Constructing spike-like energy band alignment at the heterointerface in highly efficient perovskite solar cells†

Runtao Wang, Lin Xie, * Tai Wu, Chenghao Ge and Yong Hua *

The interface between the absorber and transport layers is shown to be critical for highly efficient perovskite solar cells (PSCs). The undesirable physical and chemical properties of interfacial layers often cause unfavorable band alignment and interfacial states that lead to high charge-carrier recombination and eventually result in lower device performance. Herein, we demonstrate a simple and effective strategy to improve the performance of PSCs by constructing a conduction band offset (CBO) with a small spike, through the inductive effect induced by an organic small molecule. As a result, the modified devices show an enhancement in all photovoltaic performance characteristics with a power conversion efficiency (PCE) increase of 10.6% and retaining more than 94% of its initial PCE after 1800 h of exposure to N₂. Importantly, we find that a moderate spike-like CBO at the interface between the perovskite film and hole transport layer facilitates rapid charge-carrier injection in devices and reduces charge recombination at the interface, thereby increasing the open-circuit voltage and fill factor. Furthermore, a large spike barrier at the interface increases device resistance, leading to a reduced fill factor. Our present work provides valuable information for understanding the influence of a spike-like CBO on charge-carrier dynamics to further improve the performance and stability of PSCs.

Introduction

The use of organic–inorganic hybrid perovskite solar cells (PSCs) is currently a leading photovoltaic technique due to their impressive optoelectronic properties and potential for low-cost, high power conversion efficiency (PCE).^{1–4} Yet, much work remains to be done before commercializing this novel photovoltaic technique. Despite the theoretical limit of ~30% in single-junction solar cells, identified for perovskite with a bandgap of 1.50 eV, the highest PCE achieved for laboratory-based PSCs remains a long way off at 25.7%.^{5–7} Fundamentally, the separation and extraction of photo-generated carriers determine the performance of PSCs under illumination.^{8–11} The interfacial defects in perovskite films are generally recognized as non-radiative recombination sites and have been identified as the primary source of energy loss in PSCs.^{12–15} Indeed, given a cliff-like band alignment at the heterointerface of perovskite film, these defect-induced non-radiative recombination sites would exist due to carrier recombination at trap states near the interface. Furthermore, under external stressors, these charged defects might act as ion migration or moisture diffusion

channels, resulting in lattice deformation in the perovskite materials.^{16–20}

Interface-induced non-radiative recombination is mainly caused by misaligned energy levels, back charge-carrier transfer, and surface defects. The incorporation of organic molecules containing N-, S-, or O-donors has been universally acknowledged to show peculiarities in boosting efficiency and stability based on Lewis acid–base chemistry.^{21–30} Recently, Hagfeldt *et al.* discovered that a dipolar interlayer of azetidinium lead iodide (AzPbI₃) could increase device performance.³¹ Yang *et al.* found that tailoring the dipolar molecules to induce an extra electric field at the heterointerface can improve the performance and stability of the device.³² Our group also found that incorporating a dipolar interlayer that enhances the built-in electric field can enhance charge-carrier injection and minimize non-radiative recombination in PSCs.^{33–36} Although attempts through interface engineering have been successfully demonstrated to reduce the defect density,^{37–39} it has certain limitations in terms of inevitably massive and diverse defects.

Apart from defect passivation, effective interface engineering should also take care of the selective extraction of majority carriers and block minority carriers. An optimal interface should be designed to ensure efficient extraction of majority carriers while blocking minority carriers. For instance, the different bandgaps of the hole transport layer (HTL) and perovskite realize an energy cliff or spike at the interface. While the holes of HTL could easily overcome the barrier to return to the interface.

† Electronic supplementary information (ESI) available. See DOI: <https://doi.org/10.1039/d2sc06499e>

Furthermore, the spike in the conduction band at the interface can cause a desirable increase in the barrier to the back injection of electrons of the ETL into the interface under forward bias. Therefore, it is imperative to develop strategies to optimize the heterointerface in perovskite films to reduce the charge recombination and defects to further increase the device performance. Moreover, an understanding of the energy band alignment at the interface and the charge-carrier dynamics between the perovskite film and the charge-transporting layers is still lacking.

In this work, we present a simple modification strategy of a moderately spiked CBO for highly efficient PSCs using triflic anhydride ((CF₃SO₂)₂O, Tf₂O) *via* an inductive effect. Through prudent control over the concentration of Tf₂O, the interfacial energetics and interfacial defects can be effectively managed. This systematic study demonstrates the influence of the inductive effect on manipulating the spike-like CBO of modified perovskite films and highlights the importance of a spike-like CBO in reducing the charge-carrier recombination at the interface compared to a cliff CBO. Our strategy yields a significant enhancement in open-circuit voltage (V_{OC}) and fill factor (FF) in the resultant PSCs with a PCE exceeding 21%, retaining more than 90% of its initial PCE despite exposure to N₂ for more than 1800 h. Our findings offer a feasible and effective strategy to construct spike-like energy band alignment at the heterointerface in highly efficient perovskite solar cells.

Results and discussions

Tf₂O is a cheap and plentiful material that is often used to introduce a trifluoromethyl group (-CF₃) into organic compounds due to its strongly electrophilic nature.^{40–42} Tf₂O has a symmetric structure and two-point charge centers (negative and positive centers) owing to its uneven electronegativity, generating an electric dipole. Fig. 1a depicts the chemical structure of Tf₂O as well as its electrostatic surface potential (ESP) map derived from density functional theory (DFT) computations. S=O groups show greater electron densities (as the negatively charged groups, in red), whereas -CF₃ groups present lower electron densities (as the positively charged groups, in blue). The dipole moment of Tf₂O is determined to be 3.48 D. Fourier transform infrared spectroscopy (FTIR) was used to investigate the interaction behavior between Tf₂O and the perovskite interface, as illustrated in Fig. 1b and c. Peaks at 1033 cm⁻¹ and 1296 cm⁻¹ correspond to asymmetric and symmetric S=O stretching vibrations, respectively, while an 1189 cm⁻¹ peak corresponds to the C-F stretching vibration. When combined with lead iodide (PbI₂), the asymmetric stretching vibration of S=O shifts to 1027 cm⁻¹, whereas the symmetric stretching vibration of S=O disappears (Fig. 1b), indicating a strong chemical interaction between the PbI₂ and S=O groups in Tf₂O. Tf₂O interactions with formamidinium

(h) Schematic representation of the chemical interaction between Tf₂O and the perovskite film.

iodide (FAI) were also studied (Fig. 1c). The N–H bond in FAI displays a significant shift, with the peaks at 3323 cm^{-1} , 3195 cm^{-1} , 3170 cm^{-1} , and 3119 cm^{-1} assigned to the N–H stretching vibration shifting to 3137 cm^{-1} , 3181 cm^{-1} , 3205 cm^{-1} , and 3353 cm^{-1} , respectively. Moreover, after mixing with Tf_2O , the stretching vibration of C=N in FAI shifts from 1689 cm^{-1} to 1697 cm^{-1} . Such a spectroscopic feature points to hydrogen-bond interaction between FAI and the $-\text{CF}_3$ group in Tf_2O . High-resolution Pb 4f and I 3d X-ray photoelectron spectroscopy (XPS) spectra of the films (Fig. 1d, e, and S1, ESI[†]) also indicate that the Tf_2O -treated film has a stronger interaction with the perovskite film, as seen by the peaks shifting to lower binding energy.

To gain insight into the intermolecular interaction between Tf_2O and FAI, ^1H nuclear magnetic resonance spectroscopy (^1H NMR) was performed, as shown in Fig. 1f. For FAI, two singlet peaks at $\delta = 7.91$ and 8.85 ppm in the NMR spectra correspond to the protons of $-\text{CH}$ and $-\text{NH}_2$ of pure FAI. These two single peaks imply one uniform chemical environment for the $-\text{CH}$ and $-\text{NH}_2$ groups in FAI. When FAI was mixed with Tf_2O , the two peaks show chemical shifts compared to the proton peaks of FAI, suggesting an inductive effect due to $\text{F}\cdots\text{NH}_2$ hydrogen-bonding interaction between Tf_2O and FAI. Intriguingly, the signals for $-\text{CH}$ and $-\text{NH}_2$ in the FAI spectra are split into multiplets and two peaks by adding Tf_2O , which can be ascribed to the positive charges in FAI distributed uniformly in the N–C–N region being polarized due to the formation of

a hydrogen bond between $\text{C}=\text{NH}$ and $-\text{CF}_3$, resulting in a change in the electronegativity of the two nitrogens. The advantage of the inductive effect is that the polarized FAI can anchor hydrogen iodide to the secondary amine, which can stably move the iodide ion. The intermolecular interaction between Tf_2O and FAI is illustrated in Fig. 1g. The interfacial interaction of Tf_2O toward the uncoordinated Pb cations and organic cations in the perovskite film would be favorable to the mitigation of non-radiative recombination at the interface, as depicted in Fig. 1h. These results suggest that the inductive effect can stabilize iodide ions on the perovskite film surface, change the interfacial energetic of the perovskite film, and efficiently suppress the degradation of the perovskite film to a certain extent.

To investigate the influence of Tf_2O on device performance, we fabricated PSCs with Tf_2O -modified perovskite films on a mesoporous device architecture consisting of the following layers: fluorine-doped tin oxide (FTO)/titanium oxide (TiO_2)/(CsPbI_3)_{0.05}($\text{FA}_{0.85}\text{MA}_{0.15}\text{Pb}(\text{I}_{0.85}\text{Br}_{0.15})_3$)_{0.95}/ Tf_2O /Spiro-OMeTAD/Au. Considering the insulating property of Tf_2O , we carefully regulated the concentration of Tf_2O to control the Tf_2O residue on top of the perovskite films, as shown in Fig. 2a. The corresponding photovoltaic parameters are shown in Fig. S2 (ESI[†]). The statistical distribution of PCE values from 18 devices each for the control, Tf_2O -1, and Tf_2O -5 modified devices confirms that the enhancement in photovoltaic performance arises from the introduction of Tf_2O to the perovskite film surface. The optimal

Table 1 Summary of photovoltaic parameters (forward scan) for the control, Tf₂O-1 and Tf₂O-5 modified PSCs, measured under AM 1.5 illumination

Device		J_{SC} (mA cm ⁻²)	V_{OC} (V)	FF (%)	PCE (%)
Control	Best	24.13	1.088	72.84	19.14
	Average	24.81	1.061	71.04	18.70
Tf ₂ O-1	Best	24.69	1.111	78.92	21.64
	Average	24.73	1.109	77.17	21.17
Tf ₂ O-5	Best	24.12	1.118	75.84	20.45
	Average	24.33	1.109	72.28	19.50

concentration for the Tf₂O-treated PSCs is obtained at 1 mM. Fig. 2b presents the current density–voltage (J – V) curves of the control and Tf₂O-modified PSCs measured under standard AM 1.5G illumination in ambient conditions. The champion control device shows V_{OC} , current density (J_{SC}), FF, and PCE values of 1.088 V, 24.13 mA cm⁻², 72.84%, and 19.14%, respectively (Table 1). 1 mM Tf₂O-modified PSCs (referred to as Tf₂O-1) achieved an overall enhancement in J_{SC} up to 24.68 mA cm⁻², a V_{OC} of 1.111 V, and FF of 78.92%, resulting in a remarkable higher PCE of 21.64%. Devices treated with 5 mM Tf₂O (referred to as

Tf₂O-5) yield a lower PCE of 20.45% with a J_{SC} of 24.12 mA cm⁻², a V_{OC} of 1.118 V, and a reduced FF of 75.84%. The incident photon-to-electron conversion efficiency (IPCE) spectra of the fabricated devices are shown in Fig. 2c. The integrated J_{SC} for the control, Tf₂O-1, and Tf₂O-5 modified PSCs are found to be 23.88 mA cm⁻², 24.35 mA cm⁻², and 23.93 mA cm⁻², respectively. Subsequently, we subjected the control and Tf₂O-1 modified devices to a long-term stability test, which was monitored by periodically measuring the photovoltaic characteristics of devices that were stored in an N₂-filled glovebox. As shown in Fig. 2d and S3 (ESI[†]), the Tf₂O-1 modified device shows outstanding tolerance, retaining 94% of its initial PCE after 1800 h of storage. The control device shows a 27% reduction in PCE only after 500 h. Additionally, the maximum power point (MPP) tracking for 200 s at a voltage of 0.88 V reveals a stable power output, with a stabilized PCE of 21.40% (Fig. S4, ESI[†]).

To understand the underlying reason behind the photovoltaic performance of Tf₂O-modified PSCs, various characterizations were conducted on the control and Tf₂O-modified perovskite films. Surface photovoltage (SPV) measurement was carried out to monitor the changes in interfacial energetics caused by the generation and redistribution of photoexcited

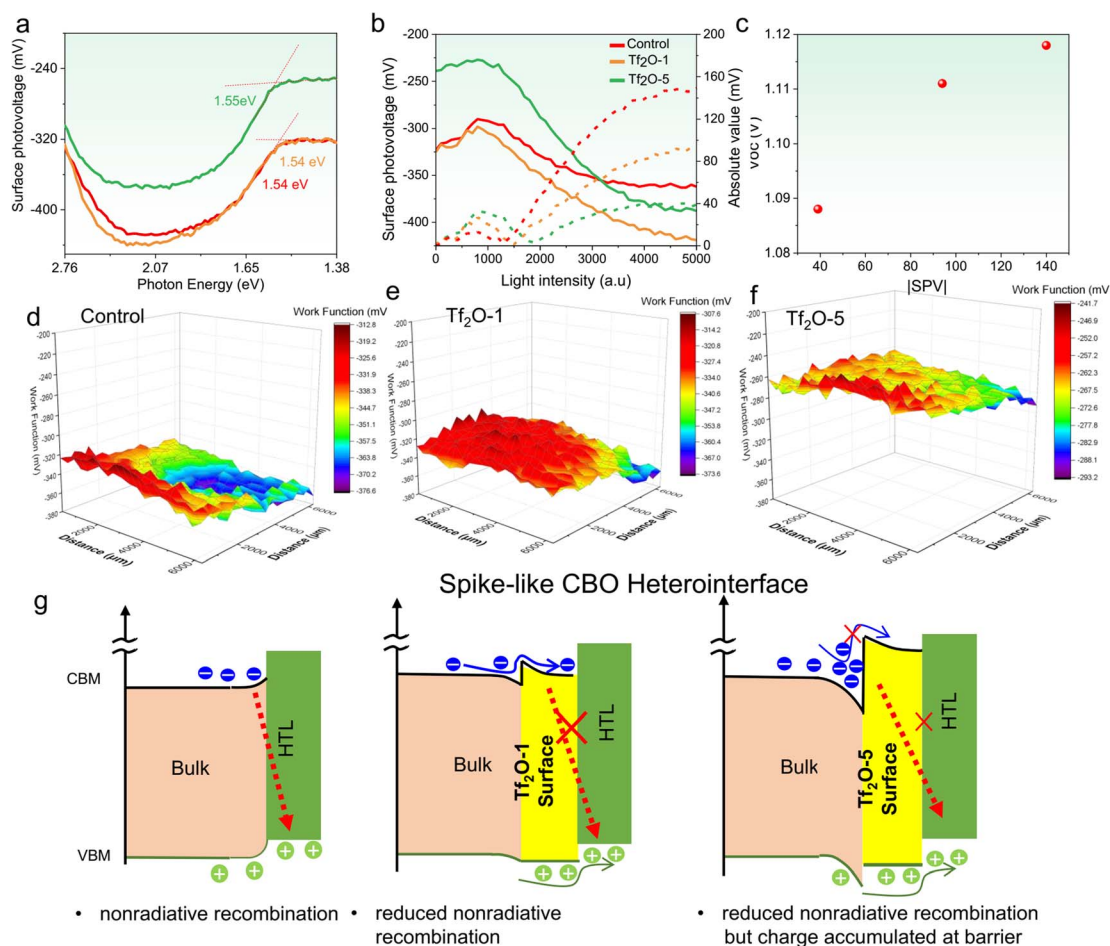

Fig. 3 (a) SPV spectra of control, Tf₂O-1, and Tf₂O-5 treated films. (b) Light-intensity-dependent SPV of samples under light irradiation. (c) Interval plot of device V_{OC} as a function of SPV absolute value. WF maps of (d) control film, (e) Tf₂O-1 modified film, and (f) Tf₂O-5 modified film, respectively. (g) Schematic of proposed band alignment at the heterointerface through Tf₂O-1 and Tf₂O-5 modification.

charge carriers in semiconductors. As illustrated in Fig. 3a, bandgap-related knees at 1.54 eV, 1.54 eV, and 1.55 eV can be found in control, Tf₂O-1, and Tf₂O-5 modified films prepared on glass, respectively. It should be noted that the perovskite material used in our study is a weak n-type film:⁴³ the photo-generated electrons spontaneously transfer from bulk to the buried interface, leaving holes and positive ions on the free surface and generating an internal electric field pointing to the buried interface. Fig. 3b depicts the light-intensity-dependent SPV of control, Tf₂O-1, and Tf₂O-5 modified perovskite films. Notably, the difference in SPV response is attributed to the different concentrations of Tf₂O on the perovskite film. The absolute values of SPV in Tf₂O-1 modified film (~90 eV) were significantly higher than in the control film without Tf₂O modification (~40 eV), indicating a greater built-in electric field (BIEF) in Tf₂O-1 modified film. By raising the concentration of Tf₂O to 5 mM, the absolute value of the SPV is further increased to ~150 eV. As can be seen in Fig. 3c, there is a clear positive association between SPV and the V_{OC} of Tf₂O-modified devices. Thus, the SPV is intimately associated with the related V_{OC}. With Tf₂O-1 and Tf₂O-5 modification, the V_{OC} of the control device gradually increased from 1.088 V to 1.119 V. Furthermore, we can visualize the Tf₂O distribution with nanoscale resolution using Kelvin probe force microscopy (KPFM). As shown in Fig. 3d–f and S5 (ESI[†]), the WF of control, Tf₂O-1, and Tf₂O-5 films are calculated to be –375.6 mV, –331.3 mV, and –264.3 mV, respectively. Accordingly, the change in WF in transition metal oxide and perovskite materials is correlated to the cation state and point defect concentrations.⁴⁴ As shown in Fig. 3d–f, a uniform WF distribution was found in the Tf₂O-1 modified film, indicating more effective passivation in comparison to Tf₂O-5. Whereas the non-uniform WF of Tf₂O-5 film might be attributed to the formation of monohydrate at high concentration levels, as illustrated in the atomic force microscopy (AFM) and scanning electron microscopy (SEM) (Fig. S6, ESI[†]). These results indicate that adding Tf₂O at the perovskite surface raises the valence-band edge of perovskite with respect to the Fermi level. Overall, the surface potential reveals larger band bending at the Tf₂O-1 modified interface and a significantly larger total charge depletion width at the heterointerface compared to the control.

According to the conclusions drawn from SPV and WF measured above, a schematic in Fig. 3g is drawn to understand the role of the spike structure in the complete device. It is known that a cliff does not impede the photogenerated electrons; however, it lowers the activation energy for carrier recombination at the interface, which results in a decrease in V_{OC}. The cliff can act as a barrier against injected electrons under forward bias, resulting in the recombination of a majority of carriers *via* defects at the interface. In contrast, a spike-like CBO was introduced when perovskite was treated with Tf₂O, which increases the energy for carrier recombination at the interface, improving the V_{OC} and overall PCE. Interestingly, we also observed a considerable up-shift in WF in Tf₂O-5 modified film, which can cause a large CBO at the heterointerface, forming a potential well to trap charges/holes at the heterointerface that traps charges and increases the resistance to hole

extraction, thereby reducing the FF. This result is very consistent with a recent study by Yang's group, in which substantial band bending might result in increased resistance and a lower FF.⁴⁵ Considering the inductive effect of Tf₂O, we believe that the changes in spike-like CBO in Tf₂O-1 and Tf₂O-5 modified films can be attributed to the polarization of the FAI, as demonstrated by the NMR and XPS results.

To investigate the effect of Tf₂O on the carrier recombination kinetics and trap states, we subjected the control and Tf₂O-1 films to a series of tests. Fig. 4a provides a comparison of the PL intensity between the control and Tf₂O-1 modified films. Clearly, the higher photoluminescence (PL) intensity noted for the Tf₂O-1 modified film compared to the control implies a reduction in defect density with Tf₂O treatment. Lengthening of carrier lifetime, in the absence of a charge extraction layer, is determined through time-resolved photoluminescence (TRPL) studies (Fig. 4b and Table S1[†]), where the average lifetime of the Tf₂O-1 modified film is 587.9 ns, up from 181.1 ns for the control. The trap densities of the control and Tf₂O-modified devices determined from space-charge-limited-current (SCLC) (Fig. 4c) are calculated to be $1.2 \times 10^{16} \text{ cm}^{-3}$ for the control and $5.5 \times 10^{15} \text{ cm}^{-3}$ for the Tf₂O-1 modified devices, respectively. Additionally, the light-intensity-dependent *J*–*V* characteristics were also evaluated. The V_{OC} and the seminatural logarithm of light intensity exhibit a linear fitting relationship. In general, the device exhibits negligible trap-assisted Shockley–Read–Hall (SRH) recombination when the slope is close to $1 \text{ } kT/q$. The slopes are calculated to be $1.55 \text{ } kT/q$ and $1.22 \text{ } kT/q$ for the control and Tf₂O-1 modified devices, respectively, where *k* is the Boltzmann constant, *q* is the elemental charge, and *T* is the temperature. The lower slope of the Tf₂O-1 modified device implies a reduction in trap-assisted SRH recombination compared to the control device. Consequently, the treatment of perovskite film with Tf₂O-1 can effectively suppress SRH recombination and enhance the carrier lifetime due to the chemical interaction between Tf₂O and the perovskite film. In line with the TRPL and SCLC results, transient photovoltage (TPV) decay curves of the modified devices also show an increasing trend from 0.057 ms to 0.085 ms when using Tf₂O modification (Fig. S7, ESI[†]). X-ray diffraction (XRD) measurements were conducted, as shown in Fig. S8 (ESI[†]). The full width at half-maximum (FWHM) of the XRD peak is estimated from a Gaussian curve fitting. The FWHM of both control and Tf₂O-modified film is calculated to be 0.119, indicating that the chemical interaction with Tf₂O does not influence the crystallinity of the perovskite films.

We performed nanosecond-(ns) and femtosecond-(fs) transient absorption (TA) measurements to understand the photo-induced carrier dynamics of Tf₂O-1 modified perovskite film, including charge-carrier injection and hot hole carrier (HC) extraction. We employed fs-TA to understand the influence of Tf₂O on hole transfer at the interface of TiO₂/perovskite, as revealed in Fig. 5a–d. All samples of the perovskite film were excited at 475 nm under an excitation energy of $14 \mu\text{J cm}^{-2}$. Fig. S9[†] exhibits the 2D pseudo-color plots of the fs-TA spectra of perovskite/HTL and perovskite/Tf₂O/HTL films. Notably, a photobleaching (PB) band at 766 nm indicates the band state

Fig. 4 (a) Steady-state and (b) time-resolved photoluminescence (TRPL) of control and Tf_2O -1 modified perovskite films prepared on glass. (c) Dark J - V curves for control and Tf_2O -1 modified electron-only devices based on FTO/ETL/perovskite/PCBM/Au. (d) V_{OC} versus light intensity for the control and Tf_2O -1 modified devices.

filling between the valence band edge and the conduction band edge of the perovskite film. Scans at various delays extracted from pseudo-color plots are presented in Fig. 5a and b. The high-energy tails gradually become narrower with time due to the hole-carrier cooling process, which can be evaluated with the carrier temperature (T_c). Accordingly, T_c can be extracted by fitting the high-energy tail above the bandgap of the TA spectra with the Maxwell-Boltzmann distribution function of $\exp(E_f - E/k_B T_c)$, where E_f is the Fermi level, and k_B is the Boltzmann constant.^{46,47} As revealed in Fig. 5c, the perovskite/HTL shows a slower HC temperature decay of 3.3 fs, whereas the perovskite/ Tf_2O /HTL film presents a faster HC temperature decay of 2.3 fs. The faster HC cooling process presented in perovskite/ Tf_2O /HTL can break the thermal photons of hot carriers, thereby improving the device's performance. The HC relaxation dynamics contain a dominant three-exponential decay component due to the recombination of charge carriers. As shown in Fig. 5d, the fs-TA curves were well fitted by a three-exponential-function equation, $I(t) = A_1 \exp(-x/\tau_1) + A_2 \exp(-x/\tau_2) + A_3 \exp(-x/\tau_3)$, where τ_1 refers to charge-carrier trapping at the perovskite interface, τ_2 is HC transport from the perovskite to the hole transport layer (HTL), and τ_3 is the carrier recombination time.^{48,49}

The fitting details and values for fs-TA are summarized in Table S3.† Clearly, the large portion of τ_1 implies that the trap filling process is dominant in the HC relaxation dynamics. The

decreased τ_1 in the Tf_2O -modified films compared to the film without Tf_2O indicates a faster trap filling process, suggesting a larger splitting in the quasi-Fermi energy levels and a larger charge depletion width in the perovskite film, which is consistent with the results of SPV measurement. Furthermore, the decreased τ_2 and τ_3 indicate that the entire recombination process can be effectively suppressed with the help of Tf_2O . Therefore, these results suggest that the dipolar layer of Tf_2O can provide a thermodynamic driving force by tuning the heterointerface, thus promoting hole transport dynamics. To understand the modified heterointerface on the charge-carrier transport, we also studied the ns-TA measurement perovskite with and without Tf_2O prepared on glass/ TiO_2 substrates. Similarly, a photobleaching peak at 766 nm is obtained in the ns-TA spectra (Fig. 5e and f). The corresponding kinetic decay traces of PB at 766 nm were studied. The lifetime of the perovskite films with electron transporting layers (ETLs) was fitted by a single-exponential function, as shown in Fig. 5g. The decay lifetime values of control and Tf_2O -modified film are calculated to be 577.6 ns and 515.6 ns, respectively. Therefore, the ETL/perovskite interfacial charge recombination velocity can be evaluated to be 1.7×10^7 and $1.94 \times 10^7 \text{ s}^{-1}$ based on $\kappa = 1/\tau$.⁵⁰ The decreased charge recombination velocity of Tf_2O -modified film demonstrates the fast charge-carrier injection from the perovskite film to ETLs and thus effectively reduces the charge aggregation and non-radiative recombinations at the

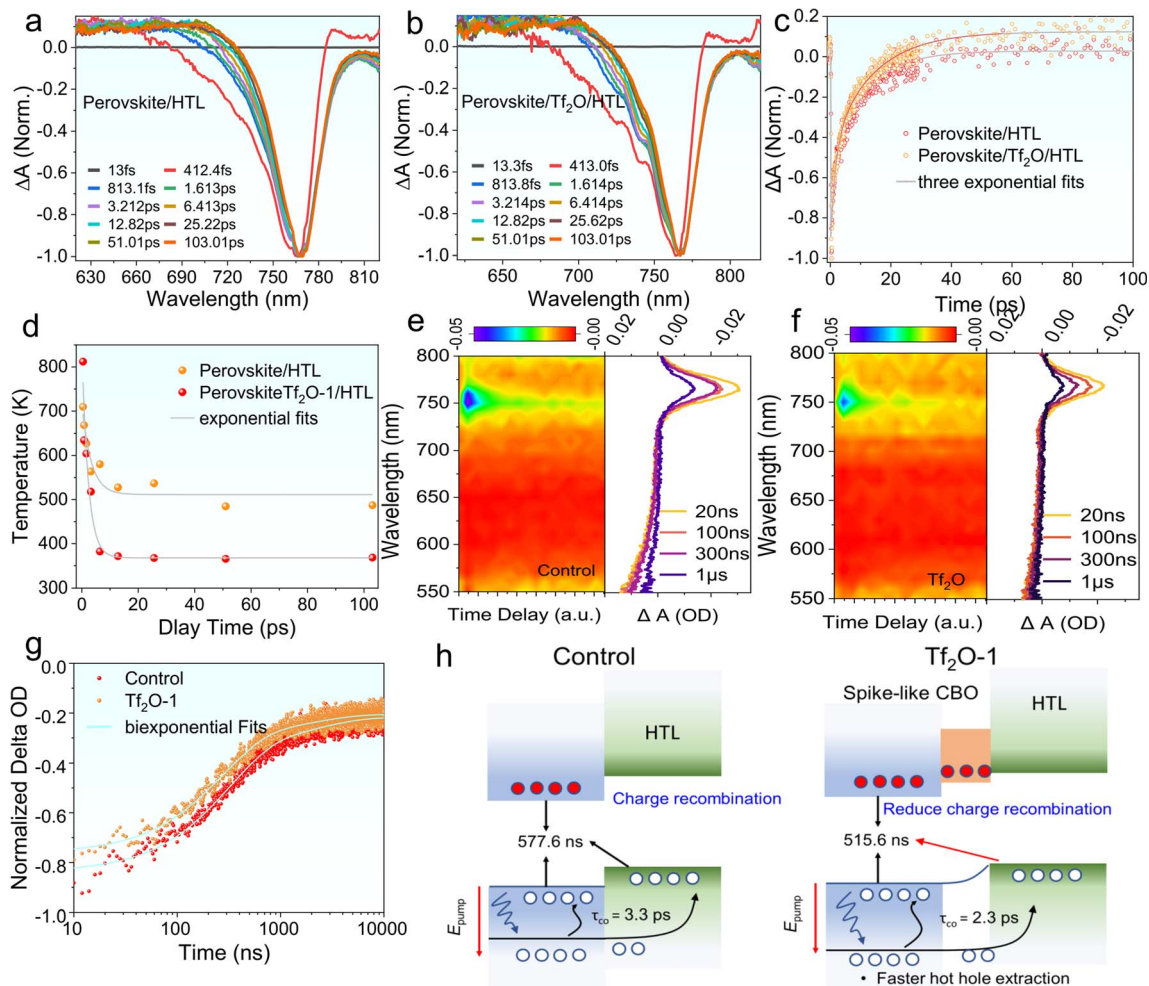

Fig. 5 Normalized fs-TA kinetics of perovskite/HTL without (a) or with (b) Tf_2O -1 treatment. (c) Normalized fs-TA spectra at early delays of perovskite/HTL and perovskite/ Tf_2O /HTL. ETL interface. As a result, both the fs-TA and ns-TA measurements confirm that the Tf_2O -induced spike-like CBO can efficiently promote the photoinduced charge/hole transfer at the interfaces, which could provide a reasonable explanation for the improved V_{OC} , FF, and PCE of the Tf_2O -modified device. Fig. 5h depicts the proposed mechanism of spike-like CBO offered by Tf_2O . A modest favorable spike-like CBO rises in the Tf_2O -modified perovskite surface, acting as a barrier to suppress the interfacial non-radiative recombination and enhancing the hot hole carrier extraction at the interface, thus enhancing the device performance and stability.

Conclusion

In summary, we have demonstrated an effective strategy to construct spike-like energy band alignment at the heterointerface between a perovskite film and HTL as an approach to reduce the potential loss in PSCs. As a result, the Tf_2O -modified device exhibits an improved PCE of 21.6% due to the reduction of non-radiative recombination. We found that the spike-like

energy band alignment at the heterointerface of perovskite film with Tf_2O modification can promote rapid charge-carrier injection and suppress non-radiative recombination at the interface. This work provides important insights into interfacial energetic engineering in PSCs to achieve both high efficiency and long-term stability.

Experimental section

Materials

Cesium iodide (CsI), lead iodide (PbI_2), lead bromide (PbBr_2), formamidiniumiodide (FAI), $\text{N}_2, \text{N}_2, \text{N}_2', \text{N}_2', \text{N}_7, \text{N}_7, \text{N}_7', \text{N}_7'$ -octakis(4-methoxyphenyl)-9,9'-spirobi[9H-fluorene]-2,2',7,7'-tetramine (Spiro-OMeTAD) and methylammonium bromide (MABr) were supplied by Xi'an Polymer Light Technology Corp. Trifluoromethanesulfonic anhydride (Tf_2O) was purchased from Energy Chemical. Fluorine-doped tin oxide (FTO)-coated glass substrates, TiO_2 paste, acetylacetone, titanium diisopropoxide bis(acetylacetonate) 75% in isopropyl alcohol, isopropanol (IPA), N, N' -dimethylformamide (DMF), dimethyl

sulfoxide (DMSO), acetone, absolute ethanol, and chlorobenzene (CB) were supplied by Aladdin. 4-*Tert*-butylpyridine (tBP), bis(trifluoromethylsulfonyl) imide lithium salt (LiTFSI), acetonitrile (ACN), tris(2-(1-*H*-pyrazol-1-yl)-4-*tert*-butylpyridine)-cobalt(III) tris(bis(trifluoromethyl-sulfonyl) imide) (FK 209), were purchased from Sigma-Aldrich.

Precursor solution preparation

Compact TiO₂ (c-TiO₂): a mixture of 0.6 mL of titanium diisopropoxide bis(acetylacetonate) and 0.4 mL of acetylacetonate in 9 mL of anhydrous ethanol was stirred overnight. It was filtered with an organic filter head before use. Mesoporous TiO₂ (m-TiO₂): a mixture of 1 g of TiO₂ paste in 6 g of anhydrous ethanol was stirred overnight. Perovskite precursor solution: a mixture of 553.4 mg of PbI₂, 73.2 mg of PbBr₂, 194.4 mg of FAI, 22.3 mg of MABr, and 18.2 mg of CsI in a mixed solvent of DMF and DMSO (v : v = 5 : 1) was stirred overnight. Hole transport layer (HTL): 85 mg of Spiro-OMeTAD was mixed in 1 mL of CB with additives of 28.8 μL of t-BP, 17.8 μL of LiTFSI (520 mg mL⁻¹ in ACN), 6.5 μL of FK209 (300 mg mL⁻¹ in ACN).

Device fabrication

The FTO substrates (7 Ω) were cleaned ultrasonically for 20 min using detergent water, deionized water, acetone, and ethanol before drying in an oven for 30 min at 65 °C. The cleaned FTO glasses were coated with a c-TiO₂ layer and then exposed to 450 °C of annealing treatment for 1 h. After that, m-TiO₂ layers were deposited on the FTO/c-TiO₂ substrates with a thermal annealing treatment at 500 °C. Subsequently, 30 μL of perovskite solution was spin-coated onto the FTO/c-TiO₂/m-TiO₂ substrates at 1000 rpm for 10 s and 5000 rpm for 30 s. During the 2nd step, 110 mL of CB was poured on the spinning substrate 15 s before the end of the program. And then the substrates were annealed first at 60 °C for 5 min and then at 100 °C for 30 min. For the Tf₂O-treated devices, different concentrations of Tf₂O in IPA were spin-coated on the substrate at a speed of 3000 rpm for 20 s and left for 30 min. Subsequently, the HTL precursor solution was spin-coated onto the FTO/c-TiO₂/m-TiO₂/with or without Tf₂O substrates at 4500 rpm for 30 s. A gold layer was thermally evaporated under a high vacuum (<2.0 × 10⁻⁴ Pa) to complete the fabrication of the devices.

Devices characterization

All the devices for characterization were made using a metal mask with an active area of 0.0625 cm². A Newport solar simulator (model 91160) and a Keithley 2400 source/meter were used to simulate and measure the current-voltage characteristics under 100 mW cm⁻² (AM 1.5G illumination). Incident photon-to-current conversion efficiency (IPCE) spectra were recorded using a computer-controlled setup consisting of a xenon light source (Spectral Products ASB-XE-175), a monochromator (Spectral Products CM110), and a potentiostat (LabJack U6 DAQ board), calibrated by a certified reference solar cell (Fraunhofer ISE). The transient photovoltage (TPV) and the change in photovoltage with light intensity were measured by an electrochemical workstation (Zennium X, Zahner). In the first-principles calculations

(DFT), electron-ion interactions of Tf₂O were described using the Vienna *ab initio* Simulation Package (VASP) and Projected Enhanced Wave (PAW) methods. The Fourier-transform infrared spectroscopy (FTIR) spectroscopy was carried out using a Nicolet iS10 (Thermo Fisher). The ¹H NMR and ¹³C NMR spectra were performed on a Bruker Ascend 400 MHz spectrometer. A vibrating Kelvin probe (probe diameter = 2 mm) (KP Technology, UK) was used to determine the surface potential. Samples were prepared by depositing perovskite films (thickness around 500 nm) on FTO glass. Ambient SPV measurements were done under illumination from a 150 W quartz tungsten halogen lamp, where the intensity was varied linearly by controlling the power supplied to the lamp. The steady-state photoluminescence (PL) measurement was performed using a spectrometer (FLS1000, Edinburgh Instruments). The time-resolved PL (TRPL) decay transients were measured using a picosecond pulse diode laser (EPL-470). Nanosecond transient absorption (TA) spectroscopy was investigated with a spectrometer (LP980, Edinburgh Instruments). Femtosecond transient absorption (fs-TA) measurements were performed for the films using a multipass amplified Ti:sapphire laser (800 nm laser pulses with a 3.5 mJ per pulse; pulse width of ~120 fs with a repetition rate of 2 kHz, Astrella from coherent; the detection time delay was in the range of 8.5 ns in conjunction with Helios spectrometers). X-ray photoelectron spectroscopy (XPS) was performed using a scanning XPS microprobe (K-Alpha+). X-ray diffraction (XRD) patterns of films were measured with a TTR-18KW diffractometer, with Cu Kα radiation (λ = 0.15405 nm) operated at 10 000 W power (40 kV, 250 mA). The surface morphology of the films was characterized by scanning electron microscopy (SEM) and atomic force microscopy (AFM) with the tapping mode. The space-charge-limited-current (SCLC) measurements were performed by collecting the *I*-*V* characteristics of the devices under dark conditions. Fourier-transform infrared (FTIR) spectroscopy was carried out using a Nicolet iS10 (Thermo Fisher).

Author contributions

Y. H. and L. X. conceived the project, and R. W. signed the experiments, analyzed the data, and prepared the manuscript. R. W. carried out the film deposition and device fabrication. R. W. carried out the characterizations, including SEM, XRD, and T. W. conducted the PL and TRPL tests. C. G. carried out the XPS measurements and analysis. All authors discussed the results and commented on the manuscript. Y. H. supervised the project and L. X. revised the manuscript.

Conflicts of interest

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.
