A 2D layered cobalt-based metal–organic framework for photoreduction of  $CO<sub>2</sub>$  to syngas with a controllable wide ratio range†

Mei-Juan Wei, $\ddagger$ <sup>a</sup> Xian-Yan Xu, $\ddagger$ <sup>\*b</sup> Jia-Qi Song, $\ddagger$ <sup>a</sup> Mei Pan D<sup>\*a</sup> and Cheng-Yong S[u](http://orcid.org/0000-0003-3604-7858)

Photocatalytic  $CO<sub>2</sub>$  reduction to syngas (a mixture of  $CO$  and  $H<sub>2</sub>$ ) with adjustable composition is a prospective way to mitigate the energy shortage and the greenhouse effect. Herein, we synthesize a thermally stable two-dimensional cobalt-based metal–organic framework (denoted as "Co-TBAPy") consisting of cobalt metal centers and  $H_4TBAPy$  (1,3,6,8-tetrakis(p-benzoic acid) pyrene) as an organic linker, which exhibits superior  $CO<sub>2</sub>$  adsorption capability and a considerable specific surface area. In accordance with the energy levels of  $[Ru(bpy)_3]Cl_2.6H_2O$  as a sensitizer, Co-TBAPy is active for photocatalytic reduction of  $CO<sub>2</sub>$  to syngas with a wide controllable ratio range between 0.14 and 1.65 under visible-light irradiation. Moreover, the proportion of CO:  $H_2 = 1:2$  and 1:3 favorable for the synthesis of methanol and methane, respectively, can be precisely regulated, which few MOF-based photocatalysts have achieved so far. Furthermore, combined with DFT calculation, we reveal the influence of the water content of the reaction system in the process of photocatalytic  $CO<sub>2</sub>$  reduction to produce a controllable proportion of syngas, which is often a profound while elusive factor in photoreduction reactions. This work provides a feasible concept for the design and application of Co-MOF materials for the photoreduction of  $CO<sub>2</sub>$  to syngas in practical industrial fields. ### Introduction

Nowadays, the storage and transformation of carbon dioxide  $(CO<sub>2</sub>)$  are two promising approaches to reduce the excessive emission of  $CO<sub>2</sub>$  and ease immoderate consumption of fossil resources.<sup>1</sup> Converting  $CO<sub>2</sub>$  into value-added chemicals or fuels by artificial photosynthesis is recognized as a reliable way to utilize  $CO<sub>2</sub>$  and store solar energy simultaneously. Since  $CO<sub>2</sub>$ reduction involves multi-electron processes and competition of hydrogen evolution, the photoreduction products of CO<sub>2</sub> are diverse, including CH<sub>4</sub>, CH<sub>3</sub>OH, HCOOH, CO, H<sub>2</sub>, etc.<sup>2,3</sup> To our knowledge, syngas, a mixture of CO and  $H_2$ , is a significant feedstock for the synthesis of high-value added fuels and chemicals by Fischer–Tropsch processes. For actual industrial applications, definite ratios of syngas correspond to certain products. Typically, syngas with the ratio of CO :  $H_2 = 1 : 1, 1 : 2$ and 1:3 can be utilized to synthesize alcohol, methanol and

methane, respectively.<sup>4</sup> However, the traditional preparation of syngas through a water gas shift reaction requires harsh conditions and might result in syngas with unsuitable ratios, which restrict its practical industrial application.<sup>5-9</sup>

Therefore, the exploration of appropriate catalysts to prepare a tunable composition of syngas under mild conditions is highly attractive. To date, various photocatalysts have been verified to be suitable catalysts for photocatalytic reduction of  $CO<sub>2</sub>$  to syngas. For instance, Co-ZIF-9 or  $Co<sub>3</sub>O<sub>4</sub>$  can serve as a photocatalyst to photoreduce  $CO<sub>2</sub>$  to syngas under visible light with unadjusted ratios.<sup>10</sup> TiO<sub>2</sub> mesoporous hollow spheres decorated with CuPt alloys and  $MnO<sub>x</sub>$  and a heterostructured CoAl-layered double hydroxide/ $MoS<sub>2</sub>$  nanocomposite photocatalyst (CoAl-LDH/MoS<sub>2</sub>) exhibit excellent performance in  $CO<sub>2</sub>$ photoreduction to CO and  $H_2$  with a tunable ratio.<sup>8,11</sup> However, in order to achieve the desired  $CO:H_2$  ratio of syngas, the structure of the above composite photocatalysts must be well modified accordingly, which is complicated and the mechanism behind is difficult to reveal. Consequently, the preparation of visible light driven catalysts that can produce an adjustable ratio of syngas efficiently and the clear clarification of the structure–performance mechanism are still daunting challenges.

Metal–organic frameworks (MOFs), a type of crystalline material composed of metal nodes and organic ligands as linkers, have been widely researched in various fields,<sup>12</sup> such as

<sup>‡</sup> These authors contributed equally to this work and should be regarded as co-first authors.

gas adsorption,<sup>13</sup> luminescence,<sup>14</sup> catalysis,<sup>15-17</sup> etc. Thanks to their adjustable cavities, large specific surface area, easy modification of the structure and excellent adsorption performance of CO<sub>2</sub>, some MOFs, like boron imidazolate frameworks (BIF-101) (ref. 18) and  $(Co/Ru)<sub>n</sub>$ -UiO67(bpydc),<sup>19</sup> have been reported as excellent heterogeneous photocatalysts for  $CO<sub>2</sub>$ photoreduction to syngas. 2D layer-like MOFs due to their readily accessible active sites and facility for mass diffusion exhibit dramatically boosted photocatalysis.<sup>20-24</sup> However, most of the MOF-based photocatalysts are unstable and prone to structural collapse leading to deactivation, and the research on MOF-based catalysts towards  $CO<sub>2</sub>$  photoreduction to syngas with tunable ratios is still in infancy.

Transition metals, especially Cu, Co, Zn and Ni with multiple redox states, can provide favorable CO<sub>2</sub> adsorption sites and advantageous catalytic sites.16,25 Among them, cobalt (Co)-based complexes are not only low-cost,<sup>26</sup> but also applicable as cocatalysts to enhance  $CO<sub>2</sub>$  photoreduction by promoting the photogenerated electron separation.27,28 Moreover, compared with Cu and Ni, Co possesses good binding capacity for both  $CO<sub>2</sub>$  and protons, which can serve as promising catalytic sites for  $CO<sub>2</sub>$  reduction to syngas. In an attempt to build an efficient CO2 photoreduction system, an effective electron-transport chain and strong light-harvesting capability are crucial. Generally, pyrene and its derivatives possess rigid extended  $\pi$ systems, which might display  $\pi$ -conjugation or intermolecular  $\pi$ – $\pi$  interaction and provide potential for visible-light absorption. Therefore, pyrene-based metal–organic frameworks have attracted much attention as photocatalysts.<sup>29</sup>–<sup>32</sup>

Herein, a thermally stable two-dimensional cobalt-based metal-organic framework,  $\{[Co_2(TBAPy)(H_2O)_2]\cdot(DMF)(H_2O)_8\}_n$ (Co-TBAPy), was assembled successfully with the pyrene-based ligand  $H_4$ -TBAPy (1,3,6,8-tetrakis(p-benzoic acid)pyrene) serving as a linker and cobalt as a node through a facile solvothermal method. Cooperating with  $\lceil \text{Ru(bpy)}_3 \rceil \text{Cl}_2 \cdot 6\text{H}_2\text{O}$  as a photosensitizer and triethanolamine (TEOA) as a sacrificial agent, Co-TBAPy exhibits excellent photocatalytic performance towards  $CO<sub>2</sub>$  reduction under visible light, and can achieve a CO evolution rate of 1856.5 µmol  $g^{-1}$  h<sup>-1</sup>. Especially, the ratio of syngas  $(CO/H<sub>2</sub>)$  can be regulated in a wide range between 0.14 and 1.65 simply by adjusting the water content in the photocatalytic system, and a precise proportion of CO :  $H_2 = 1:2$  and 1 : 3 favourable for fuel synthesis can be attained. Theoretical calculations were performed to clearly disclose the mechanisms.

### Results and discussion

Single-crystal X-ray diffraction verifies that Co-TBAPy crystallizes in a triclinic space group  $P\bar{1}$ , which is the same as that reported before (Table S1†).<sup>33</sup> Each asymmetric unit possesses a  $Co<sup>2+</sup>$  atom, a TBAPy<sup>4−</sup> ligand and a coordinated water molecule. In detail, Co-TBAPy is constructed from dinuclear  $Co<sub>2</sub>(CO<sub>2</sub>)<sub>4</sub>$  paddle-wheel secondary building units (SBUs) capped with two water molecules at the axial positions, which are further connected by four TBAPy<sup>4−</sup> ligands (Fig. 1a). It is due to the dinuclear paddle-wheel structure that gives rise to a two-

dimensional layered structure in Co-TBAPy equipped with two one-dimensional rhombus channels (size 6.34  $\times$  7.18 Å and 7.21  $\times$  9.08 Å, respectively) perpendicular to each layer (Fig. 1b). Confirmed by TOPOS software, Co-TBAPy retains a  $(4,4)$ -net topology, which can be simplified into an sql net (Fig. 1c). The crystal structure and refinement data of Co-TBAPy are supplied in Table S2.† As shown in the SEM images (Fig. S1†), Co-TBAPy presents a regular block shape with a flat surface, showing a thickness of  $\sim$ 7 μm and a length of 20–50 μm. To investigate the purity, the powder X-ray diffraction patterns (PXRD) of Co-TBAPy synthesized were obtained, which exhibited excellent consistency with the simulated one (Fig. 1d).

The powder of as-synthesized Co-TBAPy was immersed in various polar solvents, like acetone, methanol, ethanol, acetonitrile (MeCN), dimethylacetamide (DMA) and dichloromethane (DCM), in which Co-TBAPy can retain the pristine structure for 6 days at room temperature. Moreover, it can exist stably in water for 3 days. All of the PXRD diagrams without obvious changes have proved the solvent stability and universality of Co-TBAPy (Fig. S2†). Compared with the FT-IR spectrum of H4TBAPy, the disappearance of the hydroxyl vibration peak of –COOH in the range of 3400–3000  $\text{cm}^{-1}$  in the spectrum of Co-TBAPy illustrates the formation of Co–O bonds (Fig. S3†). Simultaneously, the peak at 1750–1620  $\text{cm}^{-1}$  originating from the vibration of the carbonyl group (-COOH) shifts to a lower wavenumber. Thermogravimetric (TG) analysis exhibits a weight loss of ∼12.2% in the range of 98–180 °C, which is attributed to the loss of  $H_2O$ . And the core frameworks of Co-TBAPy can remain intact even at 405 °C (Fig. S4†). Calculated by using PLATON software, the solvent accessible volume of Co-TBAPy is estimated to be 33.3% and the total potential solvent area volume is 376.6  $\AA^3$ .

A type I isotherm was observed from the nitrogen adsorption/desorption curves at 77 K (Fig. 2a), indicating the presence

Fig. 2 (a)  $N_2$  adsorption–desorption isotherms at 77 K. (b)  $CO<sub>2</sub>$ isotherms at 273 K and 298 K of Co-TBAPy. (c) Tauc plot of Co-TBAPy. (d) Mott–Schottky plot of Co-TBAPy at 500 Hz and 1000 Hz, respectively.

of micropores in Co-TBAPy. The Brunauer–Emmett–Teller (BET) surface area was calculated to be 851 m<sup>2</sup> g<sup>-1</sup> and the average pore width is evaluated to be ∼0.67 nm, demonstrating abundant potentially active sites for photocatalysis (Fig. S5†). Furthermore, Co-TBAPy displays a high affinity to  $CO<sub>2</sub>$ , whose maximum adsorption capacity is measured to be 56.5 cm<sup>3</sup> g<sup>-1</sup> at 273 K (Fig. 2b). The adsorption enthalpy for carbon dioxide is calculated to be 23.5–26.6 kJ mol<sup>-1</sup>, revealing that Co-TBAPy is a kind of potential material for photocatalytic reduction of  $CO<sub>2</sub>$ (Fig. S6†).

The ultraviolet-visible absorption (UV-vis) spectrum shows that Co-TBAPy has excellent absorption capacity for visible light, in which the maximum adsorption value reaches 680 nm (Fig.  $S7\dagger$ ). As calculated by the Kubelka–Munk (K–M) method<sup>34</sup> (Fig. 2c), the band gap of Co-TBAPy is estimated to be 1.84 eV, unveiling its potential to be a kind of semiconducting photocatalyst. Mott–Schottky measurements on Co-TBAPy were conducted at 500 Hz and 1000 Hz, respectively (Fig. 2d). The positive slope of the curves elucidates that Co-TBAPy is a typical n-type semiconductor and its flat band position is determined to be  $\sim$ −0.88 V vs. Ag/AgCl (*i.e.*, −0.68 V vs. NHE). Since it is generally accepted that the bottom of the conduction band (CB) of n-type semiconductors is more negative by about 0.1 V than the flat band position,<sup>35</sup> the CB of Co-TBAPy is forecasted to be −0.78 V vs. NHE, which is more negative than the redox potential of  $E(CO_2/CO) = -0.53$  V (vs. NHE).<sup>36</sup> In light of the band gap of 1.84 eV determined above, the value of the valence band (VB) is estimated to be 1.06 V vs. NHE.

Considering the prominent thermal and solvent stability, specific surface area, and the suitable band positions for  $CO<sub>2</sub>$ redox potential, the  $CO<sub>2</sub>$  photoreduction performance of Co-TBAPy under visible light was determined on a  $CO<sub>2</sub>$ -saturated mixture of acetonitrile and water with  $\left[\text{Ru(bpy)}_{3}\right] \text{Cl}_{2}$  serving as a photosensitizer and TEOA acting as a sacrificial agent. CO was detected as the only carbonous product and  $H_2$  was discovered

as the byproduct using a gas chromatograph. As the illumination time increases, the evolution of CO increased rapidly, while the yield of  $H<sub>2</sub>$  did not decrease significantly. As displayed in Fig. 3a and S8, $\dagger$  the amounts of CO and H<sub>2</sub> reach 27 µmol and 156  $\mu$ mol after 24 h illumination, in which the highest production yield of CO can reach 990.8 µmol  $g^{-1}$  h<sup>-1</sup>. The turnover number (TON) is calculated to be 5.4 for CO and 31.2 for  $H<sub>2</sub>$  according to the content of cobalt of Co-TBAPy used in photocatalysis.

To probe the key factors that influence the action of photocatalytic reduction of  $CO<sub>2</sub>$ , a series of control experiments were conducted (Table S2†). In the absence of light,  $[Ru(bpy)_3]$  $Cl_2 \cdot 6H_2O$  or TEOA, there are no gaseous products detected, unveiling that light, a photosensitizer and a sacrificed agent are essential for  $Co-TRAPV$  in the catalytic  $CO<sub>2</sub>$  reduction process. Without Co-TBAPy, less CO and  $H_2$  are produced, which reveals that Co-TBAPy does play a catalytic role in the photoreduction process. While replacing  $CO<sub>2</sub>$  with N<sub>2</sub>, no CO was evolved. Isotopic  ${}^{13}CO_2$  labeling experiments verified  $CO_2$  as the only carbon source (Fig. 3b). Compared with the air sample, the peak at 28  $m/z$  shown in Fig. 3b (left) originates from the N<sub>2</sub> of air leaked in the injection needle. Furthermore, recycling experiments were conducted to examine the stability of Co-TBAPy. After three rounds of recycling tests, the photocatalytic activity is well maintained (Fig. 3c and S9†). Deduced from the PXRD pattern and FT-IR spectrum of Co-TBAPy after photocatalysis, Co-TBAPy retained integrated frameworks (Fig. S10 and S11†). Obviously, Co-TBAPy is manifested to be a stable heterogeneous catalyst for photocatalytic reduction of CO2. Published on 29 November 2022. Downloaded on 29 November 2022. The state of Constrained on 2022. The state of the sta

It is acknowledged that CO and  $H_2$  are the main components of syngas for methanol synthesis and the Fischer–Tropsch

(b) GC-MS results of the isotopic experiment under a  $^{13}CO_2$  atmosphere (right) and for comparison, the air sample was detected. (c) The amounts of CO during three-run recycling experiments. (d) Plots of H<sub>2</sub>/CO generation with the tuning of the ratio of H<sub>2</sub>O under similar conditions for an 18 h reaction and the curve of the ratio of syngas (CO/H<sub>2</sub>) at different H<sub>2</sub>O contents.

reaction.<sup>37</sup> Since the carbon product selectivity is wonderful without an excess carbonous product during the process of photocatalytic reduction of  $CO<sub>2</sub>$ , it is theoretically feasible to use the competitive reaction of hydrogen evolution to adjust the output of CO and  $H_2$ , thereby realizing an adjustment of syngas in various ratios. Photocatalytic  $CO<sub>2</sub>$  reduction was performed under different contents of water added into MeCN solution. As shown in Fig. 3d, by using pure MeCN solvent without water, the evolution of CO (2924.2 μmol  $g^{-1}$ ) is less than that of hydrogen (20 893.7 µmol  $g^{-1}$ ). As the water content increases, the production of CO gradually increases, and the output of  $H_2$  first increases accordingly but then decreases when the water content is higher than 8%. When the water content reaches 10%, the CO evolution can reach 37.13 µmol after 10 h irradiation, during which the highest CO production rate reaches 1856.5 µmol  $g^{-1}$ h<sup>-1</sup> (Table S2,† entry 1). Evidently, by simply adjusting the water content of the system, we can achieve a wide range of controllable synthesis of the syngas ratio  $CO/H<sub>2</sub>$  from 0.14 to 1.65. As compared in Table S3,† in the current research on the photocatalytic reduction of  $CO<sub>2</sub>$  to produce controllable proportions of syngas, Co-TBAPy outperforms most MOF-based catalysts, homogeneous cobalt complexes and some inorganic semiconductors. It is worth mentioning that when using a  $H_2O$ content of 6%, the evolution of CO and  $H_2$  keeps a ratio nearly at 1 : 3, which can serve as raw materials for the synthesis of methane. Moreover, when the content of  $H_2O$  goes up to 8%, the yield of CO and  $H_2$  can achieve a ratio of 1:2, which is a profitable composition of syngas for methanol synthesis and industrial application in Fischer-Tropsch hydrocarbon formation.<sup>8,38,39</sup> **Journal of Materials Chemistry A**<br>

To obtain an in-depth understanding of the electron transfer process on photocatalytic  $CO<sub>2</sub>$  reduction, a series of characterization tests on Co-TBAPy were conducted. The photocurrent response curves of Co-TBAPy were investigated (Fig. S12†). A fast and regular photocurrent response was recorded for each light-on/off event under visible-light ( $\lambda > 420$  nm) irradiation, indicating that the photogenerated electrons transferred quickly on the surface of Co-TBAPy without recombination. The steady state photoluminescence (PL) spectra and time-resolved transient PL decay spectra were investigated for the as-synthesized Co-TBAPy and ligand  $H_4$ TBAPy. An obvious fluorescence quenching phenomenon and shorter lifetime appear on Co-TBAPy, demonstrating that photo-excited electron–hole pairs separated efficiently on the surfaces (Fig. 4a and S13†).

Comparing different types of photosensitizers,  $\text{Ru(bpy)}_3$ ]  $Cl_2 \cdot 6H_2O$  exhibited the best light absorption performance during the photocatalytic  $CO<sub>2</sub>$  reduction (Fig. S14†). The band energy-level accordance between Co-TBAPy and [Ru(bpy)<sub>3</sub>]  $Cl_2 \cdot 6H_2O$  is a significant factor. The highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) energy levels of  $\left[\text{Ru(bpy)}_{3}\right]Cl_{2} \cdot 6H_{2}O$  are described to be 1.22 V and −1.27 V vs. NHE, respectively. As presented in Fig. 4b, the LUMO energy level is more negative than the CB position of Co-TBAPy, which is theoretically possible because photoexcited electrons can be transferred from the LUMO level of  $\left[\text{Ru(bpy)}_{3}\right]Cl_{2} \cdot 6H_{2}O$  to the CB of Co-TBAPy to reduce the CO<sub>2</sub> molecules bound on cobalt sites. PL quenching measurements were conducted on the photocatalytic system in acetonitrile.

Fig. 4 (a) Photoluminescence (PL) spectra of as-synthesized Co-TBAPy and the ligand H<sub>4</sub>TBAPy ( $\lambda_{ex}$  = 390 nm). (b) Schematic energy level diagram for Co-TBAPy and [Ru(bpy)<sub>3</sub>]Cl<sub>2</sub>. (c) Steady state fluorescence spectra of  $[Ru(bpy)_{3}]Cl_{2}$  upon the addition of increasing amounts of Co-TBAPy ( $\lambda_{ex}$  = 395 nm). (d) The high resolution X-ray photoelectron spectroscopy (XPS) of the Co 2p orbit of Co-TBAPy before and after photocatalysis.

With the increasing amounts of Co-TBAPy, the PL intensity of excited  $\left[\text{Ru(bpy)}_{3}\right]Cl_{2} \cdot 6H_{2}O$  gradually diminished, unveiling an oxidative quenching mechanism for the excited state  $\mathrm{[Ru(bpy)_3]^{2+}}$  where the excited electrons were transferred to Co-TBAPy (Fig. 4c).<sup>40</sup> In contrast, an evident enhanced PL intensity has arisen when different amounts of TEOA were added into  $\left[\text{Ru(bpy)}_{3}\right]Cl_{2} \cdot 6H_{2}O$  (Fig. S15†).

Moreover, high resolution X-ray photoelectron spectroscopy (XPS) was carried out to analyze the composition and chemical states of elements in Co-TBAPy (Fig. 4d and S16†). Before photocatalysis, the binding energies at 781.6 eV and 797.7 eV were ascribed to Co  $2p_{3/2}$  and Co  $2p_{1/2}$ , respectively, accompanied by two satellite peaks at 786.1 eV and 802.6 eV, attributed to the shakeup excitation of high-spin  $Co<sup>2+</sup>$  ions.<sup>41</sup> After photocatalysis, a slight shift to a lower Co binding energy was observed, disclosing that some of the cobalt atoms on the surface received electrons during photocatalysis, together with a coordination environment change of cobalt.<sup>42</sup> Analogously, the XPS spectrum of Co 3s displays a strong splitting attributed to the  $3d<sup>7</sup>$  high-spin configuration of  $Co^{2+} (S = 3/2)$  before photocatalysis, while after photocatalysis, only a single peak at 102.5 eV is observed (Fig.  $S17\ddagger$ ).<sup>43</sup> These results further confirmed that Co sites served as an electron transfer intermediate station during the photocatalytic process, which can receive electrons from the photosensitizer and then transfer to the bound  $CO<sub>2</sub>$ .

On the basis of the above photocatalytic results and physical characterization, a possible mechanism of photocatalytic reduction of  $CO<sub>2</sub>$  in the Co-TBAPy participated system is proposed (Scheme 1). Under visible-light irradiation, the light absorber  $\left[\text{Ru(bpy)}_{3}\right]Cl_{2} \cdot 6H_{2}O$  is excited to generate photo-excited electron– hole pairs, in which photogenerated electrons migrate to the Co sites by oxidative quenching and excited state  $[Ru(bpy)_3]^{2^*}$  is reduced by the electron donor TEOA. Then the  $CO<sub>2</sub>$  molecules

Scheme 1 Proposed catalytic mechanism for the photocatalytic reduction of CO<sub>2</sub> catalyzed by Co-TBAPy.

absorbed on Co-TBAPy accept electrons from cobalt sites to form CO, accompanied by hydrogen evolution. Among these processes, adjusting the water content in the photocatalytic system can provide alterable protons for the formation of CO. Meanwhile,  $H<sub>2</sub>O$  molecules can stabilize the  $CO<sub>2</sub>$  reaction intermediate through the hydrogen bonding effect. It might result in a more favorable  $CO<sub>2</sub>RR$  than the HER when a higher water content is involved, which effectively realizes the controlled synthesis of syngas in different proportions.

Density functional theory (DFT) calculations were carried out to reveal the effect of the water content on the performance of Co-TBAPy photocatalytic reduction of  $CO<sub>2</sub>$  to syngas with a wide range of adjustable ratios (Fig. S18† manifesting the calculated configurations).<sup>44-46</sup> The band gap of a photocatalyst is crucial to determine its catalytic performance; therefore, the band structure of Co-TBAPy is first calculated as shown in Fig. S19,† giving the band gap at 1.79 eV, in reasonable agreement with the experimental results. In addition, the density of states (DOS) of Co-TBAPy also unveils that the bottom of the conduction band is mainly contributed by the Co and C atoms while the top of the valence band is mainly contributed by the C atoms. Next, we considered the reaction mechanism of photocatalytic  $CO<sub>2</sub>$ reduction over Co-TBAPy.<sup>47,48</sup> As shown in Fig. 3d, the evolution of CO gradually increases as the  $H<sub>2</sub>O$  content increases to a maximum of 8% and then slightly drops at 10%. According to the literature, with the presence of water in the MeCN solvent, the CO formation reaction may proceed via a proton-coupled electron transfer between  $CO_2$  and  $H_2O$  (eqn (1)).<sup>49</sup>

$$
CO_2(g) + H_2O(l) + 2e^- \rightarrow CO(g) + 2OH^-
$$
 (1)

in which the presence of  $H_2O$  as a proton source may facilitate the CO formation. Furthermore, in the cases of some cobalt complexes,  $H_2O$  molecules stabilize the  $CO_2$  molecules bound to the catalyst by forming hydrogen bonds, which also promotes the CO formation. Based on the above two facts, we propose that the interaction and charge transfer between  $CO<sub>2</sub>$ and  $H<sub>2</sub>O$  are crucial for the mechanism of the CO formation reaction catalyzed by Co-TBAPy. However, the origin of the dependence of CO evolution on the  $H_2O$  content remains unclear. To unravel the reaction mechanism, we investigated both the  $H_2O$  activation and hydrogen bond interaction which are proposed to be important for the HER and  $CO_2RR$ .<sup>50,51</sup> We found that, for single molecule adsorption, the adsorption of H2O over a Co site is much stronger (adsorption energy

 $E_{\text{ads}} = -1.23 \text{ eV}$ ) than that of CO<sub>2</sub> ( $E_{\text{ads}} = -0.25 \text{ eV}$ ), indicating a preference towards  $H_2$  evolution rather than the  $CO_2RR$  under a low  $H_2O$  content (Fig. S20†).<sup>52</sup> With an extra electron addition to Co-TBAPy,  $CO<sub>2</sub>$  only physisorbs on Co with up to  $4H<sub>2</sub>O$ molecules surrounded (Fig. 5a i-iii). Interestingly,  $CO<sub>2</sub>$  chemisorbs on Co with more than five  $H_2O$  molecules presented (Fig. 5a iv and v). Upon chemisorption,  $CO<sub>2</sub>$  attaches to Co via a side-on configuration with one of its  $C=O$  double bonds.<sup>53,54</sup> Bader charge analysis shows that barely no electrons are accumulated on the  $CO_2$  molecule upon physisorption ( $-0.03e^-$  for  $(CO_2 + 2H_2O)$  and  $(CO_2 + 3H_2O)$  systems and  $-0.04e^-$  for  $(CO_2 +$  $4H<sub>2</sub>O$ )), while considerable electrons transfer from the catalyst to CO<sub>2</sub> in chemisorbed  $(CO_2 + 5H_2O)$  and  $(CO_2 + 6H_2O)$  systems  $(-0.47e^-$  and  $-0.44e^-$ , respectively). **Paper**<br>
Published Content ( $\frac{1}{2}$  Representation of Content ( $\frac{1}{2}$ 

As a further stage in understanding the activity difference of Co-TBAPy in the HER and  $CO<sub>2</sub>RR$  and explaining the experimental observation, we investigated the reaction pathways for both the HER and the  $CO<sub>2</sub>RR$  involving different numbers of water molecules using the computational hydrogen electrode (CHE) method (Fig. 5b and c and S20).55,56 According to a previous study, HER pathways can be summarized as the following four elementary steps under alkaline and neutral conditions:<sup>57</sup>

$$
H_2O(l) + * \rightarrow H_2O^* \tag{2}
$$

$$
H_2O^* \to OH^* + H^* \tag{3}
$$

$$
H^* \to \frac{1}{2}H_2\tag{4}
$$

$$
\text{OH*} + \text{e}^- \rightarrow \text{OH}^- + \text{*} \tag{5}
$$

For the  $CO<sub>2</sub>RR$  under a low water content (corresponding to the scenarios in which less than five  $H_2O$  molecules are involved), we proposed that  $H_2O$  adsorption and dissociation first occur due to the preferred  $H_2O$  adsorption on Co. The adsorption species OH\* and H\* can be obtained after  $H_2O$ dissociation. Then OH\* accepts electrons and desorbs from the Co site, which facilitates an interaction between  $CO<sub>2</sub>$  and remaining H\* to form an intermediate COOH\*. It is followed by the dissociation of COOH\* into a CO\* intermediate and OH−. Finally, CO is obtained after desorption. All the processes are summarized as follows:

$$
CO2(g) + H^* \to COOH^*
$$
 (6)

$$
COOH^* + e^- \rightarrow CO^* + OH^-
$$
 (7)

$$
CO^* \to CO(g) + *
$$
 (8)

On the other hand, for the  $CO<sub>2</sub>RR$  under a higher water content (corresponds to the scenarios in which five and six  $H_2O$ molecules are involved),  $CO<sub>2</sub>$  chemisorption is most likely achieved and its reduction to CO is possible as proposed below:<sup>58</sup>

$$
CO_2(g) + * + e^- \to *CO_2
$$
 (9)

Fig. 5 (a) The configuration of  $CO<sub>2</sub>$  adsorption on Co-TBAPy and corresponding adsorption free energy at 298 K, which involves different numbers of H<sub>2</sub>O molecules: (i) two H<sub>2</sub>O, (ii) three H<sub>2</sub>O, (iii) four H<sub>2</sub>O, (iv) five H<sub>2</sub>O, and (v) six H<sub>2</sub>O. The brown dashed line labels the hydrogen bonding, while the blue dashed line represents the distance between atoms. (b and c) Calculated free energy diagrams for the photocatalytic HER (b), and CO<sub>2</sub>RR to CO (c) involving a multiple number of H<sub>2</sub>O molecules (pH = 8 and at 0 V vs. RHE). \* represents an active site.

$$
^{\ast}CO_{2}^{-} + H_{2}O(l) \rightarrow COOH^{\ast} + OH^{-}
$$
 (10)

We can find that under a low water content (corresponding to the scenarios with two to four  $H_2O$  molecules), the reaction mechanisms of both the HER and the  $CO<sub>2</sub>RR$  go through via the process of H2O adsorption and dissociation. Considering the fact that the H<sub>2</sub>O dissociation (H<sub>2</sub>O<sup>\*</sup>  $\rightarrow$  H<sup>\*</sup> + OH<sup>\*</sup>) is a common step for the HER and  $CO<sub>2</sub>RR$ , although it is also the determining step for systems with  $3H<sub>2</sub>O$  or  $4H<sub>2</sub>O$ , the competition of the HER and  $CO<sub>2</sub>RR$  is determined by the elementary steps with maximum reaction energy subsequent to  $(H_2O^* \rightarrow H^* + OH^*)$  for each reaction process, *i.e.* H<sup>\*</sup>  $\rightarrow \frac{1}{2}$  (eqn (4)) for the HER and OH<sup>\*</sup> +  $e^ \rightarrow$  OH<sup>−</sup> + \* (eqn (5)) for the CO<sub>2</sub>RR, which is 1.05 eV vs. 1.37 eV for the  $2H_2O$  system, 0.57 eV vs. 0.76 eV for the  $3H_2O$  system, and 0 vs. 0.42 eV for the  $4H<sub>2</sub>O$  system. Therefore, the HER is more preferred than the  $CO<sub>2</sub>RR$  due to the lower reaction free energy of  $H^* \rightarrow \frac{1}{2}H_2$  along the HER compared to that of OH\* + e<sup>−</sup> → OH<sup>−</sup> +  $\frac{2}{2}$  along the CO<sub>2</sub>RR under a low water content.

Meanwhile under a higher water content (corresponding to the scenarios with five and six  $H_2O$  molecules involved in the reaction), the HER is now determined by using  $H^* \rightarrow \frac{1}{2}H_2$  (eqn (4)). On the other hand, the CO<sub>2</sub>RR will not go through  $H_2O$ dissociation but direct protonation to \*COOH due to the

presence of  $CO<sub>2</sub>$  chemisorption, and its determining step becomes  $^*CO_2^-$  + H<sub>2</sub>O(l)  $\rightarrow$  COOH<sup>\*</sup> + OH<sup>-</sup> (eqn (10)). In these cases, the competition of the HER and  $CO<sub>2</sub>RR$  is controlled by the reaction free energies of the corresponding determining steps (i.e. eqn  $(4)$  and  $(10)$ , respectively). The calculated reaction free energies are 1.19 and 1.03 eV for  $H^* \rightarrow \frac{1}{2}H_2$  (eqn (4)) along the HER pathway in  $5H_2O$  and  $6H_2O$  systems, respectively, while the calculated reaction free energies are 0.66 and 0.68 eV for \*CO<sub>2</sub><sup>−</sup> + H<sub>2</sub>O(l) → COOH<sup>\*</sup> + OH<sup>−</sup> (eqn (10)) along the CO<sub>2</sub>RR pathway in  $5H<sub>2</sub>O$  and  $6H<sub>2</sub>O$  systems, respectively. Therefore, the  $CO<sub>2</sub>RR$  shows lower reaction free energy than the HER and thus the  $CO<sub>2</sub>RR$  suppresses the HER under a high water content. These computational results are consistent well with the experiments, showing promise to control the ratio of  $CO: H<sub>2</sub>$  in syngas photosynthesis from  $CO<sub>2</sub>$  reduction by using Co-based MOFs as a photocatalyst and water content as a modulator.

### Experimental section

### Chemicals and characterization

All reagents of analytical grade were acquired through commercial channels and used without further purification.

The PXRD spectra were recorded on a Rigaku SmartLab X-ray diffractometer using Cu-K $\alpha$  radiation ( $\lambda = 1.54056$  Å) at room temperature. The SC-XRD data were recorded at the SSRF (Shanghai Synchrotron Radiation Facility) 14B beamline. The Xray photoelectron spectroscopy (XPS) data were collected on an ESCALab 250 using a monochromatic Al Ka radiation source. The FT-IR spectra were collected on a Nicolet/Nexus-670 spectrometer using a KBr disk. The thermogravimetric (TG) analyses were performed on a NETZSCH TG209 system in nitrogen with a heating rate of 5  $^{\circ}\textrm{C}$  min $^{-1}$ . The Brunauer–Emmett–Teller (BET) specific surface area and pore volume were analysed by using a Quantachrome Autosorb-iQ2-MP gas adsorption analyzer. The gases  $(N_2 \text{ and } CO_2)$  used in the gas adsorption measurements hold ultra-high purity. The morphology of the samples was determined by using an ultra-high resolution field emission scanning electron microscope (SEM, SU8010). The UVvis absorption data were obtained on a SHIMADZU UV-3600 equipped with an integrating sphere using  $BaSO<sub>4</sub>$  as a reference. Photoluminescence (PL) and time-resolved fluorescence decay spectroscopy were performed on an EDINBURGH FLS980 fluorescence spectrophotometer. Paper<br>

#### Synthesis of Co-TBAPy  $\left[\text{Co}_2(\text{TBAPy})(\text{H}_2\text{O})_2\right] \cdot (\text{DMF})(\text{H}_2\text{O})_8\}_n$

The crystals of Co-TBAPy were obtained by a facile solvothermal method between H4TBAPy (1,3,6,8-tetrakis(p-benzoic acid)pyrene) (0.015 mmol) and  $Co(NO<sub>3</sub>)<sub>2</sub>·6H<sub>2</sub>O$  (0.1 mmol) in a mixed solution of DMF,  $H<sub>2</sub>O$ , dioxane and concentrated hydrochloric acid (v/v/v/v,  $2/1/1/0.01$ ) at 120 °C for 3 days. Green transparent flake crystals were collected and washed with DMF and acetone, respectively (yield at ∼76.5%, based on ligands). The Co-TBAPy synthesized was soaked in acetone for 3 days, during which the acetone was changed every 12 h. After that, Co-TBAPy was filtered and dried in an oven at 100  $\mathrm{^{\circ}C}$  for 12 h and activated Co-TBAPy was obtained. Elemental analysis: found for C47H49O19NCo2: C 53.49, H 4.14, N 0.95%; calcd: C 53.77, H 4.67, N 1.33%.

#### Photocatalytic test

Photocatalytic carbon dioxide reduction tests were carried out in a 54 mL closed Pyrex reactor with a LED lamp (light intensity: 100 mW cm−<sup>2</sup> , PCX50B Discover multi-channel photochemical reaction system, Beijing Perfectlight Technology Co., Ltd) serving as a visible light source. Typically, the catalyst Co-TBAPy  $(0.005 \text{ mmol}, \text{activated})$  and  $\left[\text{Ru(bpy)}_{3}\right] \text{Cl}_{2} \cdot 6\text{H}_{2}\text{O}$   $(0.01 \text{ mmol})$ were dispersed in an acetonitrile aqueous solution of different ratios, in which TEOA (1 mL) acted as a sacrificial agent to suppress the oxidation half reaction. Then the reaction flask was evacuated and filled with  $CO<sub>2</sub>$ , repeated three times before the irradiation. The gas products were detected by using a gas chromatograph (GC9790, Fuli Analytical Instrument Co., Ltd) with a thermal conductivity detector (TCD) for  $H_2$  detection and a flame ionization detector for CO detection.

#### Photoelectron measurement

All of the photoelectric tests adopted a standard three-electrode system, consisting of a platinum plate electrode (1 cm  $\times$  1 cm) as the counter electrode, Ag/AgCl as the reference electrode and MOF catalyst coated fluorine doped tin oxide (FTO) glass as the working electrode with a working area of 0.5  $\times$  0.5 cm<sup>2</sup>. In detail, 5 mg of Co-TBAPy samples and 20  $\mu$ L Nafion D-520 dispersion (5% w/w in water and 1-propanol) were added into 0.5 mL of ethanol and then ultrasonicated for 5 min to obtain a suspension. 0.2 mL of the suspension liquid was added dropwise onto the FTO glass and the coating area was restricted to 0.25  $\text{cm}^2$  by using insulating tape. The well coated FTO glass was dried at 85 °C for a day. The electrolyte was 0.5 M sodium sulfate aqueous solution. Both Mott–Schottky measurements and photocurrent response tests were performed on a CHI 660E electrochemical analyzer (CH Instruments, Chenhua Co., Shanghai, China). The Mott–Schottky measurements were performed at 500 Hz and 1000 Hz, respectively, with an amplitude at 0.01 V. During the photocurrent response tests, a Xe Lamp (300 W,  $\lambda$  > 420 nm, CEL-HXF300, Beijing Aulight Co.,) served as the visible light source. The on–off cycle of illumination was manually controlled by the operator at a time interval of 5 s.

#### Computational details

All calculations were performed in a spin-polarized fashion and by using the VASP code based on plane-wave basis sets. The generalized gradient approximation (GGA) with the Perdew– Burke–Ernzerhof (PBE) functional was for the exchange–correlation functional. Projector augmented wave (PAW) potentials were used for electron–ion interactions with an energy cutoff of 500 eV. The energy and force convergence settings were  $10^{-5}$  eV and 0.02 eV  $\AA^{-1}$ , respectively. Hubbard U correction was also introduced for the Co atom with  $U_{\text{eff}} = 3.3$ . The k-point mesh was set to be  $4 \times 2 \times 2$  for geometry optimization and  $8 \times 5 \times 3$ for electronic structure calculations. The cell parameter of Co-TBAPy after the optimization is 6.72 Å  $\times$  10.85 Å  $\times$  16.06 Å,  $\alpha$  = 90.00,  $\beta$  = 90.00, and  $\gamma$  = 102.01, in agreement with the experimental results.

As it is known that  $H_2$  evolution and the CO<sub>2</sub>RR go through a process containing proton–electron pair transfer, the computational hydrogen electrode (CHE) method thus was used to calculate the free energy of each intermediate state, of which the free energy of proton–electron pairs  $(H^+ + e^-)$  equals  $\frac{1}{2}H_2(g)$ . The Gibbs free energy change  $(\Delta G)$  for each elemental step is calculated by

$$
\Delta G = \Delta E + \Delta E_{ZPE} - T\Delta S + \Delta G_{pH}
$$

where  $\Delta E$  is the electronic energy difference between free standing and adsorption states of reaction intermediates;  $\Delta E_{\rm ZPE}$ and  $\Delta S$  are the changes of zero point energy and entropy, respectively, which are obtained based on vibrational calculations. T is the temperature and set to be 298 K in this work and pH is set to be 8 because acetonitrile is the solvent.  $\Delta G_{\text{pH}} =$  $2.303k_BT \times pH$ , where  $k_B$  is the Boltzmann constant. The free energy of CO was calculated from the known free energy change (0.21 eV) of the reaction  $CO_2(g) + 2H^+ + 2e^- = CO(g) + H_2O(l)$ under the standard conditions. The  $CO<sub>2</sub>RR$  involves two

electron transfers, while the HER involves one electron transfers, and after the correction of  $\Delta G$ <sub>pH</sub>, the final  $\Delta G = 0.21 + 0.47$  $\times$  2 = 1.15 eV for the CO<sub>2</sub>RR and  $\Delta G$  = 0.47 eV for the HER. The adsorption energy  $(E_{ad})$  is computed by using the formula:

$$
E_{\rm ad} = E_{\rm sub+A} - E_{\rm sub} - E_{\rm A} \tag{11}
$$

where  $E_{\text{sub+A}}$ ,  $E_{\text{sub}}$  and  $E_{\text{A}}$  represent the total energies of the substrate with adsorbed species and the pure substrate without the adsorbate and adsorbate, respectively. And  $G_{\text{ad}}$  is the corresponding adsorption free energy at 298 K.

### Conclusions

In summary, a 2D cobalt-based metal–organic framework consisting of dinuclear  $Co_2(COO)_4$  paddle-wheel SBUs and TBAPy<sup>4−</sup> ligands with extended  $\pi$ -systems was synthesized by a facile solvothermal method and used as a stable photocatalyst to photoreduce  $CO<sub>2</sub>$  to syngas under visible light. Notably, the ratio of syngas as-prepared  $(CO/H<sub>2</sub>)$  can be adjusted in a wide range between 0.14 and 1.65 simply by adjusting the water content in the photocatalytic system. The proportion of syngas with CO :  $H_2 = 1:2$  and 1:3 was achieved respectively, which is desirable for the practical applications of methanol and methane synthesis. Photocatalytic experiments, characterization and DFT calculation elucidate the probable electron transfer processes, and the thermodynamic and kinetic feasibility of Co-TBAPy serving as a photocatalyst. This work might present a new low-cost metal–organic framework semiconductor for the artificial photosynthesis of syngas and a more accessible preparation route of syngas at various ratios. **Four all of Materials Chemistry A**<br> **Paper**<br>
