# Structural, morphological, and optical properties of carbon nanoparticles unsheathed from date palm fronds†

Shaik Muhammad U. G. Mohiuddin, <sup>\*ab</sup> Abdulkadir Aydarous,<sup>a</sup> Ahmed Alshahrie,<sup>ab</sup> Abdu Saeed, <sup>abc</sup> Adnan Memić,<sup>b</sup> Shittu Abdullahi <sup>abd</sup> and Numan Salah <sup>\*b</sup>

Several studies have reported the synthesis of carbon nanoparticles (CNPs) by various methods. In this study, an easy one-step process to unsheathe CNPs from date palm fronds through a top-down ball milling method has been reported. The CNPs were characterized using various spectroscopic and microscopic methods to determine their structural and morphological features, optical properties, crystallinity, physicochemical properties, and particle stability. Transmission electron microscopy (TEM) revealed that the obtained CNPs' size ranged from 4 to 22 nm in a crystalline form. Scanning electron microscopy (SEM) confirmed their spherical shape, while the maximum photoluminescence (PL) intensity was recorded at 464 nm when excited at 375 nm. The unsheathed CNPs produced a good quantum yield (QY) of 3.24%. Furthermore, the CNPs exhibited high Raman ratios of  $I_D/I_G$  and  $I_{2D}/I_G$  with values of 0.59 and 0.04, respectively, verifying their multilayer crystalline graphitic nature. These Raman ratios also agree with the X-ray diffractometry (XRD) results. The CNPs'  $sp^2$  and  $sp^3$  carbon bonds were confirmed by X-ray photoelectron spectroscopy (XPS), with oxygen on the surface forming carboxyl and carbonyl groups with no other observable impurities. Furthermore, the extracted CNPs showed excellent PL properties for up- and down-conversion. These properties are exemplary for low-cost biomass with potential applications in biomedicine. Therefore, the extracted CNPs reported in this study have potential applications in optical imaging.

## 1. Introduction

Fluorescent nanoparticles (FCNPs) have attracted the attention of the scientific community after the Scrivens group reported a purifying technique for single-walled carbon nanotubes (SWCNTs) in 2004. Their group used an electrophoretic method from an arc discharge process.<sup>1</sup> The technique also involved further study of the fluorescent fractions to produce carbon nanomaterials. Since then, several studies have investigated the potential applications of FCNPs in different optoelectronic fields, including biomedical applications,<sup>2</sup> while other studies have focused on improving their potential use in theragnostics<sup>3</sup> due to their unique PL emission properties.<sup>3</sup>

For the past two decades, numerous experiments and strategies have been developed to determine the efficiency of

FCNPs.<sup>4–7</sup> The parameters responsible for CNP fluorescence are passivation reagents and size reduction, which are the key factors determining the emission wavelength.<sup>4–7</sup> It has been reported that passivating the CNP surface may drastically increase the fluorescence QY%.<sup>8</sup> Sun *et al.* (2006)<sup>8</sup> and Liu *et al.* (2009)<sup>9</sup> reported the effects of CNP size on the PL quantum yield percentage (QY%). They stated that large CNP particles present poor QY% and small CNP particles show high QY% in addition to an increasing energy gap approaching that of quantum dots.<sup>8,9</sup> However, the preparation technique controlling the CNP fluorescence remains a challenging factor. Previous reports have stated that the important parameters behind the CNP photoluminescence (PL) characteristics are the intensity and wavelengths of the emission and excitation.<sup>10</sup> Furthermore, changes in the CNP PL characteristics may be related to the tuning of surface-state properties such as the doping of heteroatoms, functional groups, excitation of carbon, emission traps, structures of the aromatic conjugate and free zigzag regions.<sup>10–13</sup>

The PL mechanism changes with the different techniques and passivating agents used during CNP extraction.<sup>14</sup> The major CNP challenges till date are achieving large-scale production with stable efficiency, their isolation techniques and their purity studies.<sup>10,15,16</sup> Retrospective studies indicate that different CNP

† Electronic supplementary information (ESI) available. See <https://doi.org/10.1039/d2ra04189h>

synthetic techniques may present different QY% values. For example, a technique involving high-energy ion-beam radiation may create point defects in the produced CNPs,<sup>17</sup> whereas a thermal decomposition technique may produce CNPs with low QY%. In addition, the gel-electrophoresis technique produces CNPs that emit assorted colors for different carbon materials derived from metal-organic frameworks by the reduction of oxygen.<sup>13,18</sup> However, separating these CNP color emissions remains a challenge.<sup>10–12,19,20</sup>

FCNPs emit distinct colors. For instance, octadecyl amine with carbon nanodiamond functionalization produces a blue color,<sup>21</sup> while nitrogen doping produces red fluorescence.<sup>22</sup> Furthermore, techniques including thermal decomposition and laser ablation produce ultrafine CNPs with full color emission and low QY%.<sup>21–23</sup> FCNPs are important biomedical materials due to their unique characteristics, including sensitivity, water solubility, photovoltaic efficiency, photostability and biocompatibility with the target. It should be noted that the origin and synthetic technique of the FCNPs determine their absorbance and PL efficiency along with their functional groups.<sup>10,15,16,20,24,25</sup>

Saudi Arabia has more than 25 million date palm trees with 400 different varieties and a date production of approximately 40 kg per tree.<sup>26</sup> Therefore, extracting CNPs from these date palms fronds has several benefits including large-scale production in an environmentally friendly, sustainable and renewable manner. Most previous studies have reported CNP preparation using bottom-up methods such as the hydrothermal procedure,<sup>11,27–29</sup> with few studies reporting top-down techniques using high-energy ball milling.<sup>30</sup> The ball milling technique produces CNPs by crushing large-carbonized particles inside a steel jar. The inner part of the steel jar may accumulate heat and pressure during crushing. CNPs produced using ball milling have features such as excellent graphitic character and low QY%.<sup>31–33</sup>

In view of the above considerations and to the best of our knowledge, no study has reported on the up-conversion PL properties and chemical structures through Raman spectroscopy for reduced-size CNPs extracted from date palm fronds. Studying the chemical structures of the CNPs through Raman spectroscopy may highlight the graphitic CNPs' purity and presence of defects in the chemical structures. Therefore, this study focuses on extracting CNPs from date palm fronds and evaluating their optical properties, including PL up-conversion, and their structural properties to determine their potential applications in optical imaging.

## 2. Materials and methods

### 2.1 Synthesis of the CNPs

The date palm fronds used in this study were sourced from Jeddah, Saudi Arabia, and prepared following the procedure in Salah *et al.*<sup>34</sup> The fronds were cut into small pieces and carbonized at 400 °C using a muffle furnace. Thereafter, ball milling with a Retsch PM 400 instrument was used to synthesize the novel CNPs by placing the carbonized particles (CPs) in the machine for 15 hours at a speed of 200 rpm.<sup>34</sup> The stated CNP preparation procedures are described in Fig. 1.

### 2.2 Unsheathing the PL of the CNPs and their size

The size of the CNPs was further reduced by dissolving 25 000 mg of CNP powder in 1500 ml deionized water (DI) and magnetically stirring for 24 hours at 80 °C. The mixture was filtered using Whatman filter paper to collect particles of homogeneous size. The mixture was further centrifuged at 4000 rpm for 1 hour to collect the smallest homogeneous particles. Hence, the mixture was found to contain a  $16.58 \pm 0.36$  mg ml<sup>−1</sup> concentration of ultrafine CNPs at pH 7.23. The mixture was prepared in three replicates to ensure the reproducibility of the results and a yield value of  $69.89\% \pm 0.47\%$  was obtained. Furthermore, the CNP mixture is a light brown aqueous hydrophilic mixture when exposed to sunlight and emitted bright blue light under ultraviolet visible light at an excitation wavelength of 365 nm.

### 2.3 Characterizations of the CNPs

**2.3.1 Morphological characterization.** Morphological studies of the CNPs were conducted using two different techniques: high-resolution transmission electron microscopy (HR-TEM) and scanning electron microscopy (SEM). The HR-TEM system used in this study was an ARM 200F system with up to 0.07 nm precision and crystallinity. It can determine the surface morphology as well as the material crystallinity. The CNP samples were studied by applying two drops of sonicated CNP mixture on the HR-TEM grid and allowing the drops to dry before inserting the samples into the system. Additionally, the surface morphology and porosity of the CNPs were studied using a LYRA A3 TESCAN system with 10 kV applied voltage. In this case, two drops of the mixture were applied on carbon tape and the tapes were allowed to dry prior to investigation.

**2.3.2 Structural and optical analysis.** X-ray photon spectroscopy (XPS) was used for identify the elemental content and related functional groups present in the CNPs. Drops of the CNP mixture were poured into a silicon substrate for XPS analysis. The CNPs' PL emission/excitation spectra were studied using spectral fluorophotometry (RF 5301, Shimadzu, Japan). In this case, the CNP mixture was studied directly by adding the mixture into a cuvette tube and recording the PL emission and excitation spectra. The photon absorption spectra were investigated using a PerkinElmer Lambda 750 with a similar cuvette as that used in the PL study. The CNPs' molecular fingerprints were analyzed using micro-Raman spectroscopy (Thermo Fisher Scientific, Boston, USA) in addition to Fourier transform infrared (FTIR) spectroscopy (Nicolet IS10 FTIR spectrometer (Thermo-Scientific)). The Raman system used an excitation wavelength of 532 nm and a power of 6 mW. The CNPs' crystalline structure was investigated using X-ray diffractometry (XRD) on an Ultima-IV system with an accelerating voltage of 40 kV, current of 30 mA, and Cu K $\alpha$  wavelength of 1.541 Å. The other preset parameters were an angular range of 10° to 80° with a step size of 0.05°. Additionally, the CNPs were further analyzed using high-resolution confocal scanning microscopy (CM) with a LSM 780 system (Carl Zeiss, Germany).

The CNPs' fluorescence images were captured using CM scanning at excitation wavelengths ranging from the blue

Fig. 1 Schematic illustration of the CNPs extracted from date palm fronds through the carbonization and ball milling processes, and finally filtered with DI water and centrifuged to obtain homogeneous CNPs. Liquefied CNPs were excited under UV light and exposed to natural light.

region to near-infrared (NIR). The samples were prepared by simply drying a few drops of the CNP mixture on glass slides and these glass slides were used for the FTIR, Raman, XRD, and CM studies. Lastly, the stability and colloidal behavior of the CNPs were studied using zeta potential analysis. The samples were prepared in a disposable cuvette that was specific for the instrument and measured at room temperature while monitoring the pH value.

**2.3.3 Quantum yield (QY) determination.** The PLQY% of the CNPs were calculated using William's method.<sup>35,36</sup> In this calculation, quinine sulfate<sup>37</sup> was used as a reference sample for analyzing the QY.

$$Q_{ys} = \frac{F_R A_S Q_{YR}}{F_S A_R} \frac{n_r^2}{n_s^2} \quad (1)$$

where  $F_S$  denotes the integral area of the CNPs' PL emission at 464 nm,  $F_R$  denotes the integral area of quinine sulfate PL emission,  $A_S$  denotes the CNPs' absorbance at the excitation wavelength of 375 nm,  $A_R$  denotes the quinine sulfate absorbance,  $Q_{ys}$  denotes the CNPs' QY,  $Q_{YR}$  denotes the quinine sulfate (QS) QY, and  $n_s$  and  $n_r$  are the refractive indexes of the CNPs and QS, respectively. The QY calculation results are summarized in Table 1.

## 3. Results and discussion

### 3.1 Physiochemical properties of the CNPs

Morphological TEM images were taken at different magnifications and are presented in Fig. 2(a–c). The images show a dendrite-like network at low magnification, as depicted in Fig. 2(a), while at higher magnification, the particles were well

separated from each other, as shown in Fig. 2(b). In addition, Fig. 2(c) shows clear lattice fringes, confirming the crystallinity, as depicted in Fig. 2c(i and ii), and the hexagonal rings of carbon in the HR-TEM images, as shown in Fig. 2c(iii). Fig. 2(d) shows the frequency distribution of TEM images with the particle diameter ranging from 4 to 22 nm and an overall average diameter of 12 nm. The CNP particle sizes recorded in this study agree with those of previous studies.<sup>27–29</sup> Additionally, the CNP particles in the SEM images depicted in Fig. 2(e–h) appear to be uniformly distributed without agglomeration, as recorded in the low-magnification TEM images. It can be observed that small CNP particles were attached to big particles, which also revealed good porosity. The CNPs were found to be hydrophilic with a transparent color. Moreover, the HR-TEM image revealed an inter-fringe distance of 3.35 Å, corresponding to a carbon material index of (002) and attributed to the crystalline graphitic phase with  $sp^2$  graphene (002).<sup>37</sup>

Fig. 3(a) shows the X-ray diffraction patterns of the CNPs. The patterns exhibit a few diffraction peaks with a prominent peak centered at 28.70° and a corresponding interlayer d-spacing of 3.108 Å. The peak also has a shoulder at 25.8° with a d-spacing value of 3.441 Å.<sup>38,39</sup> Another peak was recorded at 59° with a d-spacing value of 1.569 Å.<sup>40</sup> The sharp peak represents bulk graphite with oxygen functional groups and was recorded due to the small size of the graphitized CNPs' crystalline nature.<sup>38</sup> Meanwhile, the small peak recorded at 59° is attributed to graphitic diffraction. Furthermore, the recorded XRD d-spacing value of 3.441 Å with an index value of (002) is identical to the inner lattice spacing also observed in the HR-TEM image.

Table 1 Parameters required to calculate the quantum yield; the measured parameters for QS were taken from a reference at an excitation of 380 nm

Sample	Integrated intensity of emission ( $F$ )	UV absorbance at the desired excitation nm ( $A$ )	Refractive index of the sample ( $n$ )	Quantum yield% (QY)	
Quinine sulfate	380	0.0195	1.33	54	29
CNPs	375	0.399	1.33	3.24	This

Fig. 2 TEM images of the CNPs at different magnification, describing their size, morphology, and nature. (a) Images at 1  $\mu\text{m}$  and (b) 200 nm, describing their size. (c) Image at 50 nm displaying the crystallinity of the CNPs, hexagonal rings and the interlayer lattice spacing. (d) CNP histogram of the measured size distribution. SEM analysis of the CNPs, with images at different magnifications: (e) 10  $\mu\text{m}$ , (f) 2  $\mu\text{m}$ , (g) 1  $\mu\text{m}$  and (h) 200 nm.

There are a few studies that have reported the synthesis of CNPs sourced from date palm fronds. For instance, Kavitha *et al.*<sup>27</sup> carbonized date palm fronds through manual grinding and obtained an average size of 32 nm. However, the CNPs' mesoporous form was more amorphous than crystalline in

nature. Another study conducted by Athinarayanan *et al.*<sup>28</sup> synthesized CNPs using a hydrothermal technique and achieved CNP sizes ranging from 5 to 15 nm with an inner lattice spacing and XRD  $d$ -spacing of 3.36 and 3.34  $\text{\AA}$ , respectively. In addition, another version of the study reported by

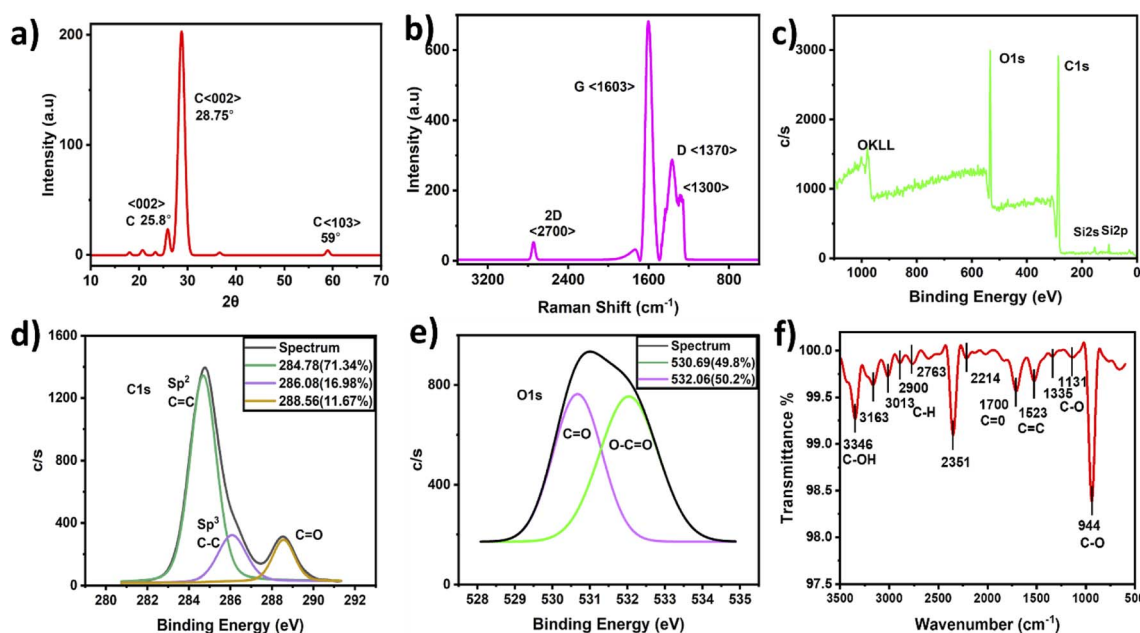

Fig. 3 (a) XRD spectrum describing the diffraction angle of the CNPs. (b) Raman spectrum of the CNPs, with the baseline subtracted Raman spectrum showing sharp peaks of D and G bands along with a 2D band. XPS spectra of the CNPs obtained and its surface-state elements. (c) Survey spectra of (d) C 1s and (e) O1s. (f) FTIR spectrum describing the transmittance % of functional groups present in the CNPs.

Athinarayanan *et al.*<sup>29</sup> synthesized CNPs using the same hydrothermal technique, which yielded CNP sizes of 2 to 15 nm, while inner lattice XRD *d*-spacings of 0.238 and 0.356 Å were recorded. In contrast, the CNPs reported herein, as shown in Fig. 2c(iii), show the presence of hexagonal rings of graphitic crystalline carbon with excess oxygen functional groups. This was also confirmed through the XRD peak centered at 28.70°, which is attributed to bulk graphitic carbon with 2D hexagonal reflections.<sup>41,42</sup> Therefore, the CNPs synthesized from date palm fronds in most previous studies show less graphitic content compared with those reported herein. This indicates that the nature of CNPs depends on the source of the date palm fronds and the synthetic technique.

Raman analysis detects structural disorder and defects in CNPs, including the functional groups, vacancies, doping, and edges.<sup>43</sup> Fig. 3(b) shows sharp D and G bands at 1603 cm<sup>-1</sup> and 1370 cm<sup>-1</sup> with a small 2D band at 2700 cm<sup>-1</sup> attributed to graphitic carbon. A peak at 1300 cm<sup>-1</sup> near the carbon nanodiamond Raman peak was also recorded<sup>36</sup> and a similar FTIR transmittance peak was also recorded at 1335 cm<sup>-1</sup>, indicating sp<sup>3</sup> hybridized carbon atoms and defects. Since the D band indicates impurity and the effects of graphitic carbon, the splitting of the sp<sup>3</sup> hybridized D-peak into two peaks is possibly associated with the amount of carbon disorder defects, functionalization effects and CNP edge effects.<sup>44</sup> In contrast, the G band indicates the presence of sp<sup>2</sup> hybridized carbon atoms. The peak at 1603 cm<sup>-1</sup> was assigned to the vibrational stretching bands, describing how the vibrations affect the structural order and purity of graphite. The graphene layers are identified with the 2D band by determining the *I*<sub>2D</sub>/*I*<sub>G</sub> value, and the value recorded herein is 0.04, corresponding to a multilayer structure. The obtained CNPs *I*<sub>D</sub>/*I*<sub>G</sub> ratio with a value of 0.59 indicates a graphitic nature. The *I*<sub>D</sub>/*I*<sub>G</sub> ratio recorded in this study is high compared with that of previous studies.<sup>43,45–48</sup> Hence, the CNPs reported in this study are predominantly carbon nanocrystalline particles, which are attributed to crystalline graphitized carbon.<sup>43,45–48</sup>

Fig. 3(c) shows the elemental structure of the CNPs through their XPS spectra. It can be observed that the CNPs' atomic percent composition was 74% and 24% carbon and oxygen, respectively, which was dissimilar to the original carbon soot before ball milling. The original carbon prior to ball milling contained 96% and 4% carbon and oxygen, respectively. Therefore, the ball milling technique, which involves crushing carbonized carbon particles into CNPs, is an oxide cutting technique, with potential oxidation causing the oxygenated groups to bind with the resultant CNPs, thereby making the CNPs negatively charged carriers.<sup>49</sup>

The carbon C 1s spectrum presented in Fig. 3(d) shows several peaks, including peaks at 284.78 eV, 286.08 eV and 288.56 eV, which are attributed to sp<sup>2</sup>(C=C), sp<sup>3</sup>(C-C) and (C=O) with FWHM (intensity counts) of 1.74 (1360.70), 1.34 (325.24) and 1.30 (298.7),<sup>43,50,51</sup> respectively. Fig. 3(e) shows the oxygen O 1s spectrum with peaks at 530.69 eV and 532.06 eV, which are attributed to C=O and C-O, with FWHM (intensity counts) of 1.86 (763.20) and 1.42 (753.86), respectively.<sup>35,36</sup> In addition,

elemental analysis indicated relatively high oxygen content that may have been caused by oxidation during sample preparation. The FTIR spectra also show similar functionalized carboxylic and carbonyl groups, indicating the dominance of oxygen with carbon.

It was also observed that the CNPs are mostly composed (71.34%) of the sp<sup>2</sup> spectrum, representing the CNPs' graphitic nature, with sp<sup>3</sup> hybridized crystalline carbon with a binding energy of 286.08 (eV) covering an area of 16.98%, attributed to π-π\* conjugation. These confirm the lower defects in the crystalline graphite.<sup>37</sup> However, this could also be formed by carbon nanodiamond (CND) oxygen defects with blue-colored emission. According to previous studies, small CNP particles present high fluorescence.<sup>36</sup>

Fig. 3(f) presents the CNPs' FTIR spectra. The spectra show a strong band at 3400 cm<sup>-1</sup> attributed to the C-OH stretching vibration, while the peaks at 3163, 3013, 2900 and 2763 cm<sup>-1</sup> were assigned to C-H stretching vibration of the symmetric and asymmetric hydrocarbons of CH<sub>2</sub>. Similarly, the sharp peaks recorded at 1523, 1700, 1398, and 1131–1335 cm<sup>-1</sup> are assigned to C=C, C=O, C-O-C and C-O vibrational stretching.<sup>38–42</sup> The strong peak at 2350 cm<sup>-1</sup> represents O=C=O vibrational stretching. However, some studies have attributed this peak to carbon dioxide,<sup>50,51</sup> followed by a weak peak at 2214 cm<sup>-1</sup>.<sup>50,51</sup> The presence of oxygen as a functional group in the CNPs confirms it to be one of the major causes of the increase in the PL property. In previous studies,<sup>52,53</sup> CNPs with date palm fronds have shown traces of nitrogen and a low percentage of oxygen and its defects. However, some studies show nearly the same percentage of C and O as the results reported herein, without a trace of nitrogen and with oxygen as the single functional group.<sup>43</sup>

The CNPs C 1s spectrum presented in the XPS results with the corresponding peak at 288.5 eV covering an area of 11.67% ascribed to carboxylic groups is analogous to the FTIR results. Therefore, the XPS results indicate that the CNPs reported in this study are composed of crystalline nanodiamonds with structural defects, which agrees with the TEM, Raman and FTIR characterization.<sup>36</sup> However, further studies are needed to verify the presence of the carbon nanodiamonds detected in this study.

The results reported in this study could be compared with those of a previous study conducted by Salah *et al.*<sup>34</sup> Salah *et al.*<sup>34</sup> reported a CNP extraction technique from date palm fronds and characterized them using various techniques, including TEM and HR-TEM, SEM, Raman, UV absorption, XPS, XRD and electrical conductivity. They studied the CNPs in the powder form rather than the liquefied form reported in this study. Although they did not mention the exact CNP size they obtained, they mentioned that they were less than 100 nm, which is much larger than the size reported herein. In addition, this study investigated the physiochemical properties using FTIR to assess their chemical composition in addition to the CNPs' Raman intensity ratios of *I*<sub>D</sub>/*I*<sub>G</sub> and *I*<sub>2D</sub>/*I*<sub>G</sub>, which are investigated herein to determine the graphitic purity and presence of multilayers, which were not previously reported by Salah *et al.*<sup>34</sup>

### 3.2 Optical properties of the CNPs

The photon absorption analysis is presented in Fig. 4(a). A sharp absorption peak located at 287 nm with a weak shoulder at around 364 nm was recorded. These peaks described  $\pi$ - $\pi^*$  transitions representing graphitic carbon C=C bonds and  $n$ - $\pi^*$  transitions attributed to carboxyl and carbonyl groups (C=O).<sup>37,54</sup> These sharp absorption peaks confirm the delocalization of  $\pi$ -state formation due to the predominance of  $sp^2$ -like graphitic carbon. In contrast, in the  $n$ - $\pi^*$  transitions, the carboxylic and carbonyl functional groups attached to conjugated carbon are responsible for the PL emission at 464 nm, as presented in Fig. 4(b and c). Such CNP behavior has been previously reported in the literature.<sup>55</sup> The PL emission spectra

show wide broadband emission with a shift from the visible to green-yellow region. The optimum PL excitation was recorded at 375 nm with a corresponding absorption intensity of 0.399. Therefore, the Stokes shift was found to be 89 nm, and it has been previously reported that a high Stokes shift exhibits better fluorescence.<sup>55</sup>

There are various sources of CNPs; however, the excitation wavelength of natural CNPs mainly depends on the PL emission wavelength, and this behavior characterizes their structural complexity.<sup>56</sup>

The CNPs' PL emission is not only dependent on the intrinsic or outer surface emission but it can also explain the CNPs' chemical composition. This is because CNPs have

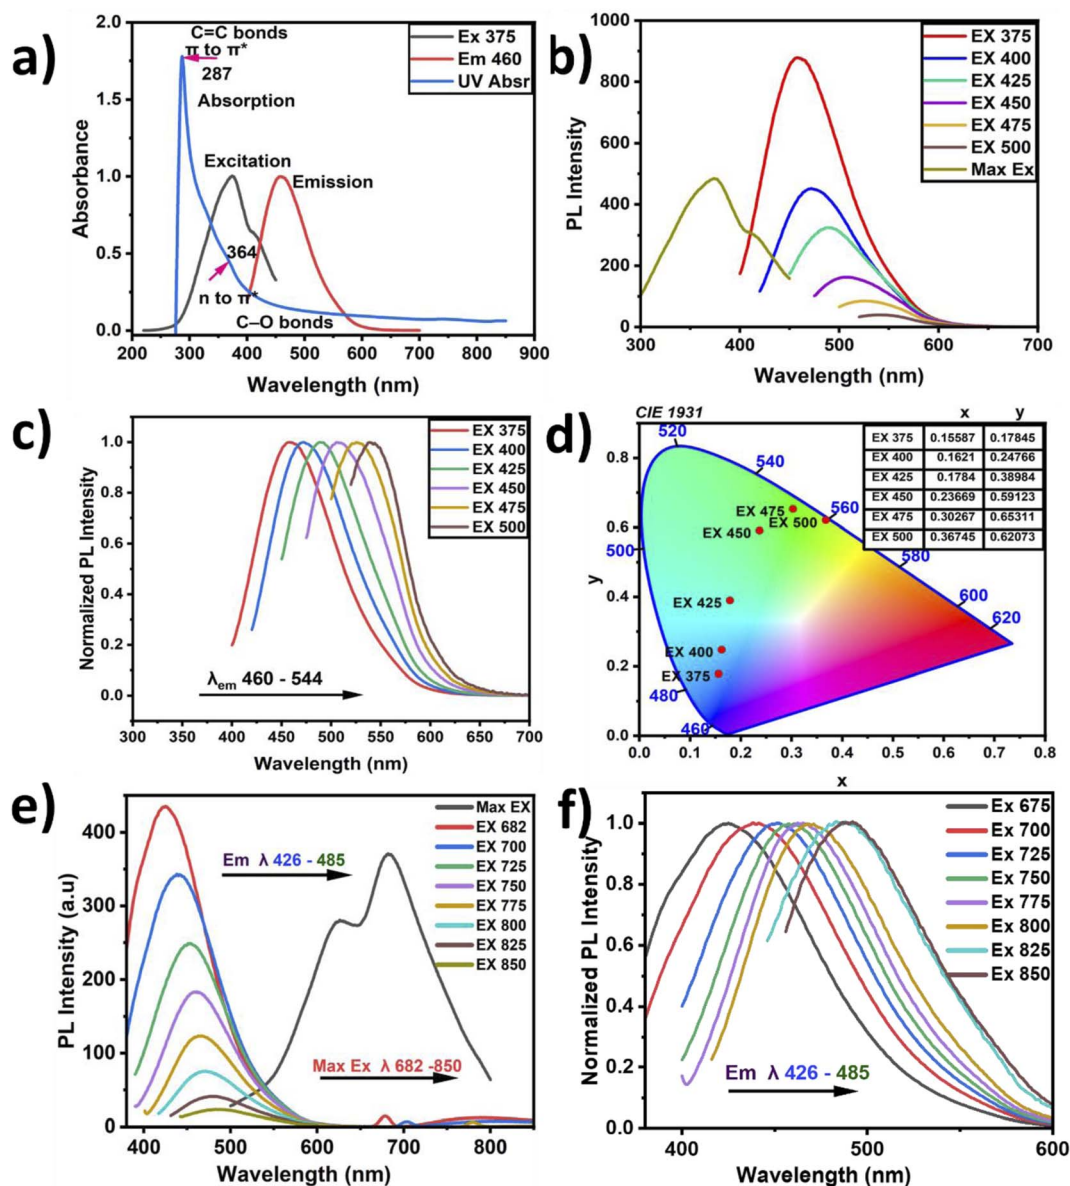

Fig. 4 Illustration of the optical properties of the CNPs obtained in liquid form. (a) PL spectra of CNP emission, which were excited sequentially from 375 nm to 500 nm. (b) PL emission spectra with normalized intensity, excited sequentially from 375 nm to 500 nm. (c) CIE 1931 chromaticity x and y coordinates of the PL CNPs. (d) Describing the UV absorption of the CNPs', and the excitation and emission wavelengths of the PL of the CNPs with normalized intensities. (e) Emission spectra of up-conversion, sequentially excited from 682 nm to 850 nm. (f) Normalized PL emission spectra of up-conversion, sequentially excited from 682 nm to 850 nm and its shift.

different layers and different sizes, which can lead to selective excitation. The graphitic carbon reported in this study showed the presence of multilayers, describing its imperfection. When the CNPs' PL emission primarily depends on the presence of a conjugated  $sp^2$  matrix rather than the CNPs' size, it is referred to as down-conversion photoluminescence.<sup>57,58</sup> Furthermore, Fig. 4(c) shows the observed systematic shift when the CNP samples were excited with a wavelength ranging from 375 to 500 nm, and the corresponding PL emission was recorded at wavelengths ranging from 464 to 560 nm, with the PL intensities normalized for convenient observation of the shifts. The shifts may be attributed to the different particle sizes in the samples, with the abundant oxygen contained as a functional group on the surface causing emission traps. Additionally, Fig. 4(d) depicts the chromaticity diagram displaying the emission color shift of the CNPs along with their  $x$  and  $y$  axes. Here, the CNPs showed a blue color at the highest emission intensity and near-yellow at the lowest emission. Fig. 4(e) presents the up-conversion PL emission, which is considered one of the vital CNP optical properties. The up-conversion PL emission is recorded using excitation wavelengths ranging from 426 to 485 nm and a considerable red-shift was recorded when the PL emission was recorded with the excitation wavelength ranging from 682 nm to 850 nm. This unique property apparently indicates excitation-independent emission, referred to as up-conversion. This property is required for biomedical applications such as bioimaging, cell labeling and theragnostics.<sup>59</sup> The computed CNPs' quantum yield is found to be 3.24%, showing good fluorescence, as presented in Table 1. Incorporation of nitrogen and oxygen can also lead to increased quantum yield according to previous reports. The fluorescence of the defect structure of diamonds is well known from previous studies. Thus, an abundant amount of oxygen and  $sp^3$  crystal-line diamond-like carbon can possibly be responsible for the blue-colored PL emission.<sup>36</sup>

There are several ways to produce carbon dots with different optical results and modifications. It has been reported that various CNP emissions originate from the transition of surface electrons to valence holes, emission from the intrinsic band surface to the ground state, and electron-phonon coupling, which occurs due to dipole emission excitations by self-trapping,<sup>40</sup> but mostly from the presence of organic molecules. Furthermore, another report on PL emission stated that it depends on excitation, and its characteristics are mostly determined through centers of multiemission.<sup>40</sup> Generally, the CNP optical property is dependent on various factors, such as the environment and the interaction of the CNPs with the environment.<sup>40</sup>

The surface structure of CNPs is responsible for the changes in their optical property, leading to the transfer of electrons from the nanoparticles to other species. It has been reported that the type of solvent also plays a major role in the solubility and interaction of particles. The scientific community has not yet come to a common understanding and agreed explanation of the CNPs' optical properties.<sup>40</sup> Fig. 3(b) shows both the  $sp^2$  and  $sp^3$  bonds of hybridized carbon atoms, which are related to their optoelectronic properties through the delocalized electron

sites, number of double bonds and spatial distribution. The PL emission dependent on excitation originates from the CNP cores and the uniformity of their surfaces in addition to the CNP size. Here, the maximum excitation peak is recorded at 375 nm with a corresponding maximum emission at 464 nm. These also present a Stokes shift of 89 nm and a full width half maximum (FWHM) of 94 nm, indicating low energy loss and good peak absorption.<sup>49,60</sup>

CNPs have a unique electron-transfer property by quenching, whereby the molecules can accept or donate electrons. Although graphene nanoparticles (GNPs) have less defects and better crystallinity than CNPs, CNPs have consistent graphene lattice spacing, graphite, and diamond. CNPs are mainly composed of C and O, which play a significant role in PL enhancement. Having carbonyl and carboxyl surface groups with better solubility also plays a vital role as a functionalizing agent. Overall, it is easy to alter the surface of these functionalized CNPs to improve their PL, solubility, and sensitivity for potential applications in optical imaging and ultimately biomedical applications. It has been reported that the efficiency of the fluorescent quantum yields mostly depends on the incorporation of oxygen elements and the subsequently produced fluorescent centers in the CNPs.<sup>61</sup> Oxygen functional group can cause deprotonation in the CNPs due to changes in the environment and pH value. Since the PL also depends on the CNPs' graphitic pH value and the presence of oxygen, a change in pH might lead to a decrease in fluorescence intensity.<sup>55</sup> Therefore, a pH value near 7 may be required to achieve excellent luminescence, as reported in this study. GNPs are a subclass of carbon materials produced mostly through top-down methods, having structures with  $\pi^*$  conjugation, and containing one or more layers of graphene oxide. In this study, XPS and FTIR analyses confirmed that our CNPs show the presence of excess oxygen components as oxygenated functional groups, and hence it is possible that our CNPs were formed by oxidative routes. The PL chromaticity diagram shows high wavelength excitation, indicating a shift from the blue region to green. A possible reason for this shift might be the formation of electron traps due to the oxygenated functional groups, directing the blue emission at 464 nm. At relaxation, this was followed with green emission, which could be due to the large wavelength excitation causing a disruption in the highest unoccupied molecular orbital (HUMO). Therefore, this optical study revealed that the PL emission reported in this study does not depend on excitation. However, other factors such as the functional groups, amount, and preparation method determine several aspects of the CNPs' PL. The CNPs reported herein exhibit light-capturing capability and therefore potential applications in optical imaging.<sup>61</sup>

**3.2.1 Up-conversion property of the CNPs.** To record the up-conversion PL, the unsheathed aqueous CNPs were excited at high wavelengths from 682 nm to 850, with a long-pass wavelength excitation filter placed in front of the light source to cut half of the excitation wavelength. The maximum excitation wavelength was achieved at 682 nm with a corresponding maximum emission intensity at 426 nm, followed by excitation wavelengths of 700, 725, 750, 800, 825, and 850 nm with the corresponding emission ranging from 426 to 485 nm, as

Fig. 5 (a–d) Confocal microscopy images of the CNPs excited at 405 nm (blue), 465 nm (green), 535 nm (yellow), and 568 nm (red). (e) Normalized fluorescent emission spectra of the CNPs recorded by confocal microscopy, which were excited sequentially at 405, 465, 536 and 568 nm. (f) Zeta potential measurement of the unsheathed CNPs.

presented in Fig. 4(e). The up-conversion is of the anti-Stokes emission type. In this emission type, two or more photons absorb and emit light at a shorter wavelength than the excitation wavelength. Having the highest intensity of emission at 426 nm, the recorded shift between each emission peak could be clearly distinguished, as depicted in Fig. 4(f). It can be observed that at each excitation wavelength, there is an intensity decrease with increasing excitation. Therefore, the NIR shift clearly indicates up-conversion PL with applications in optical imaging.<sup>59</sup> Furthermore, this study investigated the PL optical

properties of the CNPs and the QY%, which were not reported previously by Salah *et al.*<sup>34</sup>

**3.2.2 Optical imaging of the CNPs.** Salah *et al.*<sup>34</sup> did not study the optical imaging potentiality of the CNPs, which was demonstrated in this report. In addition, the surface charges of the CNPs assessed by zeta potential are reported herein. Images of the fluorescent CNPs were captured using confocal microscopy with excitation at four different wavelengths of 405, 465, 535 and 568 nm. The resultant emission was recorded at 468, 520, 516 and 668 nm, matching blue, green, yellow, and red emission,

Table 2 Summarized parameters of the CNPs obtained during their characterization

$\lambda_{\text{ex}}/\lambda_{\text{em}}$	FWHM (nm)	QY%	Raman $I_D/I_G$	TEM size (nm)	Stokes shift	pH	Zeta potential (mV)	Surface-state functional groups
375/464 nm	94	3.24	0.59	4–22 nm	89	7.23	–24.10	C–C/C=C, C=O, C–O–C, C–OH, C–H O=C=O/O–C=O

respectively, as presented in Fig. 5(a–d). The fluorescence spectra from confocal microscopy were recorded to show the shift from the blue to NIR region, as depicted in Fig. 5(e), which is comparable with the up-conversion PL property in the phenomenon of the CNPs' organic emission for the four different excitations that lead to the NIR region.<sup>62</sup> Therefore, Fig. 5(f) shows the measured CNPs' zeta potential to determine their stability and colloidal strength for possible optical imaging applications. They show a negatively charged value of  $-24.10$  mV, indicating good stability and low electrostatic repulsion between the CNPs, which is also apparent in the SEM images. The negative value recorded also indicates possible safe interaction with cells during optical imaging, allowing for biomedical usage.<sup>55</sup>

As previously reported, the energy attributed to Brownian motion hinders the agglomeration of nanoparticles, thereby making them soluble in water and stable. Optical bioimaging requires nanoparticles that emit at a certain excitation wavelength, are compatible with the environment, and are water soluble without functionalization after extraction.<sup>63</sup> The characterized results obtained for the CNPs are summarized in Table 2.

## 4. Conclusions

We report a simple and easy way to extract CNPs *via* the ball milling technique. Date palm fronds were employed as an organic source of unsheathed CNPs. The structural and optical properties of the CNPs were studied using various techniques, such as HR-TEM, XRD, XPS and FTIR, Raman, UV, and PL spectroscopy. The extracted CNPs' size was found to range from 4 to 22 nm, having a hydrophilic and crystalline graphitic nature. The crystallinity of the CNPs and the presence of bulk graphite were confirmed by XRD characterization. A Raman ratio ( $I_D/I_G$ ) of 0.59 was recorded, confirming the presence of multilayer graphite, indicating an agreement between the Raman and XRD patterns. FTIR spectroscopy confirmed the presence of carboxyl and hydroxyl functional groups. The high percentages of  $sp^2$  hybridized graphitic carbon and low  $sp^3$  were validated using XPS. Furthermore, the CNPs demonstrated exemplary PL properties, such as down-conversion and up-conversion, justifying the excitation independence of the emission within the blue region to NIR. The QY% was also computed and the value recorded is 3.24% at pH 7.23. The QY% and pH value confirmed the high recorded PL intensity. The extracted CNPs showed excellent optical behavior with particle stability, having a zeta potential value of  $-24.10$  mV, suggesting their potential application in optical imaging. These statements were also verified using confocal microscopy. Therefore, the optical properties of the extracted CNPs reported in this study are favorable for optical bioimaging and biomedical applications. However, their toxicity and interaction with different types of cells need to be further investigated to ensure their potential biomedical applications.
