Photochemical halogen-bonding assisted generation of vinyl and sulfur-centered radicals: stereoselective catalyst-free C(sp²)-S bond forming reactions†

Helena F. Piedra and Manuel Plaza *

The combination of photochemistry and halogen bonding interactions has risen in the last few years as a powerful synthetic tool for the creation of radical intermediates under mild conditions. In the formation of carbon-centered radicals, this reactivity has been to date restricted to the employment of aryl and alkyl halides as precursors. We now envisioned that the halogen-bonding initiated formation of highly reactive vinyl radicals would be a feasible process for the photochemical cross-coupling between thiols and alkenyl halides under basic conditions. The reaction shows indeed a very broad functional group tolerance, is stereoselective, simple and scalable. In-depth mechanistic studies point at the formation of vinyl and sulfur-centered radicals as the intermediates of the reaction and DFT calculations support the pre-formation of a halogen-bonding complex as the initiator of the photochemical transformation. Synthetic applications were developed to extend the utility of this methodology.

1 Introduction

The development of new methodologies for the construction of C(sp²)-S bonds is an important task in organic chemistry.¹ In particular, the synthesis of vinyl sulfides is particularly appealing due to their presence in biologically active molecules² and building blocks in organic synthesis.³ Classical thermal approaches for the preparation of these compounds typically implicate the use of either an alkenyl halide or an alkyne and a sulfur precursor (commonly, a thiol or a disulfide species) as the partner reagents for the synthesis of the desired cross-coupling products (Scheme 1a).⁴ However, the unavoidable, mandatory employment of metal catalysts, strong oxidants, harsh conditions or starting materials that are difficult to synthesize hampers the sustainability and simplicity of these methodologies. Therefore, the exploration of more environmentally benign, greener strategies that would forge vinyl sulfides in a modular way starting from easily accessible precursors and under operationally simple reaction conditions stands as a big challenge for the field.

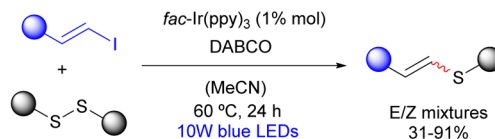

In the last few years, photochemical approaches for the construction of C-C and C-heteroatom bonds have risen as powerful synthetic tools in the context of green and sustainable chemistry.⁵ In this context, the exploitation of radical chemistry

strategies stands as an alternative to classical methodologies thanks to the intrinsic reactivity of these highly reactive open-shell intermediates, which has revolutionized the way chemists embrace nowadays the retrosynthetic analysis of

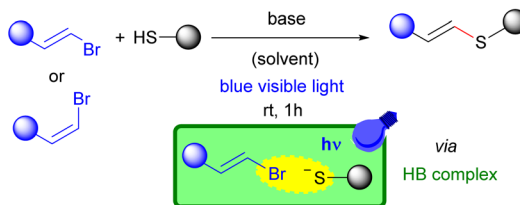

a) Thermal metal-catalyzed cross-coupling reaction between alkenyl halides and thiols

b) Previous work: photocatalytic generation of vinyl radicals in the cross-coupling between alkenyl iodides and dialkyl disulfides

c) This work: photochemical halogen-bonding assisted and catalyst-free cross-coupling of vinyl halides and thiols

molecules.⁶ In particular, photochemical reactions destined to the preparation of sulfur-containing molecules have recently received a lot of attention.⁷ In this context, König and Ananikov reported recently the synthesis of vinyl thioethers starting from alkynes and thiols through an elegant metal-free photocatalytic transformation.⁸ However, to the best of our knowledge, to date only one example has been reported for the photochemical construction of the previous molecules starting from alkenyl halides (Scheme 1b).⁹ This transformation, although promoted by visible light, requires long heating times (24 hours) and the employment of an expensive iridium-based photocatalyst and DABCO as a sacrificial donor to regenerate the photoredox catalytic cycle. A major drawback associated with this reaction is the lack of stereocontrol in the formation of the final disubstituted olefins, where the observed *E/Z* diastereomeric ratios seem to depend exclusively on the nature of each particular substrate.

Despite its apparent simplicity, the direct generation of vinyl radicals from alkenyl halides under visible-light photocatalytic processes stands as a very challenging approach. Indeed, direct irradiation of a solution of an alkenyl halide with high-energy γ -rays^{10a} or a laser pulse of low frequency UV light^{10b} (266 nm) is known to cause a scission of the C(sp²)-Br bond, generating the corresponding carbon centered vinyl radical or cation species respectively. Rather than direct irradiation, photochemical approaches for the creation of vinyl radicals normally rely on a SET or energy transfer event from a photocatalyst.¹¹ However, the high reduction potentials associated with the alkenyl halides, as well as the high instability of the vinyl radicals, are additional challenges that make the photocatalytic generation of vinyl radicals from the corresponding alkenyl halides a rather difficult strategy. Taking all of this into consideration, it is not surprising that the creation of these highly reactive vinyl radicals through photochemical transformations only promoted by visible-light irradiation in the absence of a photocatalyst starting from the corresponding alkenyl halides is still not reported.

Common activation modes in supramolecular photochemistry through the formation of aggregates *via* non-covalent interactions typically implicate the formation of electron donor-acceptor (EDA) complexes,¹² H-bonds,¹³ π -effects¹⁴ or ionic interactions.¹⁵ This synergistic prearrangement between the photosubstrate and an appropriate host molecule allows photochemical reactions to be carried out with an exquisite control in the reactivity and stereoselectivity towards the formation of the desired target molecules. Interestingly, in the last few years, a type of n - σ interactions known as halogen-bonding interactions¹⁶ has been exploited in photochemical processes for the generation of alkyl¹⁷ and aryl¹⁸ (or heteroaryl) carbon-centered radicals. These transformations consist of the formation of a halogen-bonding complex due to the interaction between an acceptor molecule that presents a halogen atom with a σ -orbital hole and a donor nucleophilic species. This complex can potentially be excited upon visible light irradiation and a photoinduced electron transfer (PET) is responsible for the generation of a radical ion pair, which after fragmentation creates two different radical species arising from each of the starting molecules. Different strategies and reactivities have

been exploited thanks to this kind of supramolecular interactions in the context of photochemistry.^{17,18} In light of all of the above, we wondered whether the employment of alkenyl halides as acceptor molecules in the reaction with nucleophilic thiolate species could potentially form a halogen-bonding complex. Direct irradiation at a suitable wavelength would potentially end up in the formation of highly reactive vinyl and sulfur-centered radicals, whose rapid recombination would forge the corresponding vinyl sulfide compound in a simple and elegant manner (Scheme 1c).

2 Results and discussion

Motivated by our initial hypothesis, we started to run a set of reactions in order to find optimal conditions for the photochemical halogen-bonding assisted cross-coupling between the alkenyl bromide **1a** and the thiol **2a** (Table 1).

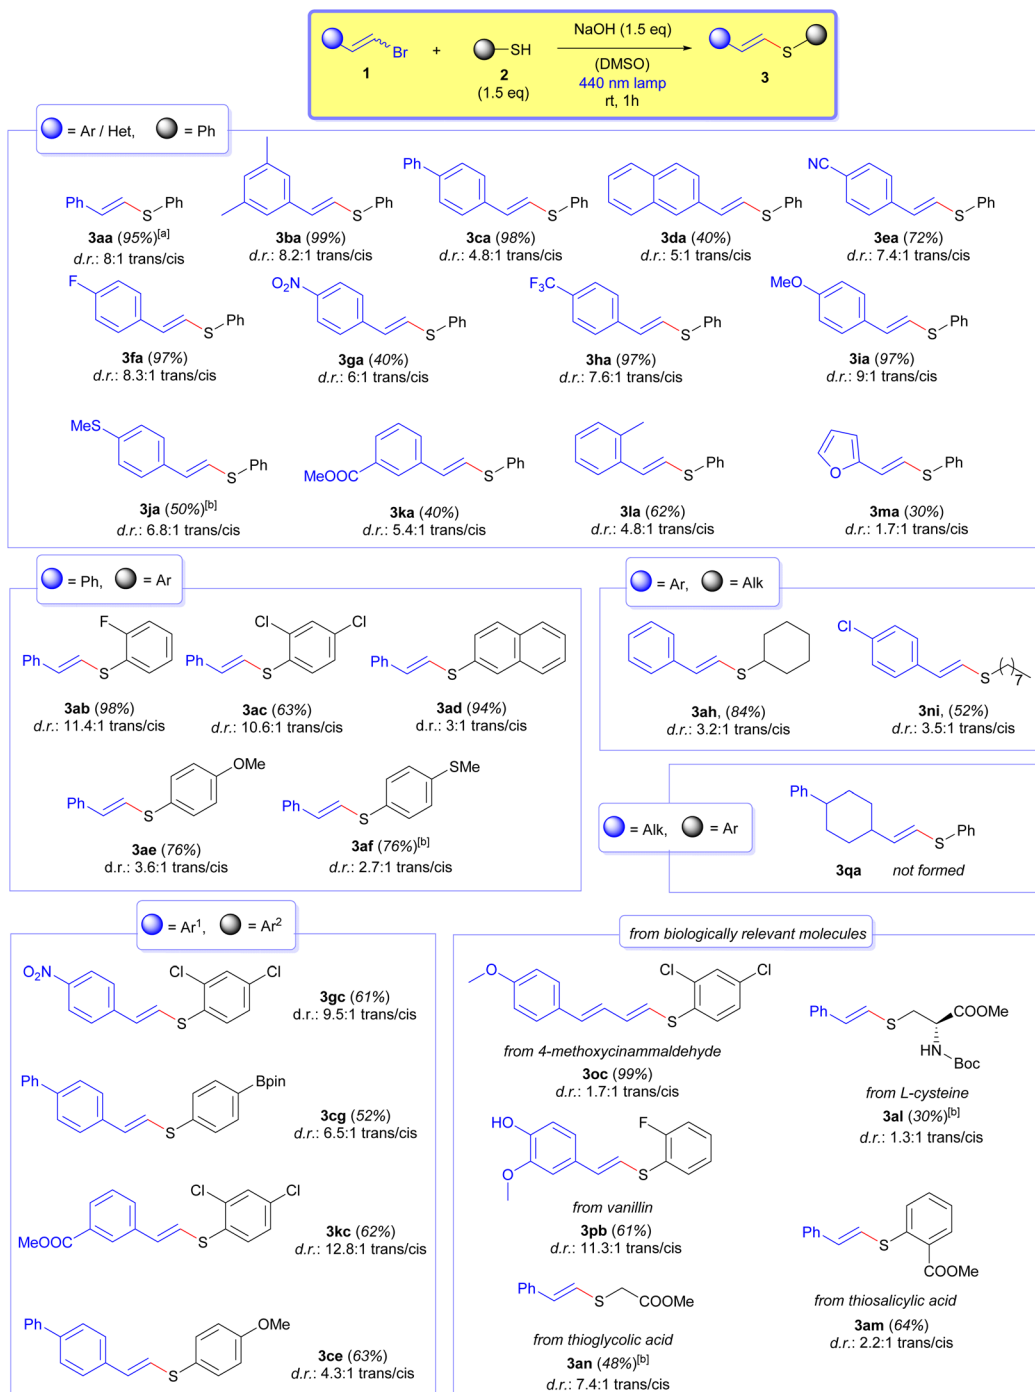

Much to our pleasure, initial experiments showed that the desired vinyl sulfide **3a** was obtained with an excellent yield and high diastereomeric ratio (8 : 1 *trans/cis*) when cesium carbonate was employed as the base and a 440 nm lamp was used as the irradiation source. Control experiments revealed that no reaction occurred in the absence of light or a base. Moreover, the employment of an inert argon atmosphere could be avoided, increasing the operational simplicity of our transformation. Other different polar solvents (DMF, acetonitrile) also afforded the formation of the desired vinyl sulfide **3a**. The employment of other bases (K₂CO₃, KOH, Na₂CO₃) was tolerated, but the shortest reaction time was secured by the usage of NaOH (reaction completed in less than 1 hour). Interestingly, when an alkenyl chloride was employed, the reaction also proceeded towards the formation of the expected vinyl sulfide,

Table 1 Screening of reaction conditions for the cross-coupling between **1a** and **2a**

| Entry | Deviation from standard conditions | Yield of 3a | d.r. <i>trans/cis</i> |
|-------|--------------------------------------------|--------------------|-----------------------|
| 1 | Dark, 72 h | — | — |
| 2 | No base, 12 h | <5% | — |
| 3 | Ar, 2 h | 93% | 8 : 1 |
| 4 | 1 eq. 2a | 69% | 8 : 1 |
| 5 | K ₂ CO ₃ as the base | 95% | 8 : 1 |
| 6 | NaOH as the base, 1 h | 96% | 8 : 1 |
| 7 | DMF instead of DMSO | 96% | 8 : 1 |
| 8 | MeCN instead of DMSO | 84% | 8 : 1 |
| 9 | X = I | 22% | 8 : 1 |
| 10 | X = Cl | 95% | 6 : 1 |
| 11 | NaOH as the base, 1 h, 427 nm | 96% | 6 : 1 |
| 12 | NaOH as the base, 1 h, 390 nm | 78% | 3 : 1 |
| 13 | NaOH as the base, 1 h, 456 nm | 35% ^a | 8 : 1 |

^a Incomplete conversion.

Scheme 2 Substrate scope for the C(sp²)-S bond forming photochemical reaction. ^aAlso 95% yield when the reaction was run in a 1 mmol scale. ^bK₂CO₃ as the base (1.5 eq.) and 2.5 h (compounds **3af**, **3an** and **3ja**) and 5 h (compound **3al**) of irradiation time were needed.

although a worse diastereomeric ratio was obtained (Table 1, entry 10). On the other hand, a low yield was obtained when the corresponding vinyl iodide was used under the standard conditions, which was most likely due to decomposition of the unstable starting material (Table 1, entry 9). It is important to note that the employment of a suitable light source was not only crucial for the photoexcitation of the HB complex, but also had an impact on the *in situ* trans/cis isomerization due to the absorbance of the obtained vinyl sulfides. In this regard, we

noticed that the employment of shorter irradiation wavelengths (366, 390 and 427 nm) failed to provide better stereoselectivity in the transformation than when the 440 nm lamp was used (d.r.: 8 : 1 *trans/cis*). This is in agreement with the absorbance profile of the *cis* (**3aa'**) and *trans* (**3aa**) isomers of the vinyl sulfide (see the ESI† for details). Finally, we noticed that if a less powerful 456 nm lamp was used, the reaction did not reach full conversion even after 1.5 hours of irradiation. All in all, the unprecedented short reaction times and operational simplicity

are noteworthy in comparison to previously reported alternative methodologies for the synthesis of vinyl sulfides. With the optimized reaction conditions at hand, we started to evaluate the scope of our transformation. The results are summarized in Scheme 2. It is worth mentioning that the irradiation time was set to 1 h to ensure full conversion, although in some cases the reaction was finished even after 20 minutes (for example, for the case of compounds **3da** and **3ka**). Longer irradiation periods at 440 nm did not affect the *trans/cis* ratio of the final products due to the lack of absorbance of the vinyl sulfides employing that lamp. First, we tested the impact of different substituents at the aryl ring of the vinyl bromides **1**. In this regard, it was observed that the presence of different electron-withdrawing and electron-donating groups was well tolerated (compounds **3aa–3la**). It is noteworthy that in all of the cases, good to excellent yields and diastereomeric ratios in favor of the *trans* isomer of the final products **3** were obtained. Remarkably, when a 2-furyl heterocyclic substituent at the alkenyl moiety was employed, the reaction also proceeded smoothly to afford the compound **3ma**, albeit with a moderate stereoselectivity. Importantly, when the reaction to forge the compound **3aa** was run in a 1 mmol scale, the reaction proceeded equally well (95% yield), which proved that our transformation is scalable in case larger amounts of the vinyl sulfides were needed. Next, we examined different substitution patterns at the thiols **2**. Once again, the obtention of the desired vinyl sulfides was successful (compounds **3ab–3af**). It must be pointed out that the presence of fluorine and chlorine atoms at the thiol unit, which could potentially present halogen-bonding interactions with other thiolate molecules, was compatible with the reaction conditions. As expected, when alkenyl bromides and thiols bearing at the same time different substituents were tested in our reaction, the cross-coupling products were obtained (compounds **3gc–3nb**). Unfortunately, when an alkyl substituent was attached to the alkenyl bromide, the reaction failed to result in the formation of the vinyl sulfide **3qa**. This fact may be attributed to the lack of absorptive properties of the HB complex derived from the vinyl bromide **3q** and the thiolate anionic form of **2a**. However, and much to our pleasure, the usage of alkylic cyclic and linear thiols was compatible with our transformation in the formation of the molecules **3ah** and **3ni**. Interestingly, a set of vinyl sulfides could be obtained derived from the employment of biologically active molecules. In this context, the obtention of the compound **3oc** is especially interesting, not only because it is derived from a naturally occurring cinnamaldehyde, but also because it illustrates the ability of the reaction to perform also with 1-bromo-1,3-butadienes, and therefore to gain access to 1,3-butadienylsulfanes. Interestingly, the employment of molecules which present enolizable hydrogens in the strongly basic reaction media could be adapted to our methodology if a weaker base (K_2CO_3) and longer irradiation times were used. With this protocol, the vinyl sulfides derived from L-cysteine **3al** and thioglycolic acid **3an** could be prepared. Finally, other appealing vinyl sulfides derived from biologically active scaffolds such as thiosalicylic acid and vanillin gave correspondingly the compounds **3am** and **3pb**.

Scheme 3 Set of mechanistic experiments. PMP = *para*-methoxyphenyl.

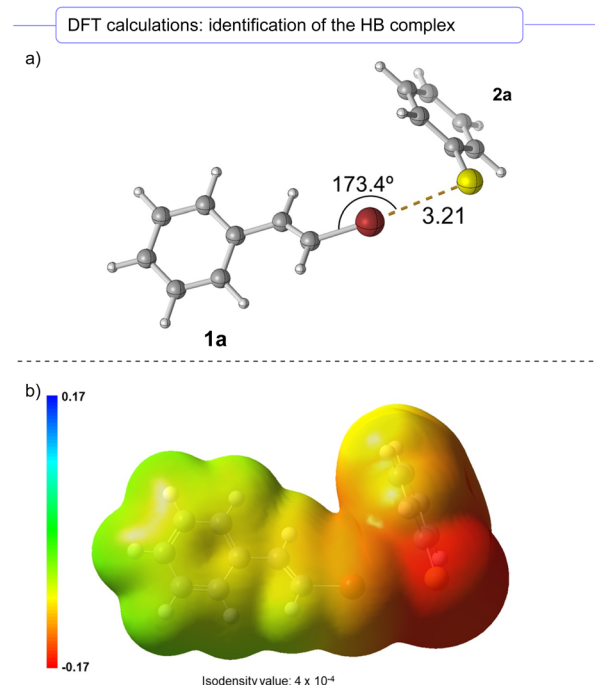

A set of different mechanistic studies were carried out to support the radical nature of the intermediates involved in the transformation (Scheme 3). We hypothesized that the formation of a vinyl radical derived from the alkenyl bromides **1** is due to a PET at the irradiated HB complex. Thus, we performed different control experiments orientated to validate this fact. Two different structures are normally speculated for a vinyl radical: a linear σ -type or a bent π -type.¹⁹ To gain insight into the nature of the vinyl radicals formed in our reaction, we performed a stereoconvergence experiment in which two different reactions, one starting from the *trans* vinyl bromide **1a**, and from the corresponding *cis* isomer **1a'** respectively were evaluated. We observed that the stereogenic information of the alkenyl bromide did not affect the stereoselectivity of the reaction and the vinyl sulfide **3a** was furnished with an 8 : 1 *trans/cis* diastereomeric ratio regardless of the stereochemistry of the starting bromide (Scheme 3a). This observation indicates that the formation of a linear sp-hybridized vinyl radical **5** should be preferred, either through its direct formation from the vinyl bromide precursor, or due to a fast interconversion of the two different bent π -type radicals **4** and **6** (which could arise from each of the precursors **1a** and **1a'**, respectively) towards the linear σ -type one in each of the reactions. This conclusion is consistent with previous reports and experiments oriented to elucidate the structure of vinyl radicals in photochemical reactions.¹⁹ This stereoconvergent nature of our transformation should be highlighted, since this concept has been previously exploited in photochemical reactions by other research groups.²⁰ Inhibition experiments showed that the reaction was shut down if two equivalents of a radical scavenger such as TEMPO were added to the reaction media, giving additional support to a radical mechanism (Scheme 3b). Importantly, intermolecular radical-clock probe experiments employing the vinyl bromide **1a**, thiol **2e** and compound **7** as the radical trapping agent afforded not only the formation of the expected cross-coupling product **3ae** as the major reaction product, but

also a small amount (13% yield) of the product **8** (Scheme 3c). This molecule is most likely forged from an addition of the sulfur-centered radical arising from **2e** to **4**, followed by a ring opening of the cyclopropane to give a linear chain, which provides additional support to the presence of radical species being formed within our reaction.^{6,21} Given that the photochemical catalyst-free cross-coupling reaction between aryl halides and thiols had been previously reported under similar conditions to the ones of our work,²² we designed a competition experiment in which the vinyl bromide **1c** and the aryl bromide **9** were made to react with one equivalent of the thiol **2e** (Scheme 3d). Considering the high reactivity vinyl radicals,²³ it was expected that our reaction would be much faster than the corresponding competing cross-coupling of the thiol with the aryl bromide. Indeed, we observed that the formation of the compound **3ce** outcompeted the one of the compound **10**, showcasing once again the high efficiency of our transformation. Finally, light on/off experiments and quantum yield measurements were run (Scheme 3e). Indeed, in the reaction between **1d** and **2a**, it was observed that the reaction only proceeded during the irradiation times, showing no conversion in the periods in which the light had been turned off. Additionally, we calculated quantum yield for the same reaction (see the ESI† for a detailed description) and its value is below the unit ($\phi = 0.1$). The combination of these two last experiments proves the lack of radical chain propagation processes within our transformation.²⁴

A set of different mechanistic studies were also performed in order to provide evidence for the formation of the halogen-

Scheme 4 (a) ^{13}C -NMR spectra recorded for the compound **1a** in d^6 -DMSO. (b) Overlap of the ^{13}C -NMR spectra obtained in the titration experiments. Different ratios of the acceptor **1a** and electron-donor (NaSPh) were employed to prepare the d^6 -DMSO solutions (from 1 : 1 to 1 : 10).

Scheme 5 (a) HB complex between **1a** and the anionic form of **2a** calculated at the $\omega\text{B97x-D3/Def2TZVPP}$. (b) Calculated electrostatic potential (red = negative electrostatic potential) on the 0.0004 au isodensity surface.

bonding complex. First, we performed UV-Vis measurements of different solutions in DMSO of **1a**, **2a**, **2a** + Cs₂CO₃ and a mixture of **1a** + **2a** + Cs₂CO₃ in equimolar amounts (see Section 3 of the ESI† for details). Satisfyingly, comparison of the UV-Vis absorption profile of this last mixture with each of the individual reaction components pointed at the formation of a halogen-bonding complex due to the identification of a new charge-transfer band at higher wavelengths than the one observed for the individual starting materials. This explains the selective excitation of the halogen-bonding complex at 440 nm, which is believed to be the driving force of our transformation.

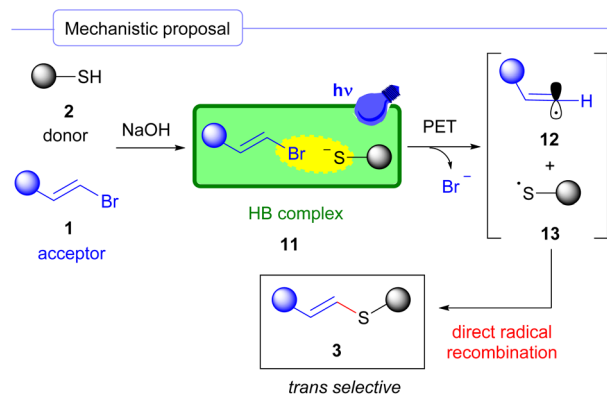

Further support to the formation of the halogen-bonding complex was found by performing NMR titration experiments (Scheme 4). In this regard, when we prepared solutions in d⁶-DMSO of increasing concentrations of sodium thiophenolate maintaining the same quantity of the vinyl bromide **1a** (see Section 8 of the ESI† for a detailed description), we observed a significant increasing downfield shift in the ¹³C-NMR signals of the vinylic carbons of the starting alkenyl bromide **1a**. For instance, we noticed that the signal of the carbon C1 (marked with a red dot, initially at 108.07 ppm) was increasingly deshielded to 108.95 ppm (almost a 1 ppm shift) when a 1 : 10 **1a**/NaSPh was present in the solution. This increase in the chemical shift is most likely due to the formation of a complex between **1a** and the thiolate of **2a**.²⁵ This strategy has been employed in various recent studies for the structural identification of halogen-bonding complexes in solution.^{17a,18c}

Finally, preliminary DFT calculations were run (ωB97x-D3/Def2TZVPP level). Delightfully, a halogen-bonding aggregate between **1a** and the anionic form of **2a** could be identified (see the ESI† for details) as a minimum in the potential energy surface (Scheme 5a). The halogen bond interaction between the bromine and sulfur atom presents a great directionality, displaying a dihedral angle of 173.4° between the Csp²-Br-S bonds, which results in a nearly linear structure for the halogen-bonding complex. Indeed, in the electrostatic potential surface it is observed that the positively charged bromine σ-hole zone is located at almost the center of the C-Br axis (Scheme 5b). This linear geometry with dihedral angles between 160° and 180° for the HB complex is in agreement with previously reported

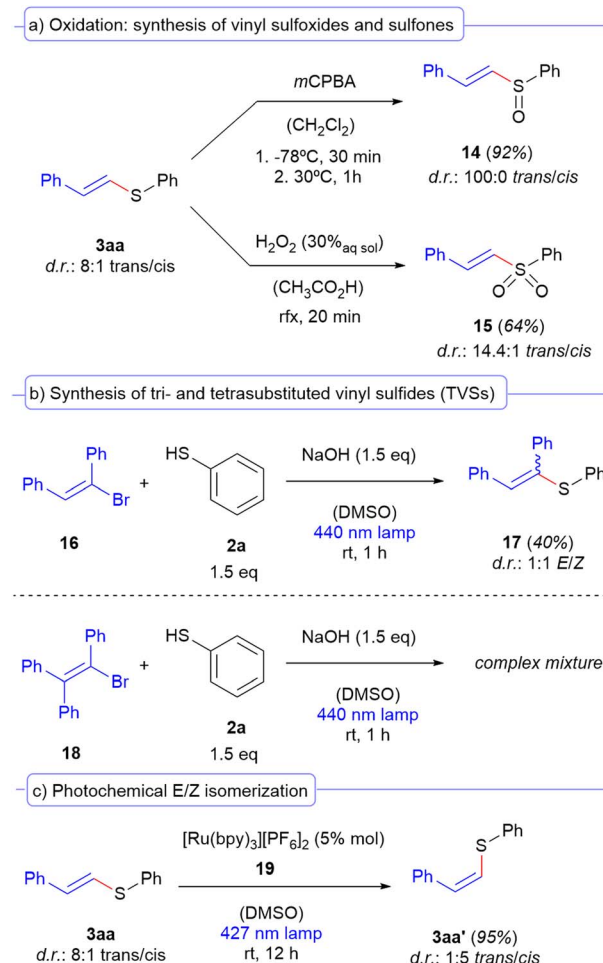

observations on parent complexes.²⁶ Furthermore, we found that in the halogen-bonding complex the distance between the bromine and sulfur atoms was 3.21 Å, which is shorter than the sum of the van der Waals radii of the sulfur and bromine atoms (3.65 Å). This fact supports the existence of a non-covalent weak interaction between these atoms, which is most likely due to the halogen bond formation.

In light of our DFT calculations and mechanistic studies, and previous well-established reports on the photochemical halogen-bonding promoted generation of carbon centered radicals,^{17,18} we propose the mechanism described in Scheme 6. First, a thiolate anion is formed in the basic reaction media from the corresponding thiol **2**. Next, the formation of a halogen-bonding complex between this molecule and the alkenyl halide **1** is hypothesized to occur. Subsequent photo-induced electron transfer (PET) followed by fragmentation would afford the radical species **12** and **13**. Recombination of these intermediates eventually affords the formation of the vinyl sulfides **3** in a stereoselective manner where the *trans* isomer prevails in most of the cases.

In order to prove the usefulness of our reaction, we searched for synthetic applications of our compounds. Given the

Scheme 6 Mechanistic proposal for the photochemical halogen-bonding assisted cross-coupling reaction between alkenyl halides and thiols.

Scheme 7 Synthetic applications of the vinyl sulfides. *m*CPBA = *meta*-chloroperbenzoic acid.

importance of vinyl sulfoxides and sulfones in naturally occurring molecules²⁷ and as valuable building blocks in organic synthesis,²⁸ we looked for conditions to oxidize the vinyl sulfides to both of these molecules (Scheme 7a). In this regard, starting from the vinyl sulfide **3aa**, we optimized a procedure²⁹ which employs *m*CPBA as an oxidant for the obtention of the corresponding vinyl sulfoxide **14**, which was delightfully furnished in our case with a 100 : 1 *trans/cis* diastereomeric ratio. On the other hand, the overoxidation of the same vinyl sulfide to the sulfone **4** could be accomplished under reflux conditions using an aqueous solution of hydrogen peroxide.³⁰ Next, we decided to evaluate the effect of the substitutions in the alkenyl bromide (Scheme 7b). In this context, the synthesis of trisubstituted vinyl sulfides³¹ from the vinyl bromide precursor **16** could be accomplished albeit with no stereoselectivity (d.r.: 1 : 1 *E/Z*). It is known that phenyl substituents at the position of a vinyl radical induce a stabilization effect,³² which could explain the different behaviour of the starting material **16** in our transformation. However, when a tetrasubstituted alkenyl bromide **18** was employed, the reaction failed to provide the desired coupling product and a complex mixture was obtained. This may be attributed to the higher stability of the vinyl radical, which is potentially delocalized at the olefin and therefore fails to provide chemical selectivity in the coupling with the sulfur-centered radical arising from **2a**. As a last synthetic application, we wondered if our *trans*-configured substrates **3** could potentially be converted into the corresponding *cis* isomers *via* a photochemical *E/Z* isomerization process (Scheme 7c). This class of reactions has been extensively studied in the last few years.³³ However, we realized that to date there were no reports on the photochemical isomerization of vinyl sulfides. Therefore, we decided to carry out an extensive optimization (see the ESI† for a detailed description of the optimization studies) to find the best conditions for this reaction to take place. We found that when we employed the ruthenium complex **19** as the photosensitizer ($E_T = 205 \text{ kJ mol}^{-1}$), a photostationary state is reached after 12 hours in which we could invert the stereogenic information in favor of the *cis* isomer **3a'** (from 8 : 1 to 1 : 5 *trans/cis* d.r.). These preliminary results are intended to be a proof of concept within the context of this work, but are currently being in-depth investigated in our research group to extend this methodology to the photochemical isomerization of other sulfur-containing olefins.

3 Conclusions

In conclusion, we have developed a novel, simple, sustainable and general synthetic methodology for the photochemical catalyst-free construction of vinyl sulfides. The activation of the vinyl halides through halogen-bonding interactions with a thiolate anion would form a HB complex, which is believed to be the key to this transformation. In-depth mechanistic studies support the participation of vinyl and sulfur centered radicals as the intermediates of this reaction, which are expected to be generated *via* PET after irradiation of the HB complex. The reaction was proven to be general, functional-group tolerant, operationally simple and scalable. Moreover, it could be applied

to the structural modification of biologically relevant molecules. Eventually, synthetic applications were found which enhance the utility of our transformation in diversity-oriented synthesis.

Data availability

All of the experimental and computational data is available and has been included in the ESI† of this publication.

Author contributions

H. F. Piedra conducted most of the reactions, experimental mechanistic studies and full characterization of the compounds. M. Plaza conceptualized and directed the project, performed the DFT calculations and wrote the manuscript. Both authors contributed to scientific discussions.

Conflicts of interest

There are no conflicts to declare.

Acknowledgements

Financial support of this work by an FICYT (Principality of Asturias) "Margarita Salas Jóven" postdoctoral grant to M. P. (AYUD/2021/58397) is gratefully acknowledged. We wish to thank Prof. Carlos Valdés for his assistance with the DFT calculations and helpful discussions during the development of this work.
