrodes were operating at a stable 61% EE. The voltage-capacity plot in Fig. 6b demonstrates how the increased kinetic polarization, caused by the larger R_{CT} of the T-GF electrode in Fig. S8,† affects the maximum usable capacity of the system. The T-GF electrode exhibits significant polarization as seen by the starting potentials for the charging and discharge curves (dashed lines) in Fig. 6b, resulting in low system capacity. To assess the stability of the K-GF electrodes, the system was cycled 30 times at a high current density of 400 mA cm^{-2} (Fig. 7a). The K-GF electrode exhibited a remarkable stability in performance with stable CE values of 98%, EE values of 60% and VE values of 61%. From cycles 1–10, EE dropped about 0.5% to 59.5%, where it stabilized throughout the rest of the test within cycles 11–30. The stable EE performance of the system is in line with the stable cell HFR values around 440 mOhm cm^2 shown in Fig. 7b and confirms stability of the treatment as well as other cell properties such as membrane or electrode conductivity over the cycling experiment. To assess the contribution of the electrodes to cell HFR, the battery was assembled without the membrane included. A current sweep test was performed and from the generated I - V plot, the slope was isolated and the electrode resistance was extracted using Ohm's Law. The contribution of the K-GF electrodes at a compression of 60% was 87 mOhm (348 mOhm cm^2). The contribution of the P-GF and T-GF electrodes at 60% compression were 49 mOhm (196 mOhm cm^2) and 45 mOhm (180 mOhm cm^2) respectively. The high value of the K-GF electrode is attributed to 79% of the observed cell HFR values displayed in Fig. 7b. The increased resistance can be linked to the substantial increase in surface-based oxygen functional groups and surface defects which decrease electrical conductivity. Therefore, in order to improve the cell HFR, the electrode thickness must be decreased. Successfully decreasing the cell HFR would allow current densities $>400 \text{ mA cm}^{-2}$ to be achieved while also increasing EE and VE values for lower current densities. A

Fig. 7 K-GF electrode cycling at 400 mA cm^{-2} for 30 cycles. (a) CE, EE and VE values for the K-GF electrode cycled at 400 mA cm^{-2} for 30 cycles. (b) Average cell HFR values of the system during cycling.

recent report by Jiang *et al.*⁴⁵ demonstrated how a VRFB, that has undergone extensive optimisation of all essential cell components, is capable of reaching a maximum current density of 1 A cm^{-2} while maintaining an EE of 70%. As this article reports to our knowledge battery data amongst the best VRFB performances in literature, it can be used as reference to the efficiency values reported in this work: comparing our work in medium current densities of 200 – 300 mA cm^{-2} , Jiang *et al.* obtained EE values of 76%, 72% and 68% when cycling at 200 mA cm^{-2} , 250 mA cm^{-2} and 300 mA cm^{-2} , respectively, when using a Nafion 212 membrane which is slightly worse than EE values obtained in this work of 77.5%, 74% and 70%. This confirms the high efficiency of the herein reported electrode treatment.

Conclusion

In this work we report an acidified permanganate activation procedure of Rayon-based electrodes which is rapid (1 hour) and yields high performance electrodes for use in vanadium redox flow batteries. In comparison to pristine (P-GF) and thermally (T-GF) activated electrodes, acidified permanganate

activated electrodes (K-GF) show numerous physical and electrochemical improvements. The activation process results in increased BET surface area of $9.93 \text{ m}^2 \text{ g}^{-1}$ compared to $0.74 \text{ m}^2 \text{ g}^{-1}$ for the reference (P-GF). Graphitic structural disorder, as measured by Raman, is increased to 1.24 ± 0.07 compared to 1.20 ± 0.12 (T-GF) and 0.92 ± 0.13 (P-GF). Half-cell measurements show increased reversibility and increased peak currents for both the positive and negative redox couples for K-GF felts. In contrast to the employed P-GF and T-GF electrodes, the K-GF electrode was the only electrode capable of separating the V^{2+} reduction reaction from the HER. The K-GF electrode showed therefore remarkable electrochemical performance and reached a maximum cycling rate of 400 mA cm^{-2} with coulombic efficiencies $> 98\%$ for rates higher than 300 mA cm^{-2} . Energy efficiency remained over 80% when cycling at 150 mA cm^{-2} and dropped to 60% when cycling at 400 mA cm^{-2} . Multiple cycles at 400 mA cm^{-2} revealed promising system stability with EE stabilizing at about 60% and a stable cell HFR of about $440 \pm 5 \text{ m}\Omega \text{ cm}^2$. These preliminary tests indicate promising stability of the K-GF electrodes when exposed to the harsh environment of the electrolyte during the tested timeframe. For future work, a comprehensive aging study utilizing longer cycling times and extensive post-cycling surface characterization should be performed. In addition, further analysis of chemically activated electrode felts is required to further understand the underlying activation mechanisms compared to thermal activation of electrode felts.

Further room for improvement of the electrodes was identified as a large proportion of cell's high frequency resistance stems from the electrodes ($348 \text{ m}\Omega \text{ cm}^2$). The increase in electrode resistance can be linked to the increase in surface oxygen content as identified by XPS (5.6% for the P-GF to 25% for the K-GF). Therefore, a straightforward next step in battery development is an optimized ratio between the application of the herein reported treatment with a minimized electrode thickness to combine high electrochemical reversibility and low electrical cell resistance for higher battery efficiency.
