Nucleation and growth mechanism in the early stages of nickel coating in jet electrodeposition: a coarse-grained molecular simulation and experimental study†

 Fan Zhang,^{‡a} Shenggui Liu^{‡b} and Fei Wang^{ID *a}

In jet electrodeposition, microscopic nucleation and growth in the early stages of nickel coating are crucial and directly related to the consistency and reliability of the coating structure. We set up a three-electrode device with flow-injection function based on the vertical distribution and further studied the early stages of nanocluster formation corresponding to parallel and vertical distribution states. According to the nucleation diffusion and growth analysis, a coarse-grained molecular dynamics model is established for the first time to reveal the influences of different growth environments on the microscopic nucleation growth of the coating structure. Thus, the ion dynamic diffusion and nucleation kinetic mechanism could be further achieved, these vary under different electrodeposition conditions. In addition, the physical structure of the surface coating can be obtained by element analysis and density functional theory (DFT) calculations. These findings provide a theoretical and experimental basis for the efficient preparation of nickel coatings.

Introduction

Nickel coatings are widely used in various industries, including metal decoration,^{1,2} corrosion-resistant materials,³ self-cleaning materials⁴ and electronic components,⁵ due to their excellent corrosion resistance, surface stability, good morphology, plasticity, and ductility, as well as the wide range of reserves. Meanwhile, nickel is also extensively applied to photo/electrocatalytic hydrogen production because of free electrons in the 3d orbitals of transition metals.^{6,7}

At present, the methods to prepare nickel coatings include plasma spraying, electroless plating, hydrothermal/solvothermal methods and electrodeposition.^{8,9} Among them, electrodeposition is the most extensively used because of its simple process, low preparation cost, environmental friendliness, and excellent coating quality.¹⁰ Currently, to further enhance the preparation efficiency and achieve outstanding structure performance, jet electrodeposition has been developed. Wang *et al.* prepared a Ni–CeO₂ composite coating by jet electrodeposition, leading to an outstanding corrosion effect.¹¹ Liu *et al.* adopted composite technology consisting of rolling

and jet electrodeposition. A nickel coating with excellent surface quality can be prepared by optimizing the process parameters.¹² Therefore, jet electrodeposition can successfully achieve the high-efficiency fabrication of nickel coatings with superior characteristics.

The morphology of the coating surface is sensitively related to the nucleation and growth process in the initial state. Many reports have focused on the exploration of the deposition kinetics.¹³ Various 3D nucleation models of the diffusion control process were established to reveal the metallic reduction mechanism.^{14,15} However, few studies focused on the jet electrodeposition process, especially the simulation to explore nucleation and growth through the process of the molecular dynamics. Therefore, utilizing an appropriate kinetic method to illustrate the nucleation mechanism of coating prepared by jet electrodeposition is urgent, further leading to the promotion of the high-quality preparation of nickel coatings.

This work aims at characteristics of different electrodeposition processes. We develop a vertical distributed three-electrode system to analyze the nucleation deposition behaviors of jet electrodeposition. The coarse-grained molecular model is adopted for the first time to simulate the deposition of nickel ion combined with the setting condition of nucleation and diffusion, corresponding to traditional, vertical, and jet electrodeposition. The morphology and element analysis reveal that jet electrodeposition could induce the coating to grow with dendritic structure accompanied by fast nucleation and growth rate. Finally, the DFT result further confirms that the coating prepared by jet electrodeposition has superior conductivity and

electrocatalytic performance. Our work provides a deep insight into the nucleation and growth mechanism of jet electrodeposition. It offers a steady a steady foundation for theory and experiment for preparation of nickel coating.

Result and discussion

Electrodeposition measurement mode

Aimed at the characteristic of jet electrodeposition, the three-electrode cell for electrochemical test is optimized, as shown in Fig. 1a. The platinum wire is chosen to be the counter electrode to replace the platinum foil. It is inserted into an outer hose connected to a micro peristaltic pump, thereby achieving the local injection effect. The new cell is shown in Fig. 1b inside. From the linear voltammogram of optimized three-electrode cells (Fig. 1b), the nickel electrodeposition onset potential shifts to a lower value. Simultaneously, the current density at the same potential is enhanced with increasing potential compared with those of traditional three-electrode cell, indicating that the effect of rapid flow could promote the mass transfer and ion diffusion to facilitate the nucleation and growth process.

Simulation and analysis of nucleation and growth by molecular dynamics

Three electrodeposition conditions are simulated as follows: low potential, high potential, and high potential with jet flow. These correspond to the traditional electrodeposition with parallel distribution of two electrodes, vertical electrodeposition meaning that two electrodes distributed vertically, and jet electrodeposition with vertical electrode distribution and liquid flow, respectively. Except for the nucleation morphology of the cathode surface, the simulation area is divided into the three regions to calculate the particle number at different times to judge the influence of different environmental states on the diffusion of Ni^{2+} ions.

Traditional electrodeposition. In the traditional parallel distribution of two electrodes, the model uses the diffusion of ions to carry out the random movement, whereas the electric field only adopts a lower potential (0.1 V setting). The

simulation results are shown in Fig. 2a–c. When $t = 1$ s, the surface of the cathode begins to deposit a layer of dense cluster particles. Although the sizes of each cluster vary from one another, the overall trend demonstrates a uniform coating morphology. In the range of solution, the particle numbers in the range of 35–50 nm (number: 46) and 15–35 nm (number: 42) are larger than that of 0–15 nm (number: 12), suggesting that under the control of the solution diffusion, the ion distribution around the surface of the electrode is less, and the Ni^{2+} ions are mostly concentrated at the inner solution. When $t = 2$ s, clusters grow on the surface of the electrode, indicating the start of the coalescence of particles. However, the ion concentration is further reduced to the value of 8, indicating that the rate of ion supplement is inferior to that of consumption. When the time increase to 3 s, the overall morphology of cathode still remains to be a coating. Meanwhile, the ion concentration in the range of 0–15 nm begins to be supplied, maintaining the value of 9. The particle number in the range of 15–35 nm is supplemented to about 45. This result illustrates that the metal ions around the electrode surface always remains at a low concentration and only relies on the diffusion movement of the solution, further leading to a sluggish electrodeposition. As shown in Fig. 2d, the deposition heights at three time periods are counted and agree with the above analysis. Furthermore, the above model is repeated to simulate for three times. The result is shown in Fig. S2† with error bar to demonstrate the accuracy of the model.

Vertical electrodeposition. By further increasing the potential to a high value of 0.5 V, the influence of electromigration on the ion movement is promoted. The results of ion movement and electrode morphology at different time period are obtained, as shown in Fig. 3a–c. At $t = 1$ s, the size of clusters on the electrode surface is obviously larger than that of traditional electrodeposition, but the whole morphology still tends to be flat. In the region of 0–15 nm, the ion number increases to the

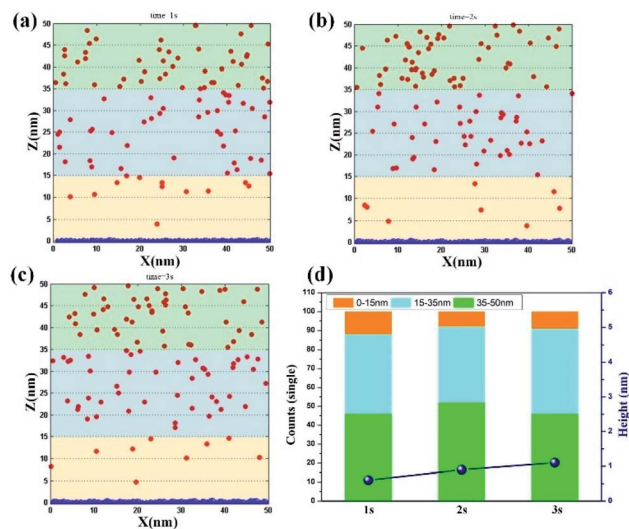

Fig. 2 Deposition morphology with time in traditional electrodeposition with the potential of 0.1 V. (a) 1 s; (b) 2 s; (c) 3 s; (d) data statistics.

Fig. 3 Deposition morphology with time in the vertical electrodeposition with the potential of 0.5 V. (a) 1 s; (b) 2 s; (c) 3 s; (d) data statistics.

value of 15, and the ion number decreases to 39, thereby corresponding to the range of 15–35 nm. This finding presents that the increase of potential could directly promote the effect of electromigration and drive Ni^{2+} ions to reach around the electrode surface. When $t = 2$ s, the clusters on the electrode surface further increase, and the average size at this time exceeds the size of the clusters at 3 s in traditional electrodeposition. The number of ions in the region of 15–35 nm is also supplemented to reach the value of 46. At the same time, the value of 14 on the electrode surface remains unchanged in the region of 0–15 nm, thereby verifying that ions in the solution are also supplemented in the rapid deposition process. When $t = 3$ s, the surface morphology of the electrode begins to grow in the vertical direction, indicating that the volume of the bottom clusters reaches the set value at this time. This phenomenon further proves that the deposition rate improves effectively through strong electromigration. Meanwhile, the number of ions near the electrode surface reaches the value of 18, illustrating that electromigration could induce the ion motion and maintain the ion concentration under fast nucleation and growth process. By conducting a visual comparison of deposition height at different time periods (Fig. 3d), the result at 3 s is found to be twice that at 1 s, which further reveals that rapid electrodeposition efficiency could be achieved at a high potential. Also, the repeated simulation is shown in Fig. S3† with the consistent results.

Jet electrodeposition. Fig. 4a–c show the simulation results of jet electrodeposition contributed from the synergy effect of high potential (0.5 V) and liquid flow. At $t = 1$ s, the vertical growth has appeared on the cathode surface, indicating that the clusters have completed the process of diffusion and coalescence in a short time and have formed the nucleation to deposit on the surface. Furthermore, the number of ions in the region of 0–15 nm reaches the value of 19 (Fig. 4d), implying that the ion concentration around the electrode surface is further increased

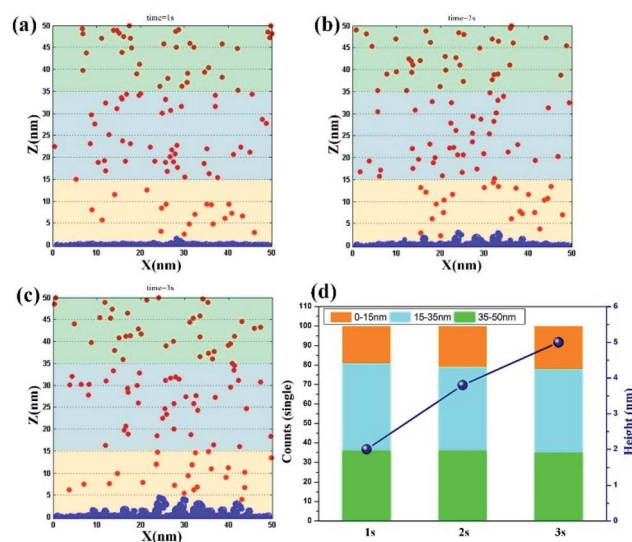

Fig. 4 Deposition morphology with time in the jet electrodeposition with the potential of 0.5 V. (a) 1 s; (b) 2 s; (c) 3 s; (d) data statistics.

by the influence of strong electromigration with high potential and fast convection. When $t = 2$ s, the dendritic structure on the cathode surface becomes obvious, which indicates that more nucleation growth points are formed at the bulge sites, thereby keeping the nucleation and growth continuous along these sites. However, the number of ions on the electrode surface at this time could remain at 20. This finding confirms that even in the rapid deposition process, the ion movement would be still promoted through electromigration and strong convection, leading to the maintenance of a high ion concentration. When the time reaches 3 s, the height of nucleation and growth reaches about 5 nm, which is twice that of 1 s, suggesting that the surface morphology is no longer a smooth structure. It tends to become dendritic with fast nucleation rate, because of the synergy effect of high potential and rapid liquid flow. Furthermore, this rapid deposition state would be maintained in the subsequent deposition process due to a stable ion concentration around the cathode surface. In Fig. S4,† the accuracy of the result is further proved.

Morphology and element characteristic

Traditional electrodeposition. Fig. 5a–c show the morphology in traditional electrodeposition with parallel distribution of electrode and the potential of 0.1 V. In the initial deposition period of 1 s (Fig. 5a), the ITO electrode keeps the primary morphology, and other structures nearly appear. Very few nucleation points exist on the surface of ITO. When the deposition continues to be at 2 s (Fig. 5b), the surface morphology of ITO changes significantly. The number of nucleation increases, and the volume also enlarges relatively. At $t = 3$ s (Fig. 5c), the coating morphology appears on the surface of ITO, but it does not completely cover the primary morphology of ITO. This finding indicates that the amount of nucleation points increases continually, leading to coalescence and

Fig. 5 Change of morphology in traditional electrodeposition (a) 1 s; (b) 2 s; (c) 3 s.

nucleation. Finally, a smooth coating is formed, which is consistent with the simulation results of traditional electrodeposition. From EDS result (Fig. S5[†]) shows that oxygen element is obtained on the surface due to air oxidation, but the amount is tiny.

Vertical electrodeposition. Two electrodes are distributed vertically to realize a local high potential (0.5 V) region on the surface of cathode; this distribution corresponds to the simulation process of vertical electrodeposition. The morphologies at different time periods are shown in Fig. 6. At the electro-deposition time of 1 s (Fig. 6a), a mass of nucleation points is distributed and grown uniformly on the surface of ITO; the amount of which exceeds the amount of nucleation in the traditional electrodeposition. After deposition for 2 s (Fig. 6b), the nucleation points continue to agglomerate, grow, and uniformly cover the surface of ITO, indicating that the nucleation rate is promoted greatly. When the electrodeposition time reaches 3 s (Fig. 6c), the primeval morphology of ITO could not be observed, and the volume of new points is larger than that of

Fig. 6 Change of morphology in vertical electrodeposition (a) 1 s; (b) 2 s; (c) 3 s.

the above moment, leading to a rough and bulging structure. This result demonstrates that Ni^{2+} ions could be affected through stronger electromigration, resulting in a driving force that promotes the diffusion motion and coalescence. Finally, rapid nucleation and growth are realized. According to EDS (Fig. S6[†]) analysis, the content of oxygen element does not further increase, indicating that the oxygen element from the cathode electrodeposited at high potential is still caused by air oxidation.

Jet electrodeposition. Under the jet condition with the potential of 0.5 V, the nucleation sites are generated and covered uniformly on the surface of ITO at the initial stage ($t = 1$ s), as shown in Fig. 7a. At the electrodeposition time of 2 s (Fig. 7b), the volume of nucleation increases obviously, and the morphology appears a hemispherical covering structure, suggesting that the nucleation and growth has reached a high rate with the fast flow and high potential. At 3 s (Fig. 7c), the volume of nucleation expands further, and the trend of morphology shows the development of the dendritic structure, which is completely consistent with the above simulation results. The morphological result confirms that the rate of nucleation and growth could be effectively promoted through the synergy of high potential and fast flow, which likely leads to the generation of dendritic structure. Based on the result of EDS (Fig. S7[†]), the oxygen content increases obviously in jet electrodeposition. This phenomenon also shows that the anode may be accompanied by the strong oxygen evolution reaction at high potential. Under the influence of strong convection, oxygen concentration on the surface of the cathode is maintained at a high level at all times, leading to a chemical oxidation process in the deposition and the doping of the oxygen element in the nickel lattice.

Physical characteristic analysis

The electrodeposition microstructures of the surface of ITO under different condition are further investigated *via* high-resolution transmission electron microscopy (HRTEM).

Fig. 7 Change of morphology in jet electrodeposition (a) 1 s; (b) 2 s; (c) 3 s.

Fig. 8 HRTEM images (a) traditional electrodeposition, (b) vertical electrodeposition, and (c) jet electrodeposition.

Fig. 8a–c show that the interplanar spacings in the surface of traditional and vertical electrodeposition is 0.202 nm, which corresponds to the (111) plane of metal Ni.¹⁶ However, the 0.208 nm for interplanar spacings corresponds to the (200) plane of NiO, as observed on the surface of jet electrodeposition. This result reveals that the jet condition could induce a core–shell structure of NiO@Ni that is decorated on the electrodeposition surface. Furthermore, amorphous structures without obvious interplanar spacings are observed in NiO, suggesting that the combined effect of jet flow and high potential promotes the rapid nucleation process, further resulting in the development of a large amount of defect structure.

The chemical valence of the electrodeposition surface is probed *via* X-ray photoelectron spectroscopy (XPS). The high-resolution Ni 2p_{3/2} spectra are shown in Fig. 9a, c and e, corresponding to traditional, vertical and jet electrodeposition, respectively. The three pairs, including metal Ni (852 eV), Ni–O (855.7 eV), and satellite, can be obtained obviously in the surface of traditional and vertical electrodeposition.^{17,18} However, the peak of metal Ni is weakened in vertical electrodeposition, suggesting that the high potential could lead to a degree of oxidation. Interestingly, this metal Ni peak disappears on the surface of jet electrodeposition combined with a strong oxidation process as compared with the traditional and vertical electrodeposition. Similarly, all O 1s spectra (Fig. 9b, d and f) from samples exhibit two peaks; one is assigned to the air oxidation group and the other to the hydroxyl group from H₂O. Furthermore, a slightly negative shift of air oxidation from the 531.46 eV to 531.12 eV suggests the different degrees of oxidation. Meanwhile, a clearly new peak is found at 529.07 eV, corresponding to the metallic oxide,¹⁹ and this finding is in good agreement with the microstructure as a core–shell heterostructure of NiO@Ni.

The electron structure of the sample at the jet condition is from the X-ray absorption structure (XAS). As shown in Fig. 10a, the Ni K-edge X-ray absorption near-edge structure (XANES) demonstrates that the curve of sample is located between the Ni foil and NiO, suggesting that the valence state of sample is

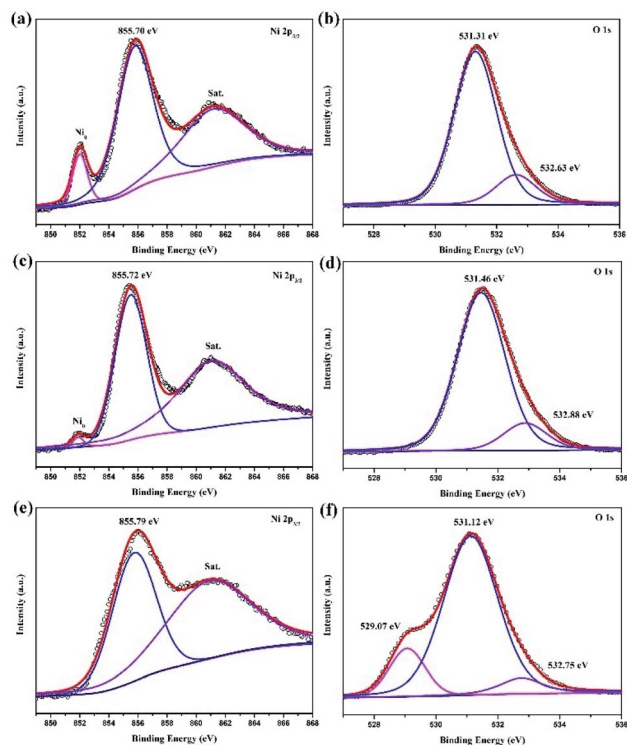

Fig. 9 XPS spectra Ni 2p_{3/2} (a) traditional electrodeposition, (c) vertical electrodeposition, and (e) jet electrodeposition; O 1s (b) traditional electrodeposition, (d) vertical electrodeposition, and (f) jet electrodeposition.

attributed to the Ni⁰ and Ni²⁺.²⁰ This result reveals the coexistence of NiO and Ni in the surface of sample that is electrodeposited through the jet condition, which is in accord with the

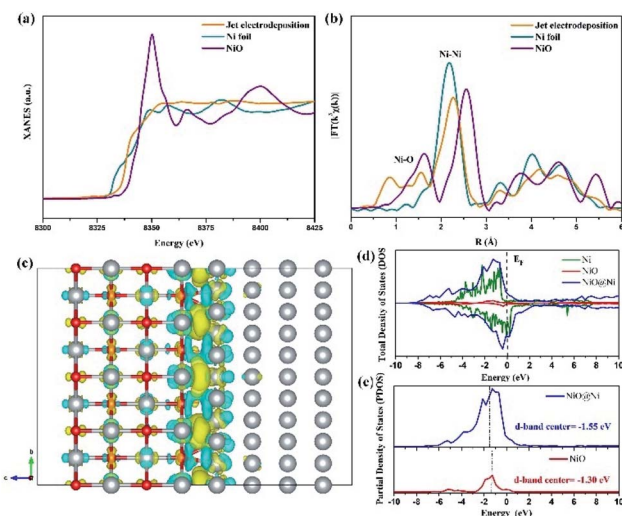

Fig. 10 (a) The Ni K-edge XANES spectra of sample of jet electrodeposition, Ni foil, and NiO. (b) The corresponding charge Fourier transformed EXAFS spectra of Ni. (e) Projected DOS for the d orbitals of Ni atoms in NiO@Ni and NiO.

Fig. 11 Morphology of ITO conductive glass (a) macroscopic; (b) microcosmic.

above-mentioned analysis. Ni K-edge X-ray absorption fine structure (EXAFS) characterization is conducted to explore the coordination structure of Ni species. As shown in Fig. 10b, a prominent peak at 2.11 Å is assigned to the Ni–Ni bonds, and a weak signal of Ni–O bonding is located at 1.6 Å.²¹ This result shows that metal Ni and NiO coexist in the sample prepared *via* the jet electrodeposition, which is in line with HRTEM and XPS analysis.

To reveal the intrinsic contributions of the heterointerface of NiO@Ni, DFT simulation is conducted by using the atomic theoretical models. Fig. 10c shows that the optimized electron density difference is obviously obtained. The electrons transferring from NiO to Ni lattice is due to the strong electronegativity of O atoms, resulting in electron redistribution at NiO@Ni heterointerface. As shown in Fig. 10d, the total density of states (DOS) of NiO@Ni, NiO, and Ni are calculated. The NiO@Ni exhibits the strongest conductivity among the three models. Also, the d-band center of NiO@Ni (−1.55 eV) is downshifted as compared with that of NiO (−1.30 eV) (Fig. 10e). This finding indicated that the bonding strength of H on the heterointerface is weakened and is thus conducive to a rapid HER reaction.²² In addition, NiO structures as active sites could facilitate the OER process effectively, and the heterostructure of NiO@Ni leads to the rapid charge transfer, thereby resulting in an enhanced electrocatalytic performance.²³

Conclusions

By the determination of the mechanism of nucleation and growth, which was influenced by the different conditions corresponding to traditional, vertical, and jet electrodeposition, we successfully reveal that the reaction rate in jet electrodeposition is higher than that of traditional electrodeposition through a linear voltammogram. Combined with a novel modelling coupling, the coarse-grained molecular dynamics with diffusion and electromigration, nickel cluster, and particle formation process at the early stage that correspond to traditional, vertical, and jet electrodeposition are simulated, respectively. Results reveal the influence of liquid flow and strong electromigration on rapid nucleation and growth kinetics. The HRTEM micrographs and characteristic analysis indicate that the oxygen element is induced into the surface in jet electrodeposition to form a heterostructure of NiO@Ni, which is further proved with the favourable electrical conductivity and adsorption by DFT simulation. This work provides vital insights into the nickel

nucleation and growth process of jet electrodeposition, thereby offering a theoretical and experimental foundation.

Experimental

Reagents and materials

The Watts solution used as the electrodeposition solution was composed of nickel sulfate ($\text{NiSO}_4 \cdot 6\text{H}_2\text{O}$), nickel chloride ($\text{NiCl}_2 \cdot 6\text{H}_2\text{O}$) and boric acid (H_3BO_3) was. All the reagents were AR grade and not further purified, which were purchased from Shanghai Aladdin Biochemical Technology Co., Ltd.

Electrochemical tests and characterizations

All electrochemical tests were taken using a CHI 760E workstation in the three-electrode cell. ITO conductive glass (10 mm × 15 mm, Wuhu Jinghui Electronics Co., Ltd.) was selected as the working electrode. The surface morphology of ITO was shown in Fig. 11. (It could be seen that the surface roughness and flatness of the ITO were favourable to provide a reliable support for the nucleation deposition of nickel.) Pt foil and saturated calomel electrode (SCE) were employed as the counter and reference electrodes, respectively. The linear voltammogram test is from −1.2 V to −0.5 V vs. SCE with the scan speed of 5 mV s^{−1}. Before the test, ITO was washed in isopropyl alcohol, ethanol and deionized water by ultrasonic for 15 min, respectively, and dried in a vacuum at 60 °C. The solution was stirred further to ensure homogeneous dispersion.

Field-emission scanning electron microscope (SEM) and high-resolution transmission electron microscope (HRTEM) were adopted to examine the morphology and microstructure characteristics of electrodeposition samples. The chemical states and element distribution in the as-prepared samples were investigated by X-ray photoelectron spectroscopy (XPS, Kratos, XSAM-800 spectrometer) and X-ray energy disperse spectrometry (EDS Oxford X-Max). Ni K-edge X-ray absorption spectra (XAS) was obtained at 1W1B station in Beijing Synchrotron Radiation Facility (P. R. China) operated at 2.5 GeV with a maximum current of 250 mA.

Coarse-grained molecular dynamic analysis

The dynamic deposition process is simulated with the two-dimensional view within a 50 nm × 50 nm domain area. The top boundary is assumed to be anode with an applied positive potential, and the bottom boundary is setting to be cathode with zero potential. Solvents and anions are neglected. The 100 particles are randomly distributed around the top boundary. The length of the simulated domains along the *x*, *z* directions are L_x and L_z . The finite difference method (eqn (1)) is used to calculate the distribution of potential field in the simulated domain,²⁴ which is given as

$$\varphi_{ij} = \frac{\frac{\varphi_{i+1,j} + \varphi_{i-1,j}}{\Delta x^2} + \frac{\varphi_{i,j+1} + \varphi_{i,j-1}}{\Delta y^2}}{\frac{2}{\Delta x^2} + \frac{2}{\Delta y^2}} \quad (1)$$

In this domain, the motion of Ni^{2+} are treated as Brownian controlled *via* the co-effect of electric field, diffusion and convection.²⁵ Therefore, the equation of motion shows the form as

$$\vec{r}(t + \Delta t) - \vec{r}(t) = \sqrt{2D_0\Delta t} \times \vec{g} + u \times \vec{E}\Delta t + \sqrt{2D_1\Delta t} \times \vec{g} \quad (2)$$

where, $r(t + \Delta t) - r(t)$ represents Δr , meaning to the motion distance within Δt . u is the migration rate, which determined by Einstein's relation ($u = D_0/(F/RT)$). \vec{g} represents a random two-dimensional unit vector. E is the electric field intensity corresponding to t . D_0 is the diffusion coefficient caused by the concentration of solution. D_1 is the diffusion coefficient caused by convection.

Based on the potential field, the distribution of electric field is given by

$$E_{i,j} = -\frac{\varphi_{i+1,j} - \varphi_{i-1,j}}{\Delta x} - \frac{\varphi_{i,j+1} - \varphi_{i,j-1}}{\Delta y} \quad (3)$$

And, the particles could be driven in the simulation area, meanwhile, the motion trail is also obtained through eqn (2).

To further solve the diffusion motion, the diffusion coefficient of each part in simulation area would be calculated by monitoring the change of solution concentration in corresponding part. When the particle moves to each part, the diffusion coefficient corresponding to this part would be adopted. Firstly, the relationship between concentration and diffusion coefficient under the combined action of forced convection and diffusion is expressed by Fick's second law:

$$\frac{\partial C}{\partial t} = -\frac{\partial(Cu)}{\partial y} + D_m \frac{\partial^2 C}{\partial x^2} + D_m \frac{\partial^2 C}{\partial y^2} \quad (4)$$

Therefore, the diffusion coefficient in simulation area could be calculated *via*

$$D_x(C) = -\frac{1}{2t} \left(\frac{dx}{dC} \right)_C \int_{C_1}^C x dC \quad (5)$$

$$D_y(C) = -\frac{1}{2t} \left(\frac{dy}{dC} \right)_C \int_{C_1}^C y dC \quad (6)$$

When the particles move to the cathode surface, the surface diffusion and mobility are mainly controlling factor. After the particle contacting the surface, the tiny clusters generate and move randomly along the surface. In order to minimize the surface energy, the atoms and clusters aggregate with each other. Further, the surface diffusion decreases with an increase of the cluster size. When reaching a setting size, the clusters would form crystal nuclei and deposit on the cathode surface. The surface diffusion coefficient D of one cluster is expressed as

$$D = D_0 N_{\text{adatoms}}^{-\alpha} \quad (7)$$

where, D_0 is the surface diffusion coefficient of an adatom. N_{adatoms} is the number of adatoms forming the cluster. α is the relative mobility of clusters, which is chosen as 5.²⁶ We set that

the diffusion motion of the particles (adatoms and clusters) is controlled by a diffusion equation, and the center r of each particle is updated through

$$r(t_{n+1}) = r(t_n) + 2\sqrt{D\Delta t}R(\cos(\varphi_r) \text{ or } \sin(\varphi_r)) \quad (8)$$

where, $R = \sqrt{-2 \ln(N)}$ and $\varphi_r = 2\pi N$ with uniform random numbers $N \in (0, 1)$. When the particles and clusters reach the set boundary condition, $\sqrt{(x_i - x_j)^2 + (y_i - y_j)^2} \leq R_i + R_j$, where the x_i and y_i are the components of r . And, the volume and mass of new particle after coalescence is updated *via* $R_{\text{new}} = \sqrt[3]{R_i^3 + R_j^3}$ and $M_{\text{new}} = m_i + m_j$, meanwhile, the new center of particle is calculated through

$$r_{\text{new}} = \frac{m_i r_i + m_j r_j}{m_i + m_j} \quad (9)$$

Finally, according to the updating of the simulation time step, the simulation of deposition morphology with the time of about 3 s is completed. This influence of substrate is ignored. The initial model under potential field and flow field is shown in Fig. S1.†

DFT calculation

All calculations were carried out by using the projector augmented wave method in the framework of the density functional theory (DFT), as implemented in the Vienna *ab initio* Simulation Package (VASP). The generalized gradient approximation (GGA) and Perdew–Burke–Ernzerhof (PBE) exchange functional was used.²⁷ The plane-wave energy cutoff was set to 500 eV, and the Monkhorst–Pack method was employed for the Brillouin zone sampling.²⁸ The convergence criterions of energy and force calculations were set to 10^{-5} eV per atom and 0.01 eV \AA^{-1} , respectively. The Ni/NiO interface model was built from the $2\sqrt{3} \times 5$ Ni(111) and 3×4 NiO(001) supercells with lattice mismatch less than 5%.²⁹ Removing one O atom from each atomic layer of NiO in the Ni/NiO interface model, the O vacancy defective Ni/NiO interface model was constructed. A vacuum region of 15 \AA is applied to avoid interactions between the neighbouring configurations.
