Local scale air quality impacts in the Los Angeles Basin from increased port activity during 2021 supply chain disruptions†

T. Nash Skipper,^a Jennifer Kaiser,^{ab} M. Talat Odman,^a Sina Hasheminassab^c and Armistead G. Russell^{*a}

Increased throughput and container ship backlogs at the ports of Los Angeles and Long Beach due to supply chain disruptions related to the COVID-19 pandemic caused a significant increase in the number of ships near the California coast, leading to concerns about increased air pollution exposure of nearby communities. We use a combination of satellite-based observations from TROPOMI and ground-based observations from routine surface monitoring sites with chemical transport model results to analyze the changes in NO₂ and PM_{2.5} in the Los Angeles Basin during a period in 2021 when the number of ships was at its peak. Using simulations to account for meteorological effects, changes are apportioned to emissions and meteorology. The largest emission-related changes in column NO₂ occurred immediately east of the ports where emission-related NO₂ increased by 28% compared to the baseline (2018–2019 average). In Central Los Angeles, emission reductions led to a 10% decrease in NO₂ during the same period. Emission-related PM_{2.5} increased by 0.7 μg m^{−3} on average with a maximum increase of 4.5 μg m^{−3} in the eastern part of Basin. The emission/meteorology attribution method presented here provides a novel approach to quantify emission-influenced changes in air quality that are consistent with observations and suggests that both NO₂ and PM_{2.5} were elevated in parts of the Los Angeles area during a period of increased port activity.

Environmental significance

Supply chain disruptions during the COVID-19 pandemic caused a backlog of container ships off the coast of California waiting to dock at the ports of Los Angeles and Long Beach. This raised concerns about increased air pollution for nearby communities which already suffer disproportionately poor air quality. Satellite-based NO₂ observations and ground-level NO₂ and PM_{2.5} observations are used with chemical transport model simulations to separate the roles of meteorology and emissions during a period in 2021 when the container ship backlog was at its peak. We find significant increases in NO₂ due to emissions in the areas immediately east of the ports and increased PM_{2.5} across much of the region which has implications for health and environmental justice.

Introduction

The ports of Los Angeles and Long Beach are adjoining seaports in Southern California which are the number one and two busiest ports in the United States (US).¹ Previous work has shown that the ports and associated freight distribution have significant impacts on local air quality.^{2–5} Due to supply chain disruption resulting from the COVID-19 pandemic, the ports experienced a significant increase in cargo throughput in 2021. The combined throughput of twenty-foot equivalent units

reached an all-time high (Fig. S1†), increasing by 16% in 2021 compared to the 2018–2019 average (Table S1†). The increased activity caused congestion at the ports, which led to many more cargo ships than normal waiting offshore for an opportunity to dock (Fig. 1). Ships were typically located near the California coast, using their auxiliary engines to provide power for ship-board functions. Many ships were waiting in waters immediately to the south of the ports and to the west of the coastline of Orange County (Fig. S2†).

The increase in ships and their proximity to the coast raised concerns about increased pollution in communities nearby. The California Air Resources Board (CARB) estimated that emissions of nitrogen oxides (NO_x) and particulate matter (PM) from ships were 30 and 0.8 tons per day above business-as-usual conditions in November 2021.⁶ In addition to increased ship emissions, increased cargo throughput and congestion led to increased truck and rail traffic from the distribution of goods

Fig. 1 Ships waiting to dock within 40 miles of the ports (black line) and the total number of ships waiting to dock (magenta line) at the ports of Los Angeles and Long Beach. During the study period of September–November 2021 (between the grey vertical lines), the number of ships near the ports reached its peak but began to decline after the ship queuing system was updated starting November 16, 2021. Data is from the Marine Exchange of Southern California via <https://www.marketplace.org/2022/09/29/ship-backlog-at-southern-californias-ports-eases/>.

Fig. 2 Map of the study domain in Southern California. County names are indicated on the map. The arrow shows the location of the ports of Los Angeles and Long Beach. The red boundary shows the location of the Carson, Wilmington, and West Long Beach AB617 community defined by the CARB. Lines showing distances of 20 nautical miles and 40 miles which are referenced in the text are provided on the map for context.

from the ports which further increased emissions nearby.⁷ According to emission inventory reports, diesel PM, NO_x, and sulfur dioxide (SO₂) emissions at the port of Los Angeles increased by 56%, 54%, and 145%, respectively, in 2021 compared to 2020.⁸ Emissions of these pollutants at the port of Long Beach also increased by 42%, 35%, and 38%, respectively, between 2020 and 2021.⁹ To alleviate the congestion, in October 2021 both ports and the Union Pacific Railroad Company

shifted to 24/7 operation. In response to the excess ships anchored near the shore, an update to the system for ship queuing was implemented effective November 16, 2021. Under the new system, ships were required to wait approximately 150 miles away from the coast, whereas under the previous system, ships entered the queue once they came within 20 nautical miles of the ports.¹⁰

The new system reduced the number of ships near the coast (Fig. 1), but concerns remained about increased exposure to air pollution during this time. Some areas near the ports are already disproportionately impacted by pollution, raising additional concerns about the environmental justice implications of the additional air pollution exposure that may have resulted from the increase in port and associated goods movement activity. In particular, the communities of Wilmington, Carson, and West Long Beach, which are part of the Assembly Bill 617 (AB617)¹¹ program established to monitor air pollution and reduce exposure in communities that are most heavily impacted by air pollution, are located near the ports (Fig. 2).

Here, we use a combination of satellite-based observations, ground-based measurements, and chemical transport model (CTM) simulations to quantify changes in air pollution in Southern California during the period September–November 2021 when the number of ships waiting near the coast reached its peak (Fig. 1). A CTM can be used to estimate the impacts of changing emissions. However, the emissions inventories used as inputs to the CTM are uncertain, and accurately updating emissions to account for unexpected changes in source activity due to the COVID-19 pandemic and resulting disruptions in the global supply chain is challenging and adds even more uncertainty. Comparing observed changes in air quality across years can give some sense of the effects of changing emissions, but year-to-year variation in meteorological effects on air pollutant concentrations can make it difficult to attribute changes in air quality directly to changes in emissions. We examine the changes in nitrogen dioxide (NO₂) and fine particulate matter (PM_{2.5}) during this period. Satellite retrievals and surface observations are readily available for NO₂, and NO₂ provides a good indication of combustion emissions from ships. PM_{2.5} surface observations are also readily available, and PM_{2.5} is the air pollutant that most contributes to adverse health impacts.¹² Effects of year-to-year differences in meteorology are estimated using a CTM. Observations are then adjusted for meteorological effects to obtain emission-related changes in 2021 compared to baseline levels in 2018 and 2019.

Methods and materials

Chemical transport model simulations

We use the Community Multiscale Air Quality (CMAQ) CTM version 5.3.3 (ref. 13) to perform the air quality simulations. The modeling domain is centered on Southern California with a horizontal resolution of 4 km (Fig. S3†). Simulations were performed for September–November (plus ten-day model spin-up over the last ten days of August to reduce the influence of initial conditions) for the years of 2018, 2019, and 2021 (B18, B19, and B21; B for base case). The average from 2018 and 2019

is used as the baseline with which to compare 2021. A simulation was not conducted for 2020 as the air quality during this year was significantly impacted by COVID-19 and thus does not provide a representative baseline since NO₂ was below typical levels.^{14,15} Two additional simulations were conducted to estimate the influence of meteorology. These were performed using emissions for 2018 and 2019 as in the B18 and B19 simulations with meteorology from 2021 as in the B21 simulation (E18M21 and E19M21; E for emissions and M for meteorology). Lateral boundary conditions and initial conditions for the simulations were taken from daily average concentrations from a northern hemisphere CMAQ simulation conducted by US EPA as part of EPA's Air Quality Time Series (EQUATES) project.¹⁶ Data from 2017 simulations were used as this was the most recent year that EQUATES results were available at the time the simulations were performed.

Emissions are based on the 2016 emissions modeling platform version 2 produced by US EPA and the emissions inventory collaborative.¹⁷ The platform uses a base year of 2016 and includes projected emissions for 2023. Emissions for 2018, 2019, and 2021 are obtained by linear interpolation of the emissions for each sector between the base 2016 emissions and the projected 2023 emissions. Details on each emissions sector and the projection methods used in the inventory are available in the platform technical support document.¹⁷ Fire emissions from the base inventory year of 2016 were used in all simulations so that the year-to-year changes in fire impacts did not obscure the effects of changes in anthropogenic emissions. We use seasonal average values to compare across years, so we expect that this averaging will reduce the influence of fires on the comparisons across years. Additionally, we expect that the incorporation of observations to apportion the changes to emissions and meteorology will capture any effects from differences in fires across years since fires will influence the observations which are used to derive the effects of emissions. Meteorological data for the CTM simulations are from the weather research and forecasting (WRF) model version 4.3.1.¹⁸ WRF data are prepared for the CMAQ simulations using the meteorology-chemistry interface processor¹⁹ version 5.1.

Satellite retrievals

Tropospheric Monitoring Instrument (TROPOMI) follows a low-earth, sun-synchronous orbit with an equator overpass time of 13:30 local solar time. Upgraded versions of the TROPOMI level 2 tropospheric NO₂ product were released during the study period. Version 1.3 was in operation during September–November 2018–2019. Versions 2.2 and 2.3.1 were in operation during September–November 2021. The upgrades lead to increases in NO₂ over cloud-free scenes, especially in polluted areas.²⁰ To avoid an artificial positive jump in NO₂, we use the product algorithm laboratory (PAL) dataset which was reprocessed with the version 2.3.1 algorithm.²¹ This dataset is available for May 1, 2018–November 14, 2021. We use the PAL data for September–November of 2018 and 2019 and for September 1–November 14, 2021. The version 2.3.1 product was used for November 15–30, 2021.

Data is filtered to include only pixels with solar zenith angle less than 75, quality assurance flag value greater than 0.5, and cloud fraction less than 0.3. Like Cooper *et al.* (2020),²² we use the NO₂ vertical profile from CMAQ with the TROPOMI averaging kernels to develop updated air mass factors (AMFs) to recalculate TROPOMI NO₂ column totals. TROPOMI data are oversampled onto the 4 km × 4 km CMAQ model grid to facilitate comparisons between TROPOMI and CMAQ using an oversampling technique by Sun *et al.* (2018).²³

Surface observations

Hourly NO₂ surface observations were obtained from the CARB Air Quality and Meteorological Information System (<https://www.arb.ca.gov/aqmis2/aqmis2.php>). We use observations from 1 to 2 pm Pacific Standard Time to compare to the TROPOMI NO₂ column totals since this includes the TROPOMI overpass time of 13:30 local solar time. We also compare TROPOMI NO₂ to daily maximum surface NO₂ as a sensitivity analysis. The comparison of surface observations and TROPOMI NO₂ columns allows for evaluation of the suitability of TROPOMI to provide an indicator for changes in ground-level exposures. Near-road monitoring sites are excluded from this analysis. These sites are not suitable for comparison to TROPOMI because the typical sharp gradients in NO₂ in the near-road environment cannot be resolved by TROPOMI. Exclusion of the near-road sites reduces the number of sites within the study domain from 44 to 39 sites. Daily average PM_{2.5} surface observations are obtained from the Air Quality System database (<https://www.epa.gov/aqs>). There are 45 PM_{2.5} sites within the study domain with data available for 2018, 2019, and 2021.

Traffic data

We use traffic volume data from the California Department of Transportation Performance Monitoring System (PeMS). Daily traffic volumes for September–November 2018, 2019, and 2021 for mainline highways were obtained from PeMS (<https://pems.dot.ca.gov/>). We calculate the change in traffic at each monitoring station as the total traffic volume in September–November 2021 compared to the average of the same period in 2018 and 2019. Data from individual stations are grouped by roadway and county, and the median change in traffic volume for stations along a particular roadway within a particular county is used to calculate the percent change in traffic along each section of roadway. We also obtained PeMS data for total vehicle miles traveled (VMT) and for truck VMT by roadway and county for the years of interest which were used to find the changes in total and truck VMT by county in 2021 compared to the baseline in 2018–2019.

Meteorological adjustments to observations

The differences between observations in 2018–2019 and 2021, whether satellite-based or ground-based, do not necessarily allow for the inference of the impacts of changing emissions. Part of the differences may be due to emissions, but some may be due to meteorology. We construct counterfactual

meteorology CMAQ simulations by using emissions from 2018 (E18) or 2019 (E19) and meteorology from 2021 (M21) to construct two counterfactuals (E18M21; E19M21) to split TROPOMI NO₂ columns and surface observations of NO₂ and PM_{2.5} into meteorological and emission effects. The change in the observed value is separated into emissions and meteorological components using the effects of meteorology derived from the CMAQ simulations (eqn (1)–(5)). Here O represents the observed NO₂ column total from TROPOMI or the observed surface NO₂ or PM_{2.5} concentration, while M is the modeled value from CMAQ coincident with the 13:30 local solar time TROPOMI overpass for NO₂ or the daily average modeled value for PM_{2.5}.

$$M_{\text{met ratio}} = \frac{\text{mean}(M_{\text{E18M21}}, M_{\text{E19M21}})}{\text{mean}(M_{\text{B18}}, M_{\text{B19}})} \quad (1)$$

$$O_{\text{E18M21,E19M21}} = \text{mean}(O_{18}, O_{19}) \times M_{\text{met ratio}} \quad (2)$$

$$\Delta O = \Delta O_{\text{emissions}} + \Delta O_{\text{meteorology}} = O_{21} - \text{mean}(O_{18}, O_{19}) \quad (3)$$

$$\Delta O_{\text{emissions}} = O_{21} - O_{\text{E18M21,E19M21}} \quad (4)$$

$$\Delta O_{\text{meteorology}} = \Delta O - \Delta O_{\text{emissions}} \quad (5)$$

Meteorological ratios ($M_{\text{met ratio}}$) are developed for both column total and surface level to separately account for meteorological effects throughout the entire vertical column and at the surface. A ratio method is used to represent the meteorological effects from CMAQ instead of an additive method that uses the modeled meteorological effect directly. One reason for this is that CMAQ column totals and surface concentrations of NO₂ may differ from the observed levels, so it is more reasonable to use the CMAQ meteorological impacts in a relative sense instead of an absolute sense. A second reason is that an additive

method can result in negative meteorologically adjusted column totals or surface observations which is avoided with the ratio method. While not identical to the method shown here, others have incorporated meteorological effects from CTMs with satellite data to estimate the effects of emission changes (e.g., Goldberg *et al.* (2020),¹⁴ Cao *et al.* (2022)²⁴). Within the study domain, the CMAQ meteorology ratio ($M_{\text{met ratio}}$ from eqn (1)) for the NO₂ vertical column totals has an average value of 1.0 and ranges from 0.7 to 1.5 (Fig. S4†).

Results and discussion

Model performance

The performance of simulated NO₂ is evaluated by comparison against surface monitors and TROPOMI vertical column densities (Fig. 3). Surface NO₂ is biased low on average across all hours of the day, but CMAQ does reproduce the diurnal pattern of observed NO₂. The seasonal average (September–November) column NO₂ is also mostly biased low. The exception is in areas where modeled column NO₂ is highest where the modeled column NO₂ tends to be biased high which is consistent with other recent modeling studies.^{25–27} The spatial variability of TROPOMI is well captured by CMAQ as indicated by the slope and correlation very close to 1 ($r = 0.96$; slope = 1.1 for 2021). Performance is similar for all simulation years for both surface and column NO₂ (Fig. S5†). Simulated meteorological values are evaluated against surface meteorological monitoring sites (Table S2†). For each meteorological parameter (relative humidity, temperature, and wind speed), CMAQ reproduces the observed diurnal variability (Fig. S6†). Wind speed has a normalized mean bias (NMB) of 47% to 49% across simulation years. Temperature is well simulated by the model but has a high bias (NMB = 7% to 8%). Relative humidity is biased low (NMB = −14% to −18%).

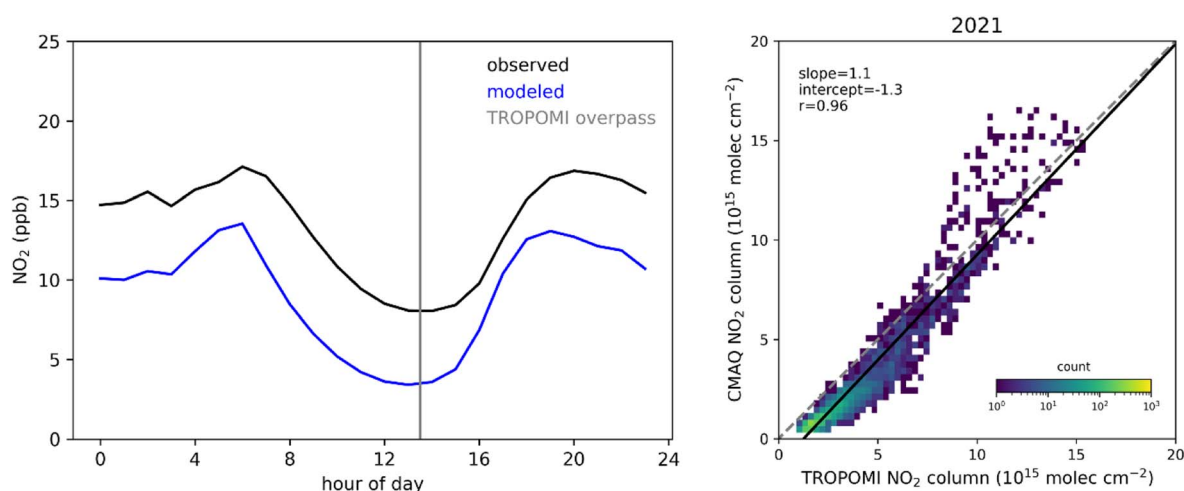

Fig. 3 Performance of CMAQ-simulated NO₂ in September–November 2021 compared to surface observations (left) and TROPOMI vertical column densities (right). For the surface monitoring sites, observed and modeled NO₂ are aggregated by hour across all sites in the CMAQ modeling domain. The TROPOMI overpass time of 13:30 local time is indicated with a grey vertical line. The comparison of vertical columns is for the average vertical column over the September–November study period. A one-to-one line is shown as a dashed grey line, and the linear regression between TROPOMI and CMAQ vertical columns is shown as a solid black line. The color scale represents the count of CMAQ/TROPOMI paired values that fall within each bin.

TROPOMI results and meteorological adjustments

TROPOMI NO₂ columns decreased over Central Los Angeles (−10% on average) and in some offshore areas. After accounting for meteorological effects, these reductions were found to be largely driven by changing emissions (Fig. 4). Emission-related increases in NO₂ were found over Tijuana, Mexico, near the southern edge of the study domain. In most other areas, column NO₂ increased. The largest increases were seen in parts of Los Angeles and Orange Counties in areas directly east of the ports and east of the area where ships were waiting offshore (+28% on average). After accounting for meteorological effects, these areas were found to be significantly impacted by emissions. We conclude that these areas were impacted by increased port activity. This is based on inference due to the vicinity to the ports and the area where ships were waiting offshore, the finding that the changes are due to emissions rather than

meteorology, and that the prevailing wind from west to east would transport emissions from the ports towards these areas (Fig. S7†). The changes in total and emission-related NO₂ over Central Los Angeles and east of the ports were found to be statistically significant (Fig. S8†).

Meteorology can impact NO₂ columns due to differences from year to year in how pollutants are transported. In some areas, the meteorological impacts showed that increases in NO₂ were solely due to meteorology. The portion of NO₂ column changes resulting from emissions decreased in northern Los Angeles County and in parts of western Riverside and San Bernardino Counties (−17% in both areas). However, increases in NO₂ because of meteorology (+25% in both areas) outweighed the emission-related reductions. In these areas, the changes in emission-related and meteorology-related changes were found to be statistically significant (Fig. S8†). Despite reductions in

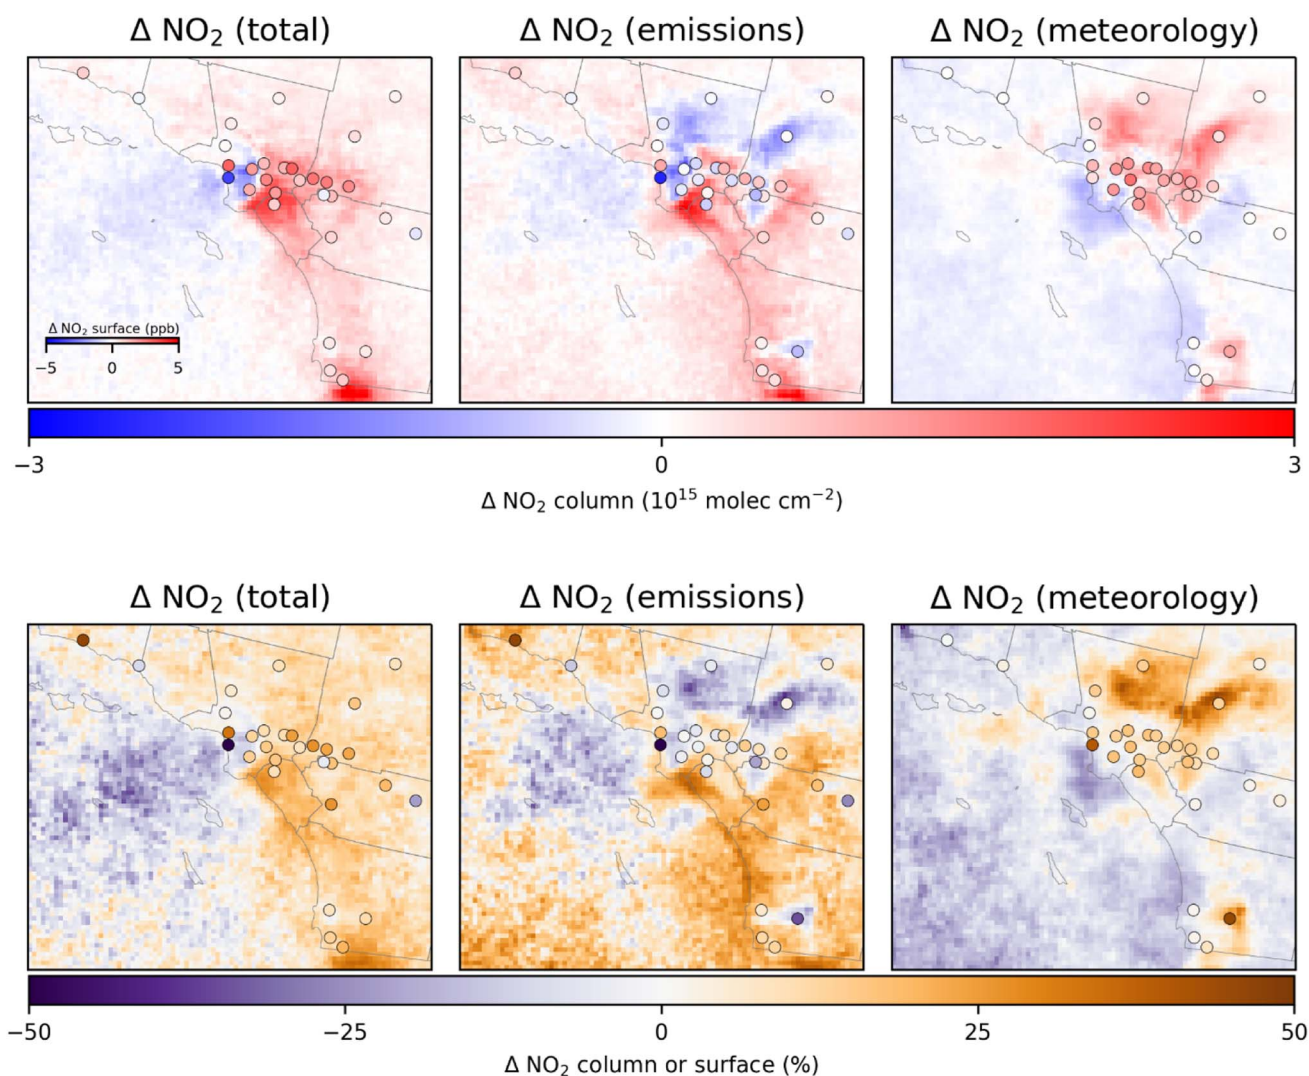

Fig. 4 Total change (left) in TROPOMI NO₂ column in September–November 2021 compared to the average over the same period in 2018 and 2019. Total changes are apportioned to emissions (middle) and meteorology (right) using meteorological effects derived from CMAQ simulations. Circles show the analogous changes for 1–2 pm observations at NO₂ surface monitoring sites. The inset color scale in the top left panel refers to the changes in surface observations (i.e., circle markers on the map) while the larger color scale below the top row of panels refers to the changes in vertical column densities. Both absolute changes (top row) and percent changes (bottom row) are shown.

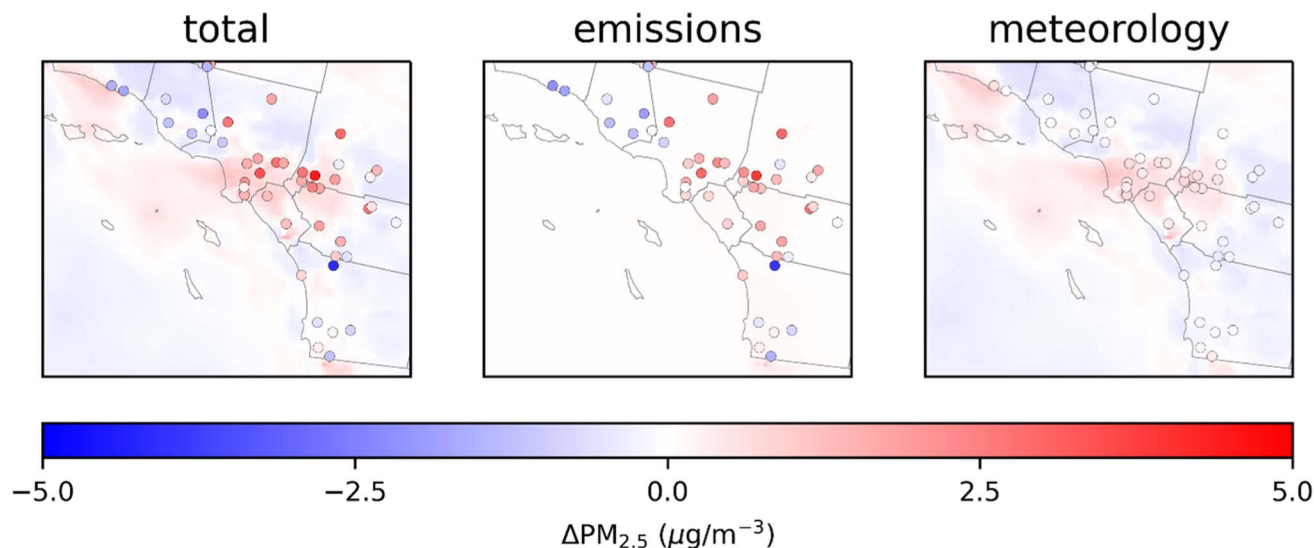

Fig. 5 Total change (left) in CMAQ-simulated average $\text{PM}_{2.5}$ concentration in September–November 2021 compared to the average over the same period in 2018 and 2019. Total changes are apportioned to emissions (middle) and meteorology (right) using meteorological effects derived from CMAQ simulations. Circles show the analogous changes for $\text{PM}_{2.5}$ observations.

emission-related NO_2 in parts of the counties, emission-related NO_2 increased throughout most of San Bernardino and Riverside Counties, though these increases were mostly statistically insignificant. In general, meteorology in 2021 (compared to 2018 and 2019) tended to decrease NO_2 in offshore areas and along the coast and tended to increase NO_2 inland.

Surface vs. column NO_2 changes

The change in 1–2 pm surface observations mostly agreed in direction with the changes derived from TROPOMI (Fig. 4 and S9†). The same was true for the emissions and meteorology influenced changes. The change in daily maximum surface NO_2 agreed in direction with the change in TROPOMI columns for only about half of observation sites analyzed (Fig. S10†). Changes in TROPOMI NO_2 columns may be a relevant indicator of changes in human exposures at the surface, but the once-per-day frequency of TROPOMI is a potential limitation. The surface NO_2 sites closest to the ports showed small decreases in emission influenced NO_2 while NO_2 column totals showed increases in emission influenced NO_2 in the same areas. This is explained by decreases in ground level local sources (e.g., traffic) near these sites offsetting increases in NO_2 from ships that have a higher effective stack height and time to more fully diffuse vertically such that they had a smaller impact on inland ground-level sites while increasing the NO_2 vertical column total.

$\text{PM}_{2.5}$ changes

The changes in $\text{PM}_{2.5}$ in the CMAQ simulations are almost entirely from the effects of meteorology (Fig. 5). The only changes in emissions included in the simulations are those that were projected based on the emissions inventory which does not account for the unexpected changes in emissions related to the port supply chain disruptions. The effects of meteorology on

the changes in observed $\text{PM}_{2.5}$ were small compared to the total change. The average meteorology ratio used to adjust observations only varied from 0.9 to 1.1 over the study domain (Fig. S11†). Observed $\text{PM}_{2.5}$ was higher in September–November 2021 compared to the baseline of 2018–2019 at nearly all sites in Los Angeles, San Bernardino, Riverside, and Orange Counties. Changes in $\text{PM}_{2.5}$ were mostly attributed to emissions rather

Fig. 6 Percent change in total traffic flow volume at Caltrans Performance Monitoring System monitoring stations in September–November 2021 compared to the average over the same time in 2018 and 2019. Traffic data from individual monitoring stations are grouped by county and roadway and shown as the median change in traffic flow for stations along each roadway within a particular county.

than meteorology. $\text{PM}_{2.5}$ increased on average across all sites by $0.7 \mu\text{g m}^{-3}$ and ranged from $-4.1 \mu\text{g m}^{-3}$ to $+4.5 \mu\text{g m}^{-3}$. The sites closest to the ports did have increased $\text{PM}_{2.5}$ attributed to emissions, but these were not the sites with the largest increases in $\text{PM}_{2.5}$ within the area.

We are not able to explicitly determine which sources of emissions may have contributed to the observed changes in $\text{PM}_{2.5}$ concentrations. There are many different sources that could have had an effect, and the fact that much of $\text{PM}_{2.5}$ is from secondary formation makes source attribution even more complicated. Notably, the site with the largest increase is in the city of Fontana in San Bernardino County in an area that has seen a significant increase in warehouses and distribution centers in recent years.^{28,29} Increased truck traffic near warehouses would be expected given the increase in port throughput during the study period. It is also possible that wildfires were a contributing factor as 2021 was a more active fire year (2.6 million acres burned across California) compared to 2018 (2.0 million acres burned) and 2019 (0.3 million acres burned) (<https://www.fire.ca.gov/incidents>). Speciated $\text{PM}_{2.5}$ measurements from Chemical Speciation Network (CSN) observation sites in Central Los Angeles and western Riverside County showed elevated concentrations of nitrate (a secondary $\text{PM}_{2.5}$ species formed from NO_2) during high $\text{PM}_{2.5}$ episodes in November 2021 (Fig. S12†), suggesting that increased NO_x contributed to the increased $\text{PM}_{2.5}$ observed during the study period.

Relationship to traffic data

Some areas where emissions-related column NO_2 decreased are near major highways (Fig. S14†). These areas include parts of Los Angeles, San Bernardino, and Riverside Counties. On the other hand, areas in Orange County and in other parts of San Bernardino and Riverside Counties where emissions-related column NO_2 increased are also coincident with major highways. Using traffic flow volume PeMS data, we find that the relationship between changes in traffic flow volume and changes in the TROPOMI NO_2 is mixed (Fig. 6). Traffic was overall lower in September–November 2021 compared to 2018–2019 except for a few roadways. In Central Los Angeles there was a decrease in traffic flow with corresponding reductions in total and emission-related TROPOMI NO_2 , particularly along the I110 freeway. Most other areas do not show a significant relationship between TROPOMI NO_2 columns and total traffic flow. There were increases observed in truck VMT in Orange and San Bernardino Counties despite decreases in total VMT (Fig. S15†) during the same period which could have contributed to increases in NO_2 and $\text{PM}_{2.5}$ seen in those areas.

Conclusions

When analyzing the air quality impacts of short-term changes in emissions such as the congestion at the Ports of Los Angeles and Long Beach, direct comparisons of year-to-year changes in observations, whether satellite-based or ground-based, do not necessarily reflect changes due to emissions. Changes in

meteorology across years can obscure the signal of emissions impacts. The method used here combines satellite-based and ground-based observations with CTM results to account for the meteorological effects. This allows for the apportionment of changes across years to emissions and meteorology separately based on changes in observations and CTM-simulated meteorological impacts. Some uncertainty in separating emissions and meteorology influences still remains. The meteorological impacts may be biased since they are derived from models. The CTM also may not accurately simulate the NO/NO_2 split of total NO_x which would affect the comparison of modeled NO_2 to observed.

Despite the uncertainties, results suggest that there was an adverse impact on NO_2 from increased ship and port activity. This was seen most predominantly in parts of Los Angeles and Orange Counties directly east of the ports and east of the offshore areas in which ships were waiting which is in the direction of the prevailing wind. Compared to prior years, there were also widespread increases in observed $\text{PM}_{2.5}$ across much of the area which were attributed mostly to emissions. $\text{PM}_{2.5}$ increased at the sites closest to the ports, but the largest increase in $\text{PM}_{2.5}$ was found at a site in an area that has seen rapid growth in warehouses and distribution centers in recent years. Additional research relating to the health and environmental justice impacts of increased port activity in the Los Angeles area is warranted. In addition to direct emissions from ships and ports, potential increases in emissions from rail, trucking, and warehousing associated with increased goods throughput should be considered. Other ports also experienced increases in activity following the COVID-19 pandemic, and further investigation into the air quality effects of supply chain disruptions on ports around the US and globally would be helpful in determining if similar impacts on air quality were seen surrounding other ports or if this was isolated to only a few areas.
