Visible–ultraviolet dual-band photodetectors based on an all-inorganic CsPbCl₃/p-GaN heterostructure†

Bingjie Ye,^a Boxiang Wang,^a Yan Gu,^a Jiarui Guo,^a Xiumei Zhang,^a Weiying Qian,^a Xiangyang Zhang,^a Guofeng Yang,^{ib}*^a Zhixing Gan^{ib}*^b and Yushen Liu^{*c}

All-inorganic metal halide perovskites (MHPs) have attracted increasing attention because of their high thermal stability and band gap tunability. Among them, CsPbCl₃ is considered a promising semiconductor material for visible–ultraviolet dual-band photodetectors because of its excellent photoelectric properties and suitable band gap value. In this work, we fabricated a visible–ultraviolet dual-band photodetector based on a CsPbCl₃/p-GaN heterojunction using the spin coating method. The formation of the heterojunction enables the device to exhibit obvious dual-band response behavior at positive and negative bias voltages. At the same time, the dark current of the device can be as low as 2.42×10^{-9} A, and the corresponding detection rate can reach 5.82×10^{10} Jones. In addition, through simulation calculations, it was found that the heterojunction has a type II energy band arrangement, and the heterojunction response band light absorption is significantly enhanced. The type II energy band arrangement will separate electron–hole pairs more effectively, which will help improve device performance. The successful implementation of visible–ultraviolet dual-band photodetectors based on a CsPbCl₃/p-GaN heterojunction provides guidance for the application of all-inorganic MHPs in the field of multi-band photodetectors.

Introduction

Organic–inorganic hybrid perovskites have been used in optoelectronic devices such as solar cells,^{1–3} light-emitting diodes,^{4–6} and photodetectors^{7–9} because of their large absorption coefficient, long photogenerated carrier lifetime, and high carrier mobility. However, the thermal instability of their organic components hinders their practical application.¹⁰ The emergence of all-inorganic metal halide perovskites (MHPs) well compensates for this defect. By substituting inorganic atoms for organic components in hybrid perovskites, all-inorganic MHPs not only have high thermal stability,^{11–13} but also have certain bandgap tunability.^{14–16}

Multi-band photodetectors, which can distinguish the intended target in the clutter and enhance the target signal, have attracted extensive attention. In a complex environment, the detection system uses a single distinguishable spectral response to collect different information in multiple targets for analysis through the multi-band photodetection capability of a single device.^{17–19} In this case, a monolithic device with excellent multi-wavelength photodetection capability is particularly important for the whole system. The emerging all-inorganic perovskite CsPbCl₃ has excellent optoelectronic properties and a suitable bandgap value, and is considered to be a promising semiconductor material for high-performance visible-blind ultraviolet dual-band photodetection.²⁰ As the application fields of multi-band photodetectors continue to expand, including in environmental sensors, optical communications,^{21,22} etc., the performance requirements of photodetectors are also constantly increasing.

Combination with other semiconductor materials to construct heterojunctions is considered to be an effective way to adjust optoelectronic performance and improve light utilization efficiency through energy band engineering.^{23–25} So far, many all-inorganic MHPs have formed heterojunctions with other materials and significantly improved their photodetection capabilities. Algadi *et al.*²⁶ significantly improved charge extraction at the heterojunction interface by combining CsPbBr₃ with carbon nanodots to form high-band alignment

between them. In addition, the carbon nanodots accelerated the extraction of electrons and holes in the CsPbBr₃ film, thereby shortening the response time of the photodetector. Lu *et al.*²⁷ combined CsPbBr₃ with In₂S₃ to form a type II energy band alignment, blocking interlayer carrier coupling and achieving spatial separation of photogenerated carriers through quantum tunneling. At the same time, the heterostructure makes the Pb–Br bond not easy to break, which enhances the environmental stability of the device. Compared with other perovskite photodetectors, CsPbCl₃ photodetectors were studied relatively late. In 2017, Liu *et al.*²⁸ used CsPbCl₃ nanocrystals as light absorbers to propose a photoconductive CsPbCl₃ photodetector for the first time. Limited by the grain boundaries and recombination loss in the layer, the device did not show excellent performance. A novel sequential evaporation deposition strategy was developed by Zhan *et al.*²⁹ to introduce a PbS buffer layer. In this process, a PbCl₂ precursor layer was first evaporated onto an indium tin oxide (ITO) substrate, and then a CsCl layer of a different thickness was evaporated onto the PbCl₂ film, and the phase composition of the resulting CsPbCl₃ film was adjusted by adjusting the thickness of CsCl. The PbS buffer layer can not only passivate the surface defects of the CsPbCl₃ layer, but also form a type II heterojunction with CsPbCl₃ to lower the interfacial energy barrier, thus contributing to a faster hole extraction rate and suppressed dark current level. However, the requirements for evaporative deposition on the environment and equipment, as well as the control of the thickness of the precursor and CsCl during the deposition process are not simple. Therefore, finding suitable semiconductor materials for easy and effective combination with CsPbCl₃ and exploring its mechanism of action are very important for the application of CsPbCl₃ in high-performance multi-band photodetectors.

GaN is considered to be the most promising candidate material for UV photodetectors because of its wide direct bandgap, high breakdown voltage, large absorption coefficient, and high carrier mobility.³⁰ So far, a variety of materials have been combined with GaN to form heterojunctions and improve the performance of the detector's switching ratio and responsivity through direct evaporation deposition, mechanical exfoliation and other simple experimental methods.^{31–33} Notably, many of these devices achieved dual-wavelength responses in addition to outperforming single-material devices. Solanke *et al.*³⁴ achieved a dual-wavelength response of 365 nm and 850 nm by exfoliating α -In₂Se₃ tape onto a GaN substrate. At a bias voltage of –3 V, the normalized responsivity values at 365 nm and 850 nm were both about 70 mA W^{–1}, the photo-dark current ratio is about 665 and 75 in turn, and the estimated specific detectivity values are about 10¹¹ Jones and 10¹⁰ Jones, respectively.

In this work, CsPbCl₃ nanocrystals were spin-coated onto GaN substrates to form a CsPbCl₃/p-GaN heterojunction for broadband photoresponse. The macroscopic orientation, optical properties and surface morphology of the material were characterized by XRD, PL, the absorption spectrum, SEM, TEM and EDS spectra. In addition, by making the heterojunction a photodetector, the measured dark current of the device is as

low as 2.31×10^{-8} A at –2 V. The device is irradiated with 365 nm and 420 nm light, and the obvious optical gain current curve is obtained. When the voltage was fixed and the wavelength of the irradiated light was changed, an obvious dual-band photoresponse behavior was observed at 365 nm and 420 nm. At the same time, the QuantumATK simulation software was used to simulate the energy band diagram, energy band projection density of states and optical absorption coefficient of the heterojunction to explain the photoresponse behavior of the device at different bias voltages. The successful realization of the device's dual-band photoresponse plays an important guiding role in the exploration of all-inorganic MHPs in the field of dual-band photoresponse photodetectors.

Methods

The p-GaN substrate used in this experiment was epitaxially grown on a sapphire substrate through metal–organic chemical vapor deposition (MOCVD). Fig. 1(a) shows a schematic diagram of the structure of the p-GaN substrate, which consists of a sapphire substrate, a 50 nm-thick AlN buffer layer, a 2.5 μ m-thick undoped GaN epitaxial layer and 300 nm-thick p-type GaN formed by Mg doping, in which the Mg doping concentration is 1×10^{19} cm^{–3}. In recent years, the spin coating method has been widely used in the preparation of nanomaterials because of its low cost, easy operation, and excellent uniformity and compactness of nanomaterials.^{35,36} The experiment in this work applies the spin-coating method for the preparation of a CsPbCl₃/p-GaN heterojunction, as shown in Fig. 1(b).

The first step in the spin coating method is to prepare the precursor solution, and CsPbCl₃ precursor solution was prepared according to previous reports.¹⁶ First, Cs₂CO₃ (0.814 g, 99.9%) was placed in a 100 mL three-necked flask together with octadecene (ODE) (30 mL, 90%) and oleic acid (OA) (2.5 mL, 90%), and the mixture was dried at 120 °C under N₂ for 2 hours. Then the temperature of the solution was reduced to 100 °C. ODE (75 mL), oleylamine (OLA) (7.5 mL, 90%), dried OA (7.5 mL) and PbCl₂ (0.675 g, 99.99%) were loaded into a 250 mL three-neck flask and dried under vacuum for 2 h at 120 °C. After the PbCl₂ salt was completely dissolved, the temperature was increased to 170 °C, and the Cs-oleate solution prepared as described above was rapidly injected. After 10 seconds, the reaction mixture was cooled in an ice water bath. In this experiment, 1 mL of trioctylphosphine (TOP) (ninety-seven percent) was added to dissolve PbCl₂ to synthesize CsPbCl₃. Nanocrystals were precipitated from the solution by centrifugation at 7000 rpm for 5 minutes. After centrifugation, the supernatant was discarded, and the nanocrystals were redispersed in anhydrous hexane (99%), and further centrifuged at 3000 rpm for 1 minute to precipitate again to remove impurities. Subsequently, as shown in Fig. 1(a), CsPbCl₃ nanocrystals were combined with the p-GaN substrate shown in Fig. 1(b) by using a simple spin-coating method at 4000 rpm for 45 seconds. Finally, the CsPbCl₃/p-GaN heterojunction was obtained by thermal annealing. After material characterization, Ni/Au was deposited on CsPbCl₃ and GaN by thermal evaporation to make device electrodes.

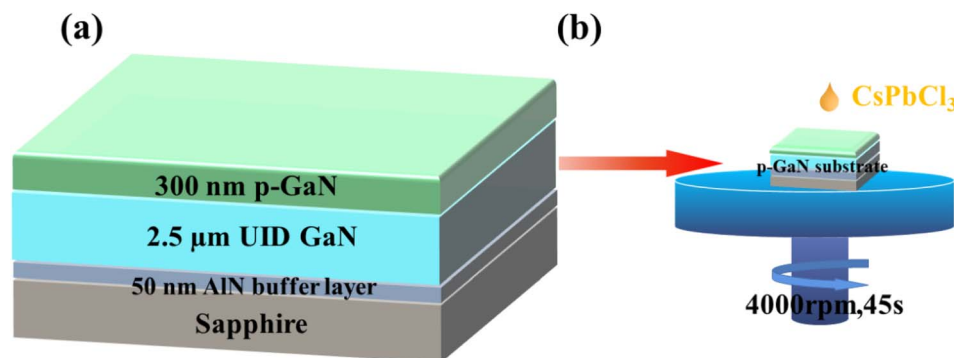

Fig. 1 (a) Epitaxial diagram of the p-GaN substrate; (b) spin coating process of CsPbCl₃ nanocrystals.

The optical properties of the materials are characterized by using absorption and photoluminescence (PL) spectra (Renishaw LabRAM Inviacromicro-Raman system). In addition, SEM (FE-SEM: JEOL JSM-7000F), TEM (FEI Tecnai F20), XRD (PANalytical X'Pert Pro MRD) and EDS mapping were used to characterize the surface morphology, lattice type, crystal plane macro-orientation, element distribution and other material properties of the sample. Meanwhile, the *I*-*V* characteristics, photoresponse and transient photoresponse of the CsPbCl₃/p-GaN heterojunction photodetector were all measured by using a probe station equipped with a semiconductor parameter analyzer (Keithley 4200-SCS).

In this experiment, the QuantumATK software package was used to construct and optimize the CsPbCl₃/GaN heterojunction, followed by its performance simulation. A Pseudo Dojo pseudopotential³⁷ optimization structure was adopted in the process of constructing materials and heterojunctions, and the cutoff energy was set to 95 Hartree. In the material optimization parameters, the maximum interatomic stress was set to 0.01 eV Å⁻¹, and the maximum energy difference convergence limit was set to 10⁻⁵ eV. In order to better simulate the electrical and optical properties of layered CsPbCl₃ and GaN heterojunctions, multilayer CsPbCl₃ was constructed to calculate the energy band, projected density of states, optical absorption coefficient and other material and heterojunction properties during the modeling process. In addition, a vacuum layer of 20 Å was added in the *Z* direction to avoid the influence of periodic interaction in the current transmission direction.

Results and discussion

In order to study the substrate quality and optical characteristics, the p-GaN substrate was characterized by PL and XRD. Fig. S1(a)† shows the rocking curves of the (002) and (102) planes, which are consistent with previous reports^{38,39} after normalization, indicating the high quality of the used substrate. To obtain the macroscopic orientation of p-GaN, the substrate was scanned by ω -2 θ XRD. According to the ω -2 θ XRD scan shown in Fig. S1(b),† the crystal plane orientation of GaN is (002), while the rest of the peaks are caused by sapphire. As shown in Fig. S1(c),† the characteristic peak of the PL spectrum is at about 365 nm, indicating that the band gap value of the

used p-GaN substrate is about 3.4 eV, which is consistent with previous reports.⁴⁰

Besides, the surface morphology of CsPbCl₃ spin-coated on the GaN substrate is tested, as shown in Fig. S2.† Fig. S2(a)† shows the SEM image of the sample. From the image, it can be seen that the surface of CsPbCl₃ prepared by the spin coating method is relatively flat and forms a continuous large-area crystal with a size of several hundred microns. Large-area uniform CsPbCl₃ nanocrystals are not only convenient for device preparation, but also conducive to improving device performance. In addition, it can be observed that there is a certain gap between CsPbCl₃ films, which is determined by the surface roughness of the substrate. The rougher the substrate surface, the stronger the bond between CsPbCl₃ and the substrate, but the larger the gap between CsPbCl₃ nanocrystals, which will affect the device performance. At the same time, in order to further observe the microstructure and transfer quality of CsPbCl₃ nanocrystals, the samples were analyzed by TEM, as shown in Fig. S2(b).† It can be seen from the figure that CsPbCl₃ nanocrystals have good monodispersity and uniform distribution of quantum dots.

In addition, through further TEM analysis in Fig. 2(a), it is not difficult to find that the stripe of CsPbCl₃ is clear, and the lattice type is a cubic lattice, which matches the previous report.⁴¹ Subsequently, the ω -2 θ XRD scan of CsPbCl₃ nanocrystals shows that their diffraction peaks can be well matched with the previously reported diffraction peaks (100), (101), (200), (201) and (220) of CsPbCl₃,^{20,42} while a small number of redundant diffraction peaks are attributed to the influence of the p-GaN substrate, as shown in Fig. 2(d).^{43,44} Meanwhile, energy dispersive spectroscopy (EDS) analysis of the sample was performed to determine the element composition and distribution of the sample, as shown in Fig. 4(c), (e) and (f). By comparing the EDS mapping diagram of each element with the light microscope diagram of EDS scanning area in Fig. 2(b), different element distribution diagrams show that each element is evenly distributed and the quality of nanocrystalline formation is good. From the figure, the distribution density of Cs and Pb elements is similar, while the distribution of Cl is the densest, which is about 1 : 1 : 3. According to the TEM images, it is further verified that the spin-coating is cubic lattice CsPbCl₃ nanocrystals.

Fig. 2 (a) TEM analysis image of CsPbCl₃; (b) EDS scanning area; (c), (e) and (f) EDS mapping images of each element of CsPbCl₃; (d) ω -2 θ XRD scan of CsPbCl₃.

In order to obtain the optical properties of CsPbCl₃ nanocrystals for the subsequent research and analysis of photoelectric characteristics of devices, PL and absorption spectra were obtained. Fig. S3(a)† shows the PL spectrum of CsPbCl₃ nanocrystals, and the characteristic peak is at 420 nm, which is mainly caused by the exciton emission of the CsPbCl₃ band. It can be seen from Fig. S3(b)† that the absorption spectrum peak position of CsPbCl₃ nanocrystals is at around 420 nm, which is consistent with the PL peak position. Combining the PL characteristic peak with the absorption peak, the band gap value of CsPbCl₃ nanocrystals prepared in this experiment is about 2.95 eV.

One of the most important reasons why all-inorganic perovskite has attracted extensive research and attention is its excellent optical properties in the visible-ultraviolet region and adjustable band gap. The schematic diagram of the CsPbCl₃/GaN heterojunction device is shown in Fig. 3(a). Ni/Au was evaporated on CsPbCl₃ and the GaN substrate to form metal electrodes, respectively. At room temperature, the dark current of the device was tested first, and the applied voltage was -2 V to 2 V. It can be seen that the device has a dark current as low as 2.42×10^{-9} A at 1 V. Meanwhile, the device shows obvious rectification behavior, which can be attributed to the presence of the CsPbCl₃/GaN heterojunction. Subsequently, *I*-*V* characteristics of the device were tested under 365 nm and 420 nm illumination, respectively, and the results are shown using the red line and blue line in Fig. 3(b), respectively. The incident light power density used in this experiment was $1.76 \mu\text{W mm}^{-2}$. As can be seen from the figure, no matter under the forward bias voltage or the reverse bias voltage, there are obvious photo-response behaviors under the illumination conditions of

365 nm and 420 nm when compared under dark conditions. As mentioned above, the PL spectral characteristic peaks of GaN and CsPbCl₃ are close to 365 nm and 420 nm, for which photons of the wavelength can provide enough energy to make carriers transition to form photocurrent. Responsivity is an important device parameter of a photodetector, which can intuitively show the photoelectric conversion capability of the device. It can be expressed by using the following formula: $R = I_{\text{ph}}/P_{\text{in}}$, where I_{ph} represents the net photocurrent and P_{in} represents the incident light power. In order to further study the photoresponse behavior of the CsPbCl₃/GaN heterojunction at different bias voltages, the responsivity of the device was measured in the range of 300–500 nm at bias voltages of -2 V, -1 V and 1 V respectively, as shown in Fig. 3(c). It can be seen from the figure that the device has obvious broadband photoresponse behavior at both positive and negative bias voltages. The difference is that there is a sudden dip at 365 nm at a positive bias voltage and no such dip at a negative bias voltage. In addition, the detectivity corresponding to the responsivity is calculated by using the formula $D^* = R/(2qI_{\text{d}}/A)^{1/2}$, which represents the capability of the device to detect weak optical signals. Among them, R is the responsivity, q represents the electron charge, I_{d} represents the dark current, and A is the effective area of the photodetector. At -2 V bias, the responsivity of the device at 365 nm and 420 nm is 15.7 mA W^{-1} and 15.0 mA W^{-1} , respectively, and the corresponding detectivity is 2.58×10^{10} Jones and 2.47×10^{10} Jones, respectively. Finally, the device is subjected to continuous switching modulation to test the response speed of the device. Fig. S4(a) and (b)† show the continuous switching modulation curves of the device under 365 nm and 420 nm light respectively, and the modulation

Fig. 3 (a) Schematic diagram of the CsPbCl₃/GaN heterojunction photodetector; (b) I - V characteristic curves of the device under dark conditions, 365 nm illumination and 420 nm illumination; (c) photoresponse of devices in the visible-ultraviolet range at bias voltages of 1 V, -1 V and -2 V.

period is 40 seconds. The rise/fall time of the device is 0.56 s/0.52 s, respectively.

To further study the electrical and photoelectric properties of CsPbCl₃, GaN and the layered CsPbCl₃/GaN heterojunction, and deeply analyze the mechanism of the heterojunction, the first-principles calculation of heterojunction materials was carried out in this experiment. First, model and calculate the energy band of isolated materials. The energy band diagram of CsPbCl₃ is shown in Fig. S5(a)†. From the diagram, it can be concluded

that CsPbCl₃ has a band gap value of 2.5 eV and is a direct band gap semiconductor, of which both the CBM and VBM are at the L point. Although the theoretical band gap value is less than the experimental value of 2.95 eV, the GGA-PBE calculation method usually underestimates the band gap value, which has not affected the subsequent simulation calculation. Besides, compared with the related literature,⁴⁵ the simulation value of this work is closer to the experimental value than that in the previous work, which shows that the simulation result is

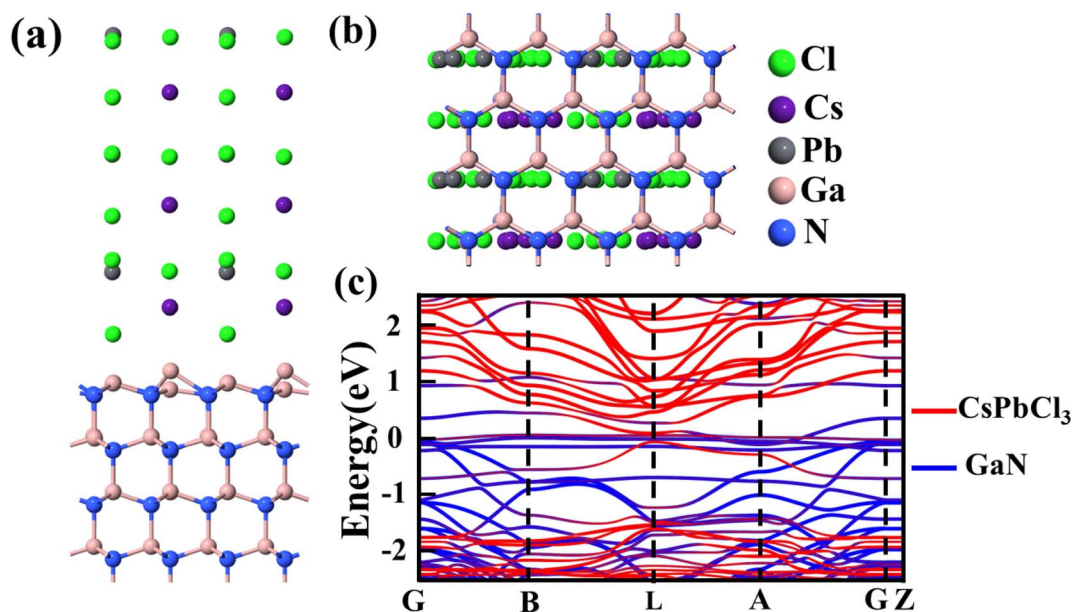

Fig. 4 (a) Side view; (b) top view; (c) projected energy band diagram of the CsPbCl₃/GaN heterojunction.

reliable. At the same time, the energy band diagram of GaN in Fig. S5(b)† shows that the simulated GaN is a direct bandgap semiconductor with both the CBM and VBM at the G point, which is highly consistent with the experimentally obtained 3.4 eV bandgap value. After optimization, the lattice constants of CsPbCl₃ and GaN are 5.751 Å and 3.180 Å, respectively, which match those in the previous work.^{46,47}

After verifying the reliability of the materials, the heterojunction of the two materials is built and optimized, as shown in Fig. 4(a) and (b). In the process of optimization, the minimum stress between heterojunction atoms is set, resulting in a change in the atom position at the interface of the heterojunction. The convergence of optimization results shows that the heterojunction has a stable structure. Fig. 4(c) shows a schematic diagram of the projected energy band of the heterojunction, in which the red line represents CsPbCl₃ while the blue line stands for GaN. The thickness in the figure represents the weight of the material in the energy band. Compared with Fig. S5,† the heterojunction energy band structure in Fig. 4(c) is modulated. In order to further analyze the band structure types of the CsPbCl₃/GaN heterojunction, the projected density of states (PDOS) of the heterojunction is calculated, and the result is shown in Fig. 5(a). Obviously, the CsPbCl₃/GaN heterojunction has a type II energy band arrangement, in which the valence band is mainly contributed by N atoms in GaN, while the conduction band is dominated by Pb atoms in CsPbCl₃.

According to the energy band structure diagram and PDOS of the heterojunction, the schematic diagram of the CsPbCl₃/GaN heterojunction energy band profile in Fig. 5(b) is obtained. Based on the previous report, CsPbCl₃ is considered as an n-type semiconductor in the drawn heterojunction band profile.⁴⁸

When CsPbCl₃ is in contact with GaN, the Fermi energy level reaches an equilibrium state, and there are different barrier heights between the conduction band and the valence band. Fig. S6(a)† shows the electron localization function of the CsPbCl₃/GaN heterojunction, which shows the strong electron localization of the heterojunction, indicating that the structure is stable.

In addition to electrical properties, the optical properties of the CsPbCl₃/GaN heterojunction are also remarkable. In order to compare the differences in optical properties before and after the formation of a heterojunction, the photon energy-related optical absorption coefficients of isolated GaN, CsPbCl₃ and the CsPbCl₃/GaN heterojunction are calculated respectively. As shown in Fig. S6(b),† isolated GaN and CsPbCl₃ have strong absorption of photons in the near ultraviolet and ultraviolet regions, but weak absorption of photons in the visible region. After the formation of a heterostructure, the absorption of the CsPbCl₃/GaN heterostructure in the visible region is greatly increased, and there is still some absorption in the near ultraviolet region. The enhancement of light absorption in the visible region and near ultraviolet region will be beneficial to the photoelectric performance of CsPbCl₃/GaN heterojunction devices, since their band gaps correspond to photon energy in visible and near ultraviolet regions, respectively. The stronger light absorption in corresponding bands will be beneficial to the collection of photons and the formation of photocurrent.

Finally, the photoresponse behavior of the device is explained in connection with the drawn energy band profiles in Fig. 5(c) and (d). Combined with the energy band diagram in Fig. 5(b), when the two materials are in contact, CsPbCl₃ electrons flow to GaN until the Fermi level is equal. As a result, a built-in electric

field is formed, whose direction is from CsPbCl₃ to GaN. When a forward bias is applied, the potential barrier decreases since the direction of the voltage is opposite to the direction of the built-in electric field. At the same time, the Fermi level of the heterojunction deviates from the equilibrium position because of the change in the potential barrier.^{49,50} When 365 nm and 420 nm wavelengths of light are used, the photon energy is sufficient to separate electron–hole pairs on GaN and CsPbCl₃. Due to the reduction of the potential barrier, the carriers have the ability to cross the potential barrier to form photocurrent. It can be seen from the energy band profile diagram that the barrier height of the valence band is smaller and lower than that of the conduction band, so the photogenerated carriers at GaN are more likely to cross the barrier to form photocurrent. When a reverse bias is applied, the photogenerated carriers have no potential barrier, forming a photoresponse curve as shown in Fig. 3(c). At the forward bias, due to the presence of the potential barrier, the photogenerated carriers on the CsPbCl₃ side are severely blocked, while the band gap value of GaN only allows photons with an energy greater than 3.4 eV to pass through. As a result, the photocurrent after 365 nm decreases sharply. Under reverse bias, the photogenerated carriers of CsPbCl₃ and GaN can smoothly reach both ends of the electrode to form a photocurrent due to the absence of a potential barrier. However, the photocurrent of CsPbCl₃ after 365 nm is larger, resulting in no obvious sudden drop observed at 365 nm. Overall, CsPbCl₃/p-GaN heterojunction photodetectors have successfully achieved visible–ultraviolet dual-band response no matter in forward bias or reverse bias.

Table 1 shows the performance comparison of our CsPbCl₃/p-GaN heterostructure dual-band photodetector with other different MHP photodetectors. It can be seen that the performance of photodetectors based on the CsPbCl₃/p-GaN heterojunction is comparable to that of other devices, and especially the response wavelength range is better than that of other MHP photodetectors.

Conclusion

In summary, the CsPbCl₃/p-GaN heterojunction was successfully fabricated by the spin-coating method and used for photodetection. Subsequent XRD, SEM, and EDS mapping proved the successful formation of the heterojunction. From the combination of PL, absorption spectrum and photoelectric test results, it can be known that the dual response bands of the heterojunction correspond to the response bands of CsPbCl₃ and GaN. At the same time, the device has obvious photo-response behavior at small forward and reverse bias voltages. Through the simulation calculation of the heterojunction, it is found that the formation of the heterojunction not only makes the two materials form a type II energy band alignment and effectively separates the electron–hole pairs, but also enhances the light absorption of the material. The successful realization of visible–ultraviolet dual-band photodetectors based on the CsPbCl₃/p-GaN heterojunction provides guidance for the application of all-inorganic MHPs in the field of multi-band photodetectors.
