# System design of large-area vertical photothermoelectric detectors based on carbon nanotube forests with MXene electrodes†

Jiaqi Wang,<sup>ID</sup> Zhemiao Xie,<sup>ID</sup> Jiayu Alexander Liu, Rui Zhou, Guanxuan Lu and John T. W. Yeow<sup>ID</sup>\*

Photothermoelectric (PTE) detectors that combine photothermal and thermoelectric conversion have emerged in recent years. They can overcome bandgap limitations and achieve effective infrared detection. However, the development of PTE detectors and the related system design are in the early phases. Herein, we present vertical PTE detectors utilizing the active layer of carbon nanotube forests with MXenes acting as top electrodes. The detector demonstrates its capacity for sensitive infrared detection and rapid infrared response. We also investigated the relationship between photoresponse and different MXene electrode types as well as their thickness, which guides the PTE detector configuration design. Furthermore, we packed the PTE detectors with a polytetrafluoroethylene (PTFE, Teflon) cavity. The photoresponse is improved and the degradation is significantly delayed. We also applied this PTE detector system for non-destructive tracking (NDT) applications, where the photovoltage mapping pattern proves the viability of the imaging track. This work paves the way toward infrared energy harvesters and customized industrial NDT measurement.

## Introduction

With the development of artificial intelligence and interactive technology, smart sensors and the internet of things (IoT) entered the mainstream market because of their excellent chemical and physical properties.<sup>1–5</sup> Typically, infrared (IR)-based technology has attracted significant attention because the corresponding spectrum of matter (including transmission and reflection spectra) contains rich physical and chemical information.<sup>6</sup> As an emerging IR thermal detector, photothermoelectric (PTE) detectors combining photothermal and thermoelectric conversion can overcome bandgap limitations and achieve effective IR detection.<sup>7,8</sup> They can operate under ambient conditions without bias and show convenient and safe manufacturing processes.<sup>9</sup>

The research on PTE detectors composed of metal electrodes and active layers mostly focuses on several fixed structures utilizing various active materials. Previously, researchers have explored the traditional silicon-based nanowires that showed a relatively long response time and poor infrared absorption.<sup>10,11</sup> The PTE detectors based on multi-layer graphenes also show similar issues.<sup>12</sup> Additionally, the unstable ambient properties

of black phosphorus and the toxic Pb element of perovskites also limit extended research.<sup>13</sup> Polymer-based composites face the challenges of low infrared absorption and temperature endurance.<sup>14</sup> Since the discovery of MXenes by Yury Gogotsi in 2011,<sup>15</sup> extensive research about the related synthesis and applications has been demonstrated.<sup>16–19</sup> Typically, MXenes show typical optoelectrical properties because of their competitive photonic phenomenon and high carrier mobility<sup>20,21</sup> as well as the thermoelectric capacity of MXenes demonstrated by Kim *et al.*,<sup>22</sup> which can be utilized as advantageous active PTE materials or electrodes. As the most comprehensively studied PTE materials, types of CNTs show ordered growth control, facile synthesis methods, and excellent PTE properties.<sup>23–26</sup>

However, there are some other challenges with current PTE detectors. First, current vertical PTE detectors mainly use metals as top electrodes. However, the thickness of metal electrodes is generally smaller than 100 nm on account of the skin effect. Such low thicknesses of metal electrodes may significantly influence the conductivity. Additionally, the existence of top metal electrodes will reduce the infrared absorption.<sup>27</sup> Thus, the alternative electrode materials of vertical PTE detectors wait to be explored. Second, PTE detectors inside the vacuum environment have demonstrated enhanced PTE response.<sup>28</sup> The vacuum conditions may potentially reduce the degradation and increase the stability and durability of devices. However, current vacuum systems of PTE detectors depend on cumbersome vacuum chambers, and integrated vacuum PTE detectors are urgently required. Third, current PTE detectors based on low-

† Electronic supplementary information (ESI) available. See DOI: <https://doi.org/10.1039/d2na00895e>

dimensional materials such as CNTs, graphenes and black phosphorus are sensitive to light polarization.<sup>8,29,30</sup> Some of the PTE detectors that are insensitive to light polarization make use of random internal atom orders of the composite film.<sup>12,23,31</sup> However, it is challenging to control the size of the detectors and achieve sensor miniaturization, eventually hindering their future smart wearable integration.

To solve the abovementioned problems, we fabricated a self-powered sensitive PTE detector utilizing the vertical CNT forest (CNTF) as the active layer and MXenes as the top electrodes. To the best of our knowledge, this paper is the first to report on the non-metal electrodes applied in PTE detectors. In this work, we investigated the photoresponse using  $\text{Ti}_3\text{C}_2$  and  $\text{Mo}_2\text{C}$  top electrodes, respectively. The electrode thickness of top MXene electrodes was also studied. A thinner MXene electrode using the drop-cast method will match a better PTE response. The potential reasons may be the electromagnetic shielding effect with a thicker electrode. Thus, the control of reasonable electrode types and thickness may be important. We encapsulated the PTE detector with PTFE, suppressing the degradation and enhancing the PTE response. The packaged system was also applied to NDT imaging. A photovoltage imaging pattern is illustrated, which demonstrates the imaging capacity of PTE detectors.

## Methods

### Materials

The  $\text{Ti}_3\text{C}_2$  and  $\text{Mo}_2\text{C}$  powder were purchased from Nanochemazone. Dimethyl sulfoxide (DMSO) was purchased from the Sigma-Aldrich company. Deionized water was produced using the purifier system in Mike and Ophelia Lazaridis Quantum-Nano Centre.

### Device manufacture

**$\text{Ti}_3\text{C}_2$  solutions.** We adopted the solvent exchange method to obtain a uniform  $\text{Ti}_3\text{C}_2$  solution. First, 0.15 g of  $\text{Ti}_3\text{C}_2$  or  $\text{Mo}_2\text{C}$  powder was added into 6.0 mL DMSO solution, followed by 24 h magnetron stirring at 1500 rpm. Then, the solution was centrifuged at 5000 rpm for 5 min. The top clear solution was removed and replaced with DI water. This replacement process was repeated five times until the pH value of the  $\text{Ti}_3\text{C}_2$  solution reached about 7.0. The  $\text{Ti}_3\text{C}_2$  or  $\text{Mo}_2\text{C}$  solution was stored under nitrogen conditions.

**CNTF Fabrication.** First, a 4-inch Si prime wafer was prepared and cleaned by a RCA method. In each pixel area, a Cr buffer layer of 100.2 nm and a Ni catalyst layer of 19.7 nm were deposited by maskless lithography and the lift-off method in order. Next, the CNTF grows using PECVD with  $\text{C}_2\text{H}_2$  and  $\text{NH}_3$  in a 200:50 volume ratio at 700 °C and 100 W plasma for 15 min.

**Device manufacture.** First, 10  $\mu\text{L}$  MXene solution was dropped on the top of the CNTF and the detector was dried in the fume hood for 24 hours. Finally, conductive silver glue was used to connect the wires to the detector (5.0 mm  $\times$  5.0 mm). The device with a PTFE package was sealed using vacuum glue.

### Measurements

The  $I$ - $V$  curve was measured using a Keithley 6487 and a Keithley 6500. Resistance was measured using a Keithley 6500. The temperature was measured using an infrared thermometer. A JEOL SEM was used for film morphology characterization at a probe current of 12–15 nA and an accelerating voltage of 12–15 kV. A blackbody radiation source (Newport 67020) was used as the infrared source.

## Results and discussion

### Vertical detector structural design

The fabrication process of the Si-based vertical PTE detector is illustrated in Fig. 1. Fig. 1(a) shows the layer preparation for CNT growth, including the Si substrate, Cr buffer layer, and Ni catalyst layer. The metal Cr plays ternary roles in the PTE cooler, bottom electrode and a catalyst supporting layer, *i.e.* buffer layer, which can help prevent the diffusion of catalyst particles.<sup>32</sup> The metal Ni acts as the catalyst for CNT growth. The vertical channel of the CNTF was designed based on several factors. According to the internal polarization, the optical absorption of CNTs can be maximized or minimized at different wavelengths. The CNTs grown by CVD show high mobilities and the Seebeck coefficient of semiconducting CNTs can reach 300  $\mu\text{V K}^{-1}$ .<sup>33</sup> Moreover, the coulombic interaction and large binding energy of 1-D materials contribute to the potentially enhanced PTE response.<sup>34</sup> Additionally, the height of CNTs can be controlled similarly to the cooling length of PTE devices, which can maximize the device's performance (Fig. 1(b)). The MXenes were processed by the low-cost and facile solvent exchange method to exfoliate and delaminate, which can produce a better conductivity (Fig. 1(c)).<sup>35</sup> After the delamination, the drop-cast MXene electrode can be thinned down to about 0.9  $\mu\text{m}$ , as measured using a Bruker profilometer. The MXenes ( $\text{Ti}_3\text{C}_2$  or  $\text{Mo}_2\text{C}$ ) were drop-casted and dried as the top electrodes instead of traditional metal electrodes, and then the basic detector structure is illustrated in Fig. 1(d).

### Material characterization

Fig. 2(a)–(c) show the scanning electron microscopic (SEM) images of the  $\text{Ti}_3\text{C}_2$  electrode, and Fig. 2(d)–(f) show the SEM images of the  $\text{Mo}_2\text{C}$  electrode. MXenes usually present a crossed atomic structure, and their surfaces are usually modified by all types of terminations such as  $-\text{OH}$  and  $-\text{F}$ , which depends on the synthesis etching method. Both  $\text{Ti}_3\text{C}_2$  and  $\text{Mo}_2\text{C}$  show layered stacks and their films are relatively uniform. The thickness of the MXene electrode can be controlled by adjusting the solution concentration or volume. Specific PTE responses related to MXene types and electrodes will be listed in Section 2.4. We think the excellent conductivity of MXenes may contribute to the inherent excellent conductivity of the MXene flake and good contact among flakes. We used the tip-growth CNTF method by PECVD, the metal Ni remained in the tip parts, resulting in a hydrophobic top region<sup>36,37</sup> (Fig. 2(g)). Water molecules will evaporate and may not flow into the CNTF, so the alignment of CNTF may not change. This drop-cast method will

produce a random orientation distribution and a relatively rough MXene surface, which may potentially enhance infrared absorption (Fig. 2(h) and (i)).

#### Photoresponse mechanism and characterization

When the illumination irradiated on the top of the MXene electrodes, the infrared radiation was mainly absorbed by the

Fig. 2 Top view of  $\text{Ti}_3\text{C}_2$  with the scale bar of (a) 10  $\mu\text{m}$ , (b) 1  $\mu\text{m}$ , and (c) 100 nm. Top view of  $\text{Mo}_2\text{C}$  electrodes with (d) 10  $\mu\text{m}$ , (e) 1  $\mu\text{m}$ , and (f) 100 nm. (g) Side view of the CNTF. (h) Side view of the PTE detector with (i)  $\text{Ti}_3\text{C}_2$  electrodes and (i)  $\text{Mo}_2\text{C}$  electrodes.

top MXene electrode. The remaining parts may be absorbed by the CNTF. The top electrode of the n-type MXene was heated and acted as the heat source. A temperature difference was created through the vertical direction. The bottom Cr electrode acted as the heat sink. The n-type carriers (electrons) transported to the cold bottom Cr electrode and the p-type carriers (holes) transported from the bottom to the top heated electrode.

Then, we performed the optoelectrical measurements, and the experiment was performed under an 873 K blackbody radiation source. Both Fig. 3(a) and (b) show the linear  $I$ - $V$  curve and demonstrate an excellent ohmic contact among MXene electrodes and CNTF. Fig. 3(c) shows the reproducible curve of the response time. The fall/decay time of the  $\text{Ti}_3\text{C}_2$  or  $\text{Mo}_2\text{C}$  electrode is 2.4/2.3 s or 2.8/2.7 s, respectively. There are several reasons that  $\text{Ti}_3\text{C}_2$  exhibits a stronger response current and a faster response than  $\text{Mo}_2\text{C}$ . First,  $\text{Mo}_2\text{C}$  electrodes may show a stronger electromagnetic shielding effect with the increase in thickness. Second, the difference in MXene particle size may cause thermoelectric properties, leading to different PTE responses.<sup>38</sup>

Fig. S3† shows the responsivity of the PTE detector with different blackbody radiation temperatures. The responsivity can be expressed as  $R_v = \frac{V_{\text{ph}}}{P_{\text{in}}}$ , where  $V_{\text{ph}}$  means the photo-voltage and  $P_{\text{in}}$  means the incident power. Both PTE detectors

with 0.9  $\mu\text{m}$   $\text{Ti}_3\text{C}_2$  and 1.2  $\mu\text{m}$   $\text{Mo}_2\text{C}$  electrodes show a responsivity of over 3.5 V/W, which demonstrate excellent mid-IR (MIR) PTE conversion. Fig. 3(d) shows the detectivity of the PTE detector with different radiation temperatures. The detectivity can be expressed as  $D^* = \frac{\sqrt{R_v A_d}}{V_n}$ , where  $A_d$  is the effective

area. The noise of PTE detectors mainly comes from the Johnson-Nyquist noise that can be expressed as,  $V_n = \sqrt{4k_B T R}$ ,<sup>39</sup> where the Boltzmann constant is  $1.9 \times 10^{-23} \text{ J K}^{-1}$ ,  $T$  is the temperature and  $R$  is the device resistance. The trends of responsivity match with the responsivity. The detector indicates a maximum detectivity of  $2.2 \times 10^8$  Jones. The maximum detectivity of  $2.2 \times 10^8$  Jones locates the blackbody peak wavelength of 3.3  $\mu\text{m}$ . Generally, the thermoelectric properties of the materials do not change with the ambient radiation peak wavelength. Thus, the reason may be that both drop-cast MXene films show an internal infrared absorption at around 3.3  $\mu\text{m}$ . The competitive PTE response may have several reasons. First, the reduced CNT channel may approximate the cooling length of hot carriers, which mostly maximizes the performance. Second, the top MXene electrode may absorb most of the infrared radiation, which helps achieve rapid and effective PTE conversion. Compared with our previous work, although the traditional CNTF can absorb the infrared radiation almost completely, the heating process may occur in the whole CNTF

Fig. 3  $I$ - $V$  curve of PTE detectors with (a)  $\text{Ti}_3\text{C}_2$  electrode and (b)  $\text{Mo}_2\text{C}$  electrode. (c) Response time. (d) Detectivity correlated with the power intensity of blackbody radiation.

channel instead of the CNT tip region.<sup>27</sup> Third, without the introduction of polymers, the thermal loss may be reduced and the effective thermoelectric conversion may be increased.<sup>31</sup> Fourth, the CNTF grown by PECVD may be mainly composed of MWCNTs with a positive Seebeck coefficient of about 30  $\mu\text{V}$ .<sup>40</sup> The CNTF grown by low-pressure CVD may be mixed p-/n-type SWCNTs, which may significantly hinder the thermoelectric capacity and even reduce the PTE conversion efficiency.<sup>27</sup> Furthermore, with a larger gap among CNTs, the PECVD-grown CNTF can be easily quantified and designed as the typical number according to specific requirements.

### Top electrode influence

We also measure the influence of electrode thickness by adjusting the dropping volume of 25 mg  $\text{mL}^{-1}$  MXene solution. When the dropped solution volume is 10/20/30  $\mu\text{L}$ , the thickness of  $\text{Ti}_3\text{C}_2$  or  $\text{Mo}_2\text{C}$  film is 0.9/1.8/2.7  $\mu\text{m}$  or 1.2/2.4/3.6  $\mu\text{m}$ , respectively (Fig. 4). Such thin MXene thicknesses indicate the dense deposition and excellent dispersion of the MXene solution. With the 873 K blackbody radiation temperature, the photovoltage of both PTE detectors shows a decreasing trend with the increase in electrode thickness. We contribute the reasons to the PTE conversion limitations, which means the MXene electrode of typical thickness can achieve a photo-thermal conversion. Once the top electrode thickness exceeds the typical value, the MXene of extra thickness may act as a heat sink and significantly reduce the thermal energy utilization efficiency of the CNTF. MXene films have been investigated as electromagnetic radiation shielding. For the thick films, the MXene may act as the radiation shielding material and cannot achieve effective photothermal conversion. Thus, only the MXene with typical thickness can realize effective photothermal conversion. Once the top MXene electrode thickness exceeds the typical value, the MXene of extra thickness may act as a heat sink and significantly reduce the thermal energy utilization efficiency of the CNTF.

### PTE detector system and NDT imaging

Then, a NDT imaging test was performed using a measurement setup (Fig. 5(a)). The blackbody radiation passed through the MIR filter. The single-pixel packaged PTE detector was fixed in

a table. The MC-200 equipment will control the aluminum arrow object to move, where the step length is 500  $\mu\text{m}$ . Typically, the PTFE cavity is manufactured by fill-mode laser cutting. In an environment full of nitrogen gas, the PTE detector can be sealed in the PTFE cavity using vacuum glue. According to ref. 41 and 42, most of the MIR radiation can be transmitted through the PTFE materials, and thus, PTFE can act as an excellent packaging and MIR filter material for PTE detectors. Here, the accumulated height of the PTE detector can be calculated as  $525 \times (1 \pm 10\%) \mu\text{m}$  (Si substrate) + 100.2 nm (bottom Cr electrode) + 5  $\mu\text{m}$  (CNTF) + 1  $\mu\text{m}$  (top MXene electrode)  $\approx 530 \mu\text{m}$ . The cut depth of the PTFE cavity by laser is 1530  $\mu\text{m}$  (Fig. 5(b)). Then, we measured the PTE response of the packed detector using blackbody radiation under the same experimental conditions. The photovoltage was recorded, and finally, the photovoltage was patterned according to the relative intensity (Fig. 5(d)). This experiment demonstrates the capacity of NDT imaging. Furthermore, the resolution can be further optimized by reducing the single-pixel size of the PTE detector, and this design idea paves the way for packaging wearable sensors.

### Stability

Given the industrial and product application in the future, the long-term stability of the PTE detectors is also crucial. Thus, we tested the PTE detectors with  $\text{Ti}_3\text{C}_2$  and  $\text{Mo}_2\text{C}$  top electrodes under 873 K blackbody radiation (Fig. 6(a)). The PTE responses of both detectors show relatively high degradation. The may be because the surface terminations are oxidized and influence infrared absorption and conductivity.<sup>43</sup> The other reason may be that the contact resistance increases between MXenes and conductive silver glue because of the degradation of silver glue. The PTE responses of both detectors show relatively high degradation. The reason may be that the surface terminations are oxidized, which influences infrared absorption. Additionally, the device resistance increases and we attribute this to the increasing contact resistance between MXenes and conductive silver glue. Another reason may be that the conductivity of MXene decreases.<sup>43</sup> Then, we tested the PTE response of the encapsulated device with PTFE (Fig. 6(b)). In comparison, the degradation was significantly suppressed after 35 days. This

Fig. 6 Relationship between the time and the photovoltage of (a) Ti<sub>3</sub>C<sub>2</sub> and (b) Mo<sub>2</sub>C electrodes with or without PTFE packaging.

result indicates that the packaging will be further beneficial for large-scale industrial applications.

To assess our detector performance, we compared our detectors with other MIR detectors. Although our detectors do not show a superior response, they have shown a competitive advantage as self-powered detectors (Table. S1†). Optimizing the CNTF channel may potentially enhance the PTE response according to the thermal decay length theory.<sup>44</sup> Additionally, patterning the MXene top electrodes toward the metamaterials may be another optimization solution.

## Conclusions

In this work, we have fabricated a self-powered vertical PTE detector working in the MIR regime. This detector adopted CNTFs as the PTE channel as well as MXenes as the top electrode. We characterized the PTE response related to the two types of MXene electrodes and their electrode thickness. The MXene electrodes showed an excellent stable ohmic contact with the CNTF. With the blackbody temperature of 873 K, the detector demonstrated a detectivity of  $2.2 \times 10^8$  Jones.

Ultimately, we packed our PTE detector into a PTFE system and performed the NDT test, which indicated a response degradation delay and competitive imaging capacity.

Overall, this PTE detector integrated with a vertical CNTF channel and MXene electrodes achieves broadband infrared detection. Unlike the laser source, the blackbody radiation source will illuminate a relatively large range, which provides a higher response challenge for the device. Our scalable detector can accept large-area radiation because the top MXene electrodes will absorb the infrared radiation and convert it into thermal energy, forming a temperature difference along the long-axis direction of the CNT and inducing thermoelectric conversion. Compared with the PTE detector using an in-plane asymmetric structure or the p–n junction, this configuration makes use of steric space and provides opportunities for device miniaturization, where we only need to consider the in-plane absorber area. Additionally, the number and height of CNT can be accurately controlled and the device performance can be quantified. The one-dimensional (1-D) CNTF also paves the path to other 1-D materials such as the nanowire array. Furthermore, the CNTF or nanowire array can be patterned into a metamaterial structure and achieve in-plane and vertical PTE optimization. The self-powered packaged PTE detectors provide new insights for the industrial long-term monitoring system and daily smart wearable sensors. Typically, the front and back sides of the smartwatch can integrate the PTE detector and achieve an energy harvester of the human body and environmental thermal radiation.
