Phototransformations of $\text{TiO}_2/\text{Ag}_2\text{O}$ composites and their influence on photocatalytic water splitting accompanied by methanol photoreforming

Photocatalytic water splitting and photoreforming of methanol by a $\text{TiO}_2/\text{Ag}_2\text{O}$ system was explored. The lack of exchange of charge carriers between TiO_2 and Ag_2O and the fast phototransformation of Ag_2O into silver nanoparticles were evidenced. Silver oxide can be considered a beneficial precursor for *in situ* photocatalytic growth of silver nanoparticles, which boost the photoactivity of the system by acting as electron sinks for electrons photogenerated within TiO_2 .

Phototransformations of TiO₂/Ag₂O composites and their influence on photocatalytic water splitting accompanied by methanol photoreforming†

Anna Jakimińska,  Kaja Spilarewicz  and Wojciech Macyk *

This work aimed to revise the mechanism of photocatalytic activity of the TiO₂/Ag₂O system in photocatalytic water splitting accompanied by methanol photoreforming. The transformation of Ag₂O into silver nanoparticles (AgNPs) during photocatalytic water splitting/methanol photoreforming was monitored using XRD, XPS, SEM, UV-vis, and DRS techniques. The impact of AgNPs, grown on TiO₂, on its optoelectronic properties was analysed through *inter alia* spectroelectrochemical measurements. The photoreduced material exhibited a significantly shifted position of the TiO₂ conduction band edge. Surface photovoltage measurements revealed the lack of photoinduced exchange of electrons between TiO₂ and Ag₂O, indicating the absence of an efficient p–n junction. Furthermore, the impact of chemical and structural changes in the photocatalytic system on the production of CO and CO₂ from methanol photoreforming was analysed. It was found that fully formed AgNPs exhibit improved efficiency in the production of H₂, whereas the Ag₂O phototransformation, resulting in the growth of AgNPs, promotes simultaneously ongoing photoreforming of methanol.

Introduction

Nowadays, commercial hydrogen production is mostly limited to steam methane reforming of natural gas and electrolysis of water by well-established technologies, *i.e.*, alkaline, polymer electrolyte membrane, and solid oxide technologies.¹ Novel perspectives for industrial hydrogen production are focused on three main technologies: electrochemical water splitting, biological processes using biomass and processing of fossil resources.² Global trends toward sustainability set the direction to use renewable energy sources. In this case, photocatalytic water splitting and photoreforming of organics (*e.g.*, polyols and sugars) appear as especially valuable pathways due to the possibility of solar energy utilization. These processes are based on the abilities of semiconductors to convert quantum solar energy conversion and involve redox reactions utilizing separated charges.

The water splitting process produces H₂ and O₂ using highly energetic electrons (conduction band) and holes (valence band) originating from photoexcited semiconductors. Design of a photocatalytic system that is able to effectively perform this process is challenging due to the necessities of (i) achieving

adequate energy of the semiconductors' band edges, (ii) inhibiting the e⁻/h⁺ pair recombination, and (iii) hindering back-reactions.³ A commonly selected strategy to overcome the last two problems is the addition of easily oxidizable sacrificial agents, which replace the water molecules in reaction with photogenerated holes. Methanol exhibits the highest propensity among other additives to donate electrons to scavenge the holes and prevents photo-generated charge recombination.⁴ The efficiency of H₂ evolution exhibits a logarithmic growth with the increase in the amount of used alcohol.⁵ For processes where the amount of alcohol is significant, and the process is performed in anaerobic conditions, the term 'photoreforming' is advised.^{6,7} This is the consequence of the fact that H₂ in these processes can also originate from the transformation of alcohol molecules during photocatalysis.⁸

Titanium dioxide is considered a potentially universal material that photocatalyzes a wide range of processes, including H₂ production.⁹ However, this material is not free of limitations.¹⁰ For example, the energy required to excite this semiconductor is confined to UV light. Moreover, it is known that fast e⁻/h⁺ recombination is one of the main issues causing limited TiO₂ activity *inter alia* towards H₂ production in photocatalytic water splitting and photoreforming of organics.^{11,12} Therefore, a strong effort is being made to find effective strategies to overcome these problems. Meanwhile, Ag₂O is considered a potential p-type semiconductor in a p–n heterojunction with TiO₂ for harvesting solar light.^{13–18} It is believed that Ag₂O

† Electronic supplementary information (ESI) available. See DOI: <https://doi.org/10.1039/d2na00910b>

can sensitize titania due to its narrow band gap of 1.1–1.3 eV, which determines visible light absorption.¹⁹ However, it is known that Ag₂O suffers from low stability – it is photosensitive and prone to degradation.²⁰ For example, corrosion of Ag₂O particles during photocatalytic degradation of methyl orange was observed by Chen *et al.*²¹ Therefore, the efforts are directed towards the protection of Ag₂O by inhibition of Ag⁺ reduction. Some authors claim that the presence of Ag clusters and nanoparticles prevents Ag₂O from further photodecomposition since the metallic structures act as the electron sinks and collect the electrons that could otherwise reduce more Ag₂O.^{20,22} Another suggested approach to increase Ag₂O stability is the application of organic compounds for scavenging photo-generated holes more rapidly than lattice oxygen. At the same time, the photogenerated electrons should be transferred to other compounds (especially O₂) *via* initially formed Ag clusters preventing further reduction of Ag⁺.²³

It is also well known that the decoration of the photocatalyst's surface with noble metal nanoparticles enhances its activity. These nanoparticles show the ability to behave as electron traps, promote interfacial charge transfer and limit e⁻/h⁺ recombination. They are also applied to inhibit the back-reaction of hydrogen and oxygen formed in water splitting, which is usually the main reason for the low efficiency of this process.^{24,25} The probability of back-reactions at the catalyst's surface is enhanced, when both hydrogen and oxygen are produced at the active sites lying nearby. However, the use of noble metal nanoparticles as co-catalysts changes the adsorption properties and transfers the hydrogen evolution reaction from the semiconductor's surface to the surface of the nanoparticles.²⁶ In this way, the production of H₂ and O₂ is spatially separated. These aspects lead to the application of noble metal nanoparticles as an eagerly selected approach for increasing the efficiency of H₂ production, which is explored up-to-date. For example, Strapasson *et al.* demonstrated the significant enhancement of hydrogen evolution from photoreforming of methanol (from 1 μmol g⁻¹ h⁻¹ for bare TiO₂ up to 7 μmol g⁻¹ h⁻¹) with the increase of silver nanoparticle loading (1–5%).²⁷ Temerov *et al.* showed that TiO₂ in an inverse opal structure exhibits no activity in H₂ evolution in gas-phase water-splitting under visible light irradiation, but after modification with silver nanoparticles, it exhibits H₂ production up to 0.86 ppm min⁻¹.²⁸ Moreover, Gogoi *et al.* reported outstanding results in H₂ production from water splitting, achieving a rate of 23.5 μmol g⁻¹ h⁻¹ (with an apparent quantum yield of 19%), using TiO₂ decorated with silver nanoparticles with 1.5% nominal concentration.²⁹ Since the presence of metal nanoparticles reveals such a boost of activity and there is a possibility of Ag₂O phototransformation into silver nanoparticles (AgNPs), it should be examined which of these components is responsible for the enhanced photocatalytic performance of the TiO₂/Ag₂O system.

A few studies discuss the phototransformation of Ag₂O into AgNPs during photocatalytic processes. For example, Mandari *et al.* studied systems of TiO₂/Ag₂O in photocatalytic water-splitting/photoreforming (using glycerol in water) under simulated solar light irradiation, where Ag₂O was synthesized *in situ*

on TiO₂ particles in different amounts.³⁰ They proved the formation of AgNPs in the samples during photocatalytic tests and proposed multiple-step mechanisms of photocatalytic reactions. The initially fabricated p–n junction changes into a three-component system, where silver nanoparticles act as a bridge in the photoexcited electron transfer from Ag₂O to TiO₂ by forming a Schottky barrier between Ag and TiO₂. A similar role of AgNPs in such systems was also reported by Liu *et al.*³¹ On the contrary, Xue *et al.* proposed a different mechanism for a similar system studied in toluene oxidation.¹⁴ First, photoexcited electrons are transferred from TiO₂ to Ag₂O creating silver nanoparticles on its surface, and then AgNPs serve as the sinks for photoexcited electrons from both Ag₂O and TiO₂, and reduction sites. Analysis of these studies shows that the mechanism of photocatalytic performance of TiO₂/Ag₂O remains unclear.

In the present work, TiO₂ was combined with Ag₂O to reveal the mechanism of photocatalytic water splitting accompanied by methanol photoreforming, taking place at TiO₂/Ag₂O under simulated solar light and visible light irradiation. The role of silver oxide phototransformations and the growth of silver nanoparticles in both processes was established. This paper revises the mechanism of TiO₂/Ag₂O photocatalytic activity.

Experimental

Reagents

AgNO₃ (Merck, 99.8%), methanol (Sigma-Aldrich, for HPLC, >99.9%), anhydrous LiClO₄ (Sigma-Aldrich), acetonitrile ACN (Avantor, HPLC/MS grade), tetrabutylammonium perchlorate (TBAP) (Sigma-Aldrich), NaOH (Chempur, pure for analysis, 99.8%) and titanium(IV) dioxide P25 Aeroxide (P-25) (ACROS Organics, ≥99.5%) were used without further purification. Water was deionized using a Hydrolab deionizer HLP 10UV (0.05 μS, *t* = 20 °C).

Synthesis of Ag₂O and TiO₂/Ag₂O

In a typical synthesis of the Ag₂O material, 1 M solutions of AgNO₃ and NaOH were mixed in equal volumes in a beaker under vigorous stirring. The solution was stirred for 3 hours and then the brown precipitate was collected by centrifugation and washed with DI water several times. The obtained material was left for drying at 60 °C overnight to remove any residual silver hydroxide. To obtain TiO₂/Ag₂O, the Ag₂O material was mixed gently with P-25 in the w/w ratio of 1 : 9.

Characterization

X-ray diffractograms (XRD) were recorded using a Rigaku MiniFlex 600 diffractometer equipped with a Cu lamp (K_α radiation wavelength – 1.5406 Å) with a Ni K_β filter. The scan step was 2° (2θ), and the scan speed was 10° min⁻¹.

SEM analysis was performed at 30 kV using a Tescan Vega 3 microscope with a LaB₆ gun equipped with SE and BSE detectors. The size of particles visible in SEM images was determined by measuring the maximum Feret diameter (linear dimension)

of each particle in the images. The particle size distribution histogram was obtained from the measurements of 100 objects.

Diffuse reflectance spectra were collected using a Shimadzu UV-3600 UV-vis-NIR spectrophotometer equipped with a 15 cm diameter integrating sphere. BaSO₄ was used as a reference and samples were ground with BaSO₄ at a 1 : 10 w/w ratio. Obtained spectra were subsequently transformed using the Kubelka–Munk function and Tauc function to estimate absorption edges and band gap energies of examined materials.

UV-vis measurements were conducted using an HP8453 diode array spectrophotometer.

Surface photovoltage (SPV) measurements were performed on an Instytut Fotonowy environmental Kelvin probe equipped with a Xe lamp (Instytut Fotonowy, 150 W) and a monochromator. The contact potential difference (CPD in mV) was measured in the cycle: 50 times in the dark and the next 50 times under irradiation with a particular wavelength. The irradiation was established in the range of 500 to 240 nm with a 20 nm interval.

Spectroelectrochemical measurements (SE-DRS) were performed on a Shimadzu UV-3600 UV-vis-NIR DRS spectrophotometer equipped with a 15 cm integrating sphere. The electrochemical setup consisted of a three-electrode system. A Ag/Ag⁺ electrode (filled with 0.01 mol per dm³ AgNO₃ and 0.1 mol per dm³ tetrabutylammonium perchlorate in acetonitrile) was used as the reference electrode, a Pt wire as the counter electrode and Pt foil covered with a layer of the examined material as the working electrode. Tests were performed in 0.1 mol per dm³ LiClO₄ in acetonitrile as the electrolyte with argon purged through it during the measurements to remove the oxygen. The range of applied potential was from OCP to −2.7 V *versus* the reference electrode with a step of 0.05 V. The potential was applied using a BioLogic SP-150 potentiostat. For observation of changes in the spectrum of the material during reduction, the DRS spectrum of the working electrode covered with the material was taken after each potential was applied. The spectrum of the electrode before the potential application was used as the reference. Reflectance spectra obtained during measurements were transformed using the Kubelka–Munk function, and the difference in the value of this function for two subsequent potentials was used to estimate the density of electronic states in the material at the given wavelength. In this case, 780 nm was chosen due to the occurrence of maximum absorption of conduction band electrons in titania in this range. The photostability of the materials during the SE-DRS measurements was confirmed and has been described in the ESI (Fig. S1†).

Photocatalytic setup and TiO₂/Ag₂O_{hv} preparation

To perform photocatalytic tests, the tested materials were dispersed in 10 ml of water (obtaining 1 mg ml^{−1}) with the addition of 100 μl of methanol. The suspension was then deoxygenated by purging Ar for 20 min. The used light source was a Xe lamp (Instytut Fotonowy, 150 W) with an air mass filter (AM 1.5G) or a cut-off filter of 420 nm. During the irradiation, the reaction mixture was continuously stirred using a magnetic stirrer. The amounts of hydrogen, carbon monoxide and carbon

dioxide, which have been evolving to the gaseous phase, were measured by gas chromatography (GC) (Thermo Scientific, Trace 1300). To prepare TiO₂/Ag₂O_{hv}, the mixture was irradiated for 30 s or 2 h with the air mass filter (AM 1.5G) and then separated and washed several times with water for further use. If not denoted otherwise TiO₂/Ag₂O_{hv} means the composite after 2 h of irradiation.

Results and discussion

Silver oxide was selected as the precursor for modification of the TiO₂ (P25) surface with silver nanoparticles due to its simple chemical composition and low solubility in water (0.0225 g ml^{−1} at 25 °C).³² It may act as a silver source under photoreduction conditions. The simple precipitation method in the absence of organic compounds was applied to obtain bare Ag₂O. Subsequently, it was mixed with TiO₂ and studied in water-splitting/photoreforming.

XRD

The precipitation method leads to Ag₂O in the form of a dark-brown powder. The crystal structure of as-prepared Ag₂O was confirmed using the XRD method (Fig. 1). The XRD pattern of Ag₂O exhibits peaks characteristic of the cubic phase at 26.9°, 32.9°, 38.2°, 55.2°, 65.7°, and 69.2°, corresponding to (100), (111), (200), (220), (311), (222) crystal planes, respectively (JCPDS #41-1104). In addition, Fig. 1 and 2 show XRD patterns of P25, Ag₂O and their mixture before and after irradiation. In the XRD pattern of TiO₂/Ag₂O before irradiation, only two characteristic peaks of Ag₂O are present at 32.9° and 65.7° corresponding to the (111) and (311) planes, respectively. The other peaks of Ag₂O are covered with TiO₂ peaks.^{33,34} These two peaks vanish after 30 s irradiation of the H₂O/MeOH suspension with simulated solar light. However, after 2 h of irradiation two new peaks emerge at 44.2° and 64.4° which are attributed to the (200) and (220) planes of the Ag⁰ cubic phase, respectively (JCPDS #04-0783). Similar results were observed by Wang *et al.*²³ During irradiation with visible light, they observed an increase

Fig. 1 X-ray diffractograms of the TiO₂/Ag₂O composite: as-prepared and modified under irradiation. Raw components (P25 and as-synthesized Ag₂O) are shown for reference.

Fig. 2 Selected areas of X-ray diffractograms exposing changes induced by irradiation (XBO lamp, AM 1.5G filter).

in the intensity of the XRD peak around 44° , which was attributed to the (200) plane of metallic Ag. Moreover, analysis of the spectrum area between 37° and 39° provides additional information confirming the presence of metallic silver in the system after prolonged irradiation. In the as-prepared mixture of P25 with Ag_2O , the peaks at 37.8° and 38.2° (Fig. 2) originating from the (004) plane of the anatase phase³⁴ and the (200) plane of Ag_2O ,³⁵ respectively, overlap. After 30 s of irradiation, the peak of Ag_2O disappears, while after prolonged irradiation (2 h) near the peak of the anatase (37.8°) a new one at 38.1° appears, indicating the formation of metallic silver (plane (111)).³⁶

XPS

The XPS measurements were used to further confirm the Ag oxidation states in the studied materials. Fig. 3 presents XPS deconvoluted spectra of the Ag 3d line ($3d_{5/2}$ and $3d_{3/2}$ doublet) for $\text{TiO}_2/\text{Ag}_2\text{O}$, $\text{TiO}_2/\text{Ag}_2\text{O}_{hv,30s}$ and $\text{TiO}_2/\text{Ag}_2\text{O}_{hv,2h}$, revealing the diminution in the Ag^{I} contribution with the irradiation prolongation. The binding energy of Ag $3d_{5/2}$ shifted from 368.6 to 368.3 eV; these energies can be assigned to Ag^{I} and Ag^{0} , respectively.³⁷ Therefore, it is clear that Ag_2O turns to metallic silver, which is the evidence of its phototransformation. After 2 h of irradiation, the signal from Ag^{I} is negligible, as its intensity does not exceed the noise level. This also supports the fact that the secondary oxidation of Ag nanoparticles is inhibited due to the highly reductive reaction environment (H_2 release in an inert atmosphere).

SEM

SEM analysis using SE imaging reveals changes in the morphology of the photocatalyst induced by irradiation. Bare Ag_2O , presented in Fig. 4a, exhibits rounded particles (approximately 200–500 nm in size) gathered in large aggregates exceeding 1 μm in size. Fig. 4b shows Ag_2O mixed with P25 and reveals two distinct phases. The agglomerates of P25 with an average size of 25 nm are noticeably separated from Ag_2O aggregates. After 30 s of irradiation, only the characteristic

Fig. 3 XPS spectra (Ag 3d line) of $\text{TiO}_2/\text{Ag}_2\text{O}$, $\text{TiO}_2/\text{Ag}_2\text{O}_{hv,30s}$ and $\text{TiO}_2/\text{Ag}_2\text{O}_{hv,2h}$ composites.

structure of P25 is visible, whereas aggregates of Ag_2O disappear (Fig. 4c). It corroborates with XRD analysis pointing at Ag_2O transformation into metallic silver, which forms clusters observed as brighter spots. Therefore, silver clusters and methanol are found not to prevent Ag_2O photoreduction. After prolonged irradiation, the structure of the photocatalyst became uniform (Fig. 4d). To prove the photocatalytic transformation of Ag_2O into metallic silver, BSE imaging was applied. Fig. 5 presents the same area imaged using SE and BSE detectors. The emerging white objects in the image area are quasi-spherical nanoparticles in the size range of 20–200 nm and the average nanoparticle size is 30 ± 11 nm. As observed, silver nanoparticles are uniformly distributed in the whole volume of the photocatalyst.

Fig. 5 SEM image of the selected area of the TiO₂/Ag₂O_{hν}2h composite recorded with SE (left) and BSE (middle) detectors along with the particle size distribution (right).

DRS UV-vis

The DRS UV-vis spectrum of non-irradiated TiO₂/Ag₂O exhibits features characteristic of bare P25 and Ag₂O (Fig. 6). The absorption edge after materials mixing follows the edge of bare P25. However, the absorption in the whole range of visible light increases which is consistent with the absorption of bare, brown Ag₂O.³⁸ After irradiation for 30 s (TiO₂/Ag₂O_{hν}30s), a significant hypsochromic shift in the absorption edge can be observed and the material turns dark violet, indicating the nucleation of metallic silver and growth of metallic clusters.^{39,40} This is an intermediate step in the growth of silver nanostructures. Prolonged irradiation (TiO₂/Ag₂O_{hν}2h) leads to a change in the material colour to red ochre and the formation of the absorption band with a maximum of ca. 430 nm on the DRS spectrum, whereas the absorption edge remains the same as for the material irradiated for 30 s. These results further confirm the growth of metallic clusters during irradiation and

Fig. 6 DRS spectra of examined materials: Kubelka–Munk function (upper picture) and Tauc transformation (lower picture). The inset shows the magnification in the range of the SPR band of silver nanoparticles.

the formation of silver nanoparticles.^{35,41} The band between 350 and 550 nm can be attributed to the surface plasmon resonance (SPR) of these nanoparticles.^{31,35}

UV-vis

UV-vis absorption spectra of the aqueous suspension of Ag₂O before and after irradiation were collected to complete the spectral analysis of this material (Fig. 7). Similar to DRS measurements, the absorption in the whole range of visible light is noticeable. Moreover, two peaks at 210 and 225 nm are present. After irradiation of bare Ag₂O, the broad peak with a maximum of around 430 nm appears, confirming the

Fig. 7 UV-vis absorption spectra of bare Ag₂O before and after irradiation (2 h).

formation of Ag nanoparticles. This process can be facilitated by P25. To reveal the progress of Ag nanoparticle growth in TiO₂/Ag₂O, UV-vis spectra were recorded before and after selected irradiation times (Fig. 8). As depicted in Fig. 8, the absorption edge of as-prepared TiO₂/Ag₂O is the same as for P25. This observation is consistent with DRS measurements. Moreover, the peaks at 210 and 225 nm characteristic of bare Ag₂O are also present. During irradiation, these peaks disappear already after 30 s, and the SPR peak around 420 nm arises (after 5 min). Then it shifts bathochromically and separates from TiO₂ absorption after 2 h, indicating a continuous growth of silver nanoparticles which is completed after 2 h (Fig. 8 and S2†).

SE-DRS

Spectroelectrochemical measurements (SE-DRS) indicate that the conduction band edge of the bare P25 material lies around -0.8 V vs. Ag/Ag⁺ electrode which equals -0.5 V vs. SHE (Fig. 9). It is consistent with the data presented in the literature.^{42,43} In comparison, for the TiO₂/Ag₂O material, increased density of states around the conduction band edge of P25 can be observed. As this range corresponds to the surface states of titania, this result reveals that in the as-prepared TiO₂/Ag₂O material (*i.e.*, directly after mixing P25 with Ag₂O), the new states are created. However, after material phototransformation, a significant shift in the state distribution towards lower potentials (higher energy) can be observed. It points to the possible enhanced reducing ability of the material after the phototransformation. Furthermore, no significant amount of additional isolated

Fig. 8 UV-vis spectra of the TiO₂/Ag₂O composite and its components (upper picture); UV-vis spectra recorded at decisive time intervals of TiO₂/Ag₂O irradiation (lower picture).

Fig. 9 SE-DRS results revealing conduction band edge positions of examined materials.

states within the bandgap, originating from the silver nanoparticles present in the TiO₂/Ag₂O_{hν,2h} material, is created. On this basis, it can be concluded that states near the conduction band edge, often attributed to the surface states and defects, are consumed during nanoparticle growth. This observation reveals the role of these states as nucleation centres for AgNPs. Therefore, upon phototransformation of TiO₂/Ag₂O, the material gains better performance in reduction processes.

SPV

Surface photovoltage measurements (SPV) were performed to elucidate the fate of charges photogenerated within the material. The studies were conducted using tablets made of bare and layered materials to reveal the direction of the charge transfer. The photoresponse of examined materials results in a change of the CPD during irradiation. Fig. 10 shows normalized SPV measurements for pristine TiO₂, Ag₂O and layered materials – Ag₂O on the top of TiO₂ and TiO₂ on the top of Ag₂O (Scheme 1). Ag₂O exhibits features of a p-type semiconductor (Δ CPD < 0), whereas TiO₂ is an n-type semiconductor (Δ CPD > 0). The range of photoactivity of both materials differs significantly. TiO₂

Fig. 10 SPV for TiO₂, Ag₂O and layered systems: TiO₂ on top of Ag₂O and vice versa.

Scheme 1 Visualization of photogenerated charge transfer in SPV measurements for TiO_2 (a), Ag_2O (b), Ag_2O on the top of TiO_2 (c) and TiO_2 on the top of Ag_2O (d).

shows photoresponse in the range of 400 to 280 nm, while the photoresponse of Ag_2O is pronounced in the whole range of incident light (500–280 nm), and $|\Delta\text{CPD}|$ decreases with the increase of the photon energy. This indicates that charges are photogenerated in Ag_2O upon irradiation with both UV and visible light. These observations are consistent with the spectral features of the materials. In comparison to TiO_2 , $|\Delta\text{CPD}|$ for Ag_2O is in general higher, which points to a better separation of the photogenerated charges in this material. However, after the deposition of both materials, the impact of TiO_2 prevails over Ag_2O . For TiO_2 covering Ag_2O , the sign of ΔCPD changes when the irradiation wavelength crosses 400 nm, which is specific to the TiO_2 absorption edge. In comparison, when Ag_2O is applied on top of TiO_2 , the effect is similar but more discrete. In this case, the switch appears at 340 nm. These observations show that effective ΔCPD results from the features of both components, however, the features of the top material prevail, as it is better exposed to light. The top material acts at the same time as an optical filter governing the light absorption by the bottom layer. An effective junction, which would enhance charge separation, could be identified by the $|\Delta\text{CPD}|$ increase. Our results do not confirm the formation of any junction facilitating a charge transfer between both components. To verify the effect of created AgNPs on charge transfer, SPV measurements were conducted for layered materials: Ag_2O on the top of TiO_2 with the surface decorated with AgNPs and Ag_2O_{hv} on top of TiO_2 (Fig. S3†). These systems reveal the same trends as Ag_2O on top of TiO_2 , proving that AgNPs do not act as charge transfer mediators between TiO_2 and Ag_2O .

The photoresponse of the $\text{TiO}_2/\text{Ag}_2\text{O}$ system changes dramatically after phototransformation. Fig. 11 depicts SPV measurements of $\text{TiO}_2/\text{Ag}_2\text{O}_{hv,30s}$ and $\text{TiO}_2/\text{Ag}_2\text{O}_{hv,2h}$ compared with those of bare TiO_2 . Both materials consisting of Ag clusters exhibit photoinduced charge separation under irradiation in the range of ca. 380–280 nm.⁴⁴ Compared to bare TiO_2 , modification with small Ag clusters ($\text{TiO}_2/\text{Ag}_2\text{O}_{hv,30s}$) results in a decrease in ΔCPD under irradiation with wavelengths longer than 340 nm. For $\text{TiO}_2/\text{Ag}_2\text{O}_{hv,2h}$ a similar effect is observed, but this material exhibits a better charge separation in the range of

Fig. 11 SPV measurements for TiO_2 (black line), $\text{TiO}_2/\text{Ag}_2\text{O}_{hv,30s}$ (violet line) and $\text{TiO}_2/\text{Ag}_2\text{O}_{hv,2h}$ (orange line).

340–300 nm compared to bare TiO_2 . The photoresponse of bare TiO_2 in the range of ca. 440–380 nm can be attributed to the excitation involving surface states and defects (within the Urbach tail), whereas for modified materials, in which these states serve as the nucleation centres, the excitation in this range does not occur. Nevertheless, irradiation within the SPR band of Ag (600–400 nm), does not lead to charge separation. The ΔCPD signal is enhanced for the $\text{TiO}_2/\text{Ag}_2\text{O}_{hv,2h}$ sample, indicating that larger Ag nanoparticles act effectively as electron sinks for e_{CB}^- from TiO_2 . Therefore, decoration with nanoparticles enhances photoresponse in the UV range and leads to better charge separation in the 340–300 nm range. This effect is not valid for visible light irradiation.

Photoactivity

The photocatalytic activity has been tested in hydrogen production during water-splitting accompanied by methanol photoreforming. Two aspects were taken into account: (i) the progress of Ag_2O transformation and (ii) the amount of released H_2 , CO , and CO_2 , of which the last two originate from the oxidation of methanol. Therefore, TiO_2 , Ag_2O , $\text{TiO}_2/\text{Ag}_2\text{O}$ and $\text{TiO}_2/\text{Ag}_2\text{O}_{hv,2h}$ (with complete transformation to silver nanoparticles) were selected to establish the factors determining the enhancement of the photoactivity under simulated solar (AM 1.5G) and visible ($\lambda > 420$ nm) light irradiation. Fig. 12 presents the photocatalytic performance of the studied materials. It was found that under simulated solar irradiation bare Ag_2O is almost inactive (Fig. S4†). Instead, other samples exhibit H_2 , CO and CO_2 release, which confirms the progress of water splitting and photoreforming of methanol. The activity of TiO_2 (anatase/rutile mixed phases) in H_2 production is well known, therefore, P25 was selected as a reference for establishing the impact of the surface modifications.⁴⁵ Silver oxide enhances the activity of titanium dioxide after phototransformation due to the formation of silver nanoparticles. It can be seen that $\text{TiO}_2/\text{Ag}_2\text{O}_{hv}$ exhibits the highest H_2 evolution rate. It can be attributed to the conduction band edge shift (as confirmed by SE-DRS

Fig. 12 Evolution of products of water splitting and methanol photoreforming under simulated solar light irradiation (AM 1.5G).

measurements), which is the result of a completed process of Ag nanoparticle growth. As confirmed by SPV measurements, silver nanoparticles acting as electron sinks introduce active sites for hydrogen evolution. The amounts of released CO and CO₂ are lower for the TiO₂/Ag₂O_{hv} composite compared to those of bare TiO₂, which indicates the enhancement of water-splitting performance compared to the photoreforming of methanol. It is worth mentioning that H₂ can be a product of water-splitting as well as photoreforming processes, but CO and CO₂ can only originate from methanol oxidation.

Photogenerated electrons can be used not only for hydrogen generation but also for Ag⁺ reduction. TiO₂/Ag₂O exhibits slightly lower activity in H₂ evolution than TiO₂/Ag₂O_{hv}, which is the effect of competition between the mentioned reduction reactions. This difference in the photoactivity of decorated materials originates also from the worse charge separation for TiO₂/Ag₂O, as confirmed by SPV measurements. The growth of silver nanoparticles can also be enhanced by the consumption of a part of produced H₂ in the chemical reduction of Ag₂O. Schimo *et al.* performed thorough studies on the effects of the exposure of variously shaped and sized

Ag₂O particles to gaseous H₂. It turned out that such exposure led to the reshaping and shrinkage of the particles due to their reduction and formation of metallic silver.⁴⁶ However, TiO₂/Ag₂O is still more active than bare TiO₂, since growing silver nanoparticles act as electron sinks. The reducing ability of this material evolves in time. It is worth noting that for TiO₂/Ag₂O the highest amounts of released CO and CO₂ were observed. Interestingly, their evolution rates decrease over time, simultaneously with AgNP formation. Since the H₂ production in the presence of TiO₂/Ag₂O is more efficient than that at bare TiO₂, we postulate that oxygen originating from Ag₂O decomposition is not transformed into O₂ (its reduction would compete with hydrogen evolution⁴⁷), but may participate in methanol oxidation.

The activity of Ag₂O, TiO₂, TiO₂/Ag₂O and TiO₂/Ag₂O_{hv} was also verified under visible light irradiation ($\lambda > 420$ nm). It was found that after 6 h of irradiation the amounts of products were very low, therefore prolonged irradiation (20 and 24 h) was applied. The as-prepared TiO₂/Ag₂O material shows slight evolution of H₂ (480 and 870 ppm, respectively). It is worth noting that bare component materials and TiO₂/Ag₂O_{hv} remained inactive under the same conditions. Varapragasam *et al.* also reported the lack of activity of the TiO₂ photocatalyst decorated with Ag nanoparticles under visible light irradiation despite the SPR band.⁴⁸ Moreover, despite the strong photoresponse of Ag₂O under visible light confirmed by SPV measurements, this material is not photocatalytically active in hydrogen evolution. Thus, the activity of TiO₂/Ag₂O originates neither from Ag₂O nor AgNP excitation. However, SPV measurements reveal weak photoresponse in the range of 420–460 nm for bare P25. SE-DRS data indicate that in the case of TiO₂/Ag₂O there is a higher density of electronic states close to the conduction band edge. These states, populated upon material excitation with visible light, can be responsible for silver reduction reactions. In the case of TiO₂/Ag₂O_{hv}, where AgNPs have already grown, a lack of activity under visible light irradiation is observed due to the altered position of the CB edge (Fig. 8). These results indicate that visible light plays only a marginal role in photocatalytic processes and is limited only to TiO₂/Ag₂O. Therefore, under solar light irradiation, UV light is responsible for hydrogen evolution.

In our studies, the UV-vis measurements (Fig. 6 and 7) prove the formation of AgNPs both on bare Ag₂O and TiO₂/Ag₂O under solar light irradiation. Inefficient Ag₂O excitation (mainly by visible light) is possible and can lead to Ag⁺ reduction accompanied by Ag₂O decomposition (Scheme 2). It seems that both semiconductors operate separately under simulated solar light irradiation because there is no evidence for the transfer of photogenerated charge between them, as confirmed by SPV measurements. TiO₂ is excited by the UV component of the solar spectrum – photogenerated electrons from the CB participate in the reduction of H⁺ and Ag⁺, while photogenerated holes take part in the oxidation of water, methanol and intermediates. The formation of AgNPs enhances Ag₂O dissolution, observed as a rapid disappearance of Ag₂O particles (compare Fig. 3). Therefore, the photocatalytic performance of Ag₂O is observed only at the beginning of irradiation, as TiO₂/Ag₂O rapidly changes into TiO₂ decorated with AgNPs. Noteworthy, the

Scheme 2 Proposed mechanism of photocatalytic activity of the $\text{TiO}_2/\text{Ag}_2\text{O}$ system in water-splitting/methanol photoreforming under solar light irradiation.

photogenerated charges are not transferred between Ag_2O and TiO_2 , even when AgNPs are formed. Nanoparticles can boost photoactivity only by acting as electron sinks for electrons photogenerated within TiO_2 . The mechanism of photocatalytic activity of the $\text{TiO}_2/\text{Ag}_2\text{O}$ system is summarized in Scheme 2.

Conclusions

The $\text{TiO}_2/\text{Ag}_2\text{O}$ system was examined in water splitting/methanol photoreforming processes to establish the mechanism of its photocatalytic activity. It turned out that the p-n junction is not created, as confirmed by the surface photovoltage measurements. Moreover, it was found that upon irradiation with simulated solar light, Ag_2O in such systems turns into metallic silver in the form of plasmonic nanostructures as confirmed by UV-vis and UV-vis-DRS spectroscopy, X-ray diffractometry, and scanning electron microscopy. The obtained results indicate that the growth of silver clusters does not increase the stability of Ag_2O in the presence of TiO_2 . The presence of the formed plasmonic metallic nanostructures is also not responsible for the enhanced composite activity upon visible light irradiation. This is partially due to the significant change in the state distribution and conduction band shift caused by the growth of nanostructures, which was measured using the spectroelectrochemical method. Moreover, the lack of photo-response of the material decorated with nanostructures in the range of the Ag SPR band is observed in the SPV measurements and is pronounced also in the lack of material activity in this range. Nevertheless, it is confirmed that under solar light irradiation, the nanostructures act as electron sinks which is beneficial for photocatalytic activity. The phototransformation of Ag_2O in the presence of TiO_2 accompanies the H_2 evolution, increasing the activity in comparison to that of bare TiO_2 . After the complete formation of AgNPs, due to the CB edge shift towards lower potentials, the reduction processes (*inter alia* reduction of water) are more plausible. Therefore, it can be stated that during phototransformation, $\text{TiO}_2/\text{Ag}_2\text{O}$ gains better photocatalytic activity in reduction processes which is correlated with its new intrinsic properties, but not with the formation of the junction or enhancement of activity by the SPR effect. These findings are in contrast to the previous reports.^{13–18,30}

The application of Ag_2O can rather be considered a beneficial precursor for *in situ* AgNP growth. This approach enables AgNP formation without contamination of the environment with organic or inorganic residues. When this process is

performed in the presence of methanol, photocatalytic water splitting/methanol photoreforming occur simultaneously. Therefore, this method can also be perceived as process optimization, which enables the modification of TiO_2 and H_2 production in a one-pot procedure at the same time. This approach eliminates the one time-consuming preparation step, and thus it can be useful in the design of a novel technology.
