# Electrical properties of disordered films of van der Waals semiconductor WS<sub>2</sub> on paper†

Fatima Zahra Kharchich, <sup>a,b</sup> Andres Castellanos-Gomez <sup>c</sup> and Riccardo Frisenda <sup>\*a</sup>

One of the primary objectives in contemporary electronics is to develop sensors that are not only scalable and cost-effective but also environmentally sustainable. To achieve this goal, numerous experiments have focused on incorporating nanomaterial-based films, which utilize nanoparticles or van der Waals materials, on paper substrates. In this article, we present a novel fabrication technique for producing dry-abraded van der Waals films on paper, demonstrating outstanding electrical characteristics. We assess the quality and uniformity of these films by conducting a spatial resistivity characterization on a 5 × 5 cm<sup>2</sup> dry-abraded WS<sub>2</sub> film with an average thickness of 25 μm. Employing transfer length measurements with varying channel length-to-width ratios, we extract critical parameters, including sheet resistance and contact resistance. Notably, our findings reveal a resistivity approximately one order of magnitude lower than previous reports. The film's inherent disorder manifests as an asymmetric distribution of resistance values for specific geometries. We explore how this behavior can be effectively modeled through a random resistance network (RRN), which can reproduce the experimentally observed resistance distribution. Finally, we investigate the response of these devices under applied uniaxial strain and apply the RRN model to gain a deeper understanding of this process.

## Introduction

Electronic sensors have become ubiquitous in the modern society since they are fundamental in many technological and economic areas, from the production of smartphones and cars, to manufacturing and logistics. Also, novel applications such as electronic skins, human-machine interfaces or the internet of things are completely based on electronic sensors.<sup>1–5</sup> Thus, one of the present world challenges is the fabrication of sensors that are scalable, inexpensive, and environmentally friendly. For this reason, many researchers focused on the combination of paper, which is a biodegradable and inexpensive substrate, with films based on nanomaterials, such as nanoparticles or van der Waals (vdW) materials.<sup>6,7</sup> To this end the typical fabrication approach found in the literature is based on depositing the electronic material of choice on a paper substrate through inkjet printing or solution dipping.<sup>8,9</sup> One recently demonstrated alternative strategy is the direct abrasion of van der Waals materials on paper, which allows to fabricate films without the need of solvents, thus reducing both the impact on the environment and the fabrication costs.<sup>10,11</sup> This method, which has been demonstrated first with graphite (from pencils), has been extended only recently to other van der Waals materials, such as semiconducting MoS<sub>2</sub> or WS<sub>2</sub> or superconducting NbSe<sub>2</sub>.<sup>12,13</sup>

Achieving highly conductive films using ink suspensions containing vdW materials is challenging, due to the presence of solvent-related adsorbates on the deposited vdW materials that

reduce the coupling between platelets.<sup>9,14–17</sup> In contrast, films fabricated from the direct abrasion method using a manually operated cotton swab, have already demonstrated outstanding electrical properties, with improvements of the film resistivities of more than one order of magnitude compared to vdW inks.<sup>18</sup> In this work we demonstrate a fabrication method capable of improving the film electrical resistivity based on the use of an electric drill with a modified spherical drill bit to deposit the vdW powder on paper. This setup allows to fabricate homogenous and large area (larger than  $5 \times 5 \text{ cm}^2$ ) films of  $\text{WS}_2$  or  $\text{MoS}_2$  on paper in a relatively short time, which, thanks to the solvent-free processing, yields a disordered network of intimately interconnected platelets. Transfer length methods measurements performed in a statistical way give a resistivity  $\rho = 19.7 \text{ } \Omega\text{m}$  and contact resistance  $R_C = 0.13 \text{ M}\Omega$ , which to our knowledge are the lowest values reported in literature for disorder  $\text{WS}_2$  thin films and are more than one order of magnitude lower than previous reports.<sup>18</sup> Our electrical results can be reproduced by a random resistor network (RRN) solved by a combination of Ohm's law and Kirchhoff's circuit law, which capture the essential physics of these disordered films such as the intrinsic device-to-device variation.<sup>19,20</sup> We also demonstrate the strain sensing capabilities of our devices by subjecting them to controlled uniaxial strain and discuss the results using the RRN model.

## Results and discussion

To fabricate large area  $\text{WS}_2$  thin films we exploit the dry abrasion of APS micronized  $\text{WS}_2$  in powder form (Hagen

Automation Ltd, average platelet size of  $0.6 \text{ } \mu\text{m}$ ) on standard A4 copy paper ( $80 \text{ g m}^{-2}$ ) as substrate. Fig. 1a shows the steps to deposit a  $5 \times 5 \text{ cm}^2$  film of  $\text{WS}_2$  on paper, firstly we mask the deposition area (1) and then we rub the  $\text{WS}_2$  powder using an electric drill with a modified spherical drill bit (2). The standard spherical ceramic stone drill bit is wrapped by eight layers of polyester knitted wipers (RS Pro, 162-5686) to allow deformation in the drill bit and achieve a more homogenous pression. The film can then be drawn quickly (3) and the final appearance is shiny and rather homogenous (4). From an inspection with an optical microscope operated in reflection or transmission illumination mode, in Fig. 1b, the film appears optically homogenous apart from a gradient, visible in transmission illumination mode, about  $200 \text{ } \mu\text{m}$  long in the region that separates the film from the bare paper substrates. To measure the thickness of the film, which is needed to determine its resistivity, we slice the film with a sharp razor blade and using a calibrated optical microscope we inspect the cross-section. Fig. 1c shows the cross-section of the film that appears rather homogenous with a thickness of  $20 \text{ } \mu\text{m}$  and Fig. 1d shows an histogram of the thicknesses estimated from 16 different cross-sections. The average thickness is  $t = (25 \pm 6) \text{ } \mu\text{m}$ , which confirms the homogeneity of the final films.

After depositing the film we test the electrical properties of the film such as its resistivity by depositing graphite electrodes onto the film. Fig. 2a shows the electrode deposition and the electrical testing setup. Firstly we draw an array of graphite electrodes using an 8B pencil separated by  $5 \text{ mm}$  one from the other (1) and labelled with numbers 1,2...9. By varying this

(b) Color map of the measured resistance of the WS<sub>2</sub> film on paper (channel length  $L$  and width  $W$  both equal to 5 mm). (c) Histogram of the resistances calculated from the values in panel (b). (d) Transfer length method representation of the resistance of the WS<sub>2</sub> film versus the channel length ( $W = 5$  mm) where the circles are the individual data points, and the thick black lines represent the mode and the standard deviation of each set of data points. The linear fit (red line) allows to extract the contact resistance ( $R_c$ ) and the sheet resistance ( $R_s$ ) of the film.

separation we can achieve different channel lengths. We then cut, using a sharp razor blade, the film in the direction perpendicular to the electrodes in 5 mm wide ribbons (2) labelled with letters  $a, b, \dots, i$ . In this way we obtain 81 different devices with channel length  $L = 5$  mm and channel width  $W = 5$  mm, which, thanks to the labelling, can be spatially localized in the film. We then proceed to recording the resistance of each device using two electrical probes supported by a magnet to achieve reproducible probe pressure, as shown in (3). After fabrication we recorded the individual resistance (at a low constant voltage of 0.1 V) of each of the 81 devices finding values in the 0.5 to 2.7 MΩ range. Fig. 2b shows these resistance values as a colormap where black regions correspond to low resistance devices and yellow/white to large resistance ones. Thanks to the device labelling this colormap gives information on the spatial homogeneity of the electrical properties of the WS<sub>2</sub> film. As can be seen, the film homogeneity is good on a few cm scale demonstrating the capabilities of the proposed deposition method in producing large area films. Fig. 2c shows an histogram of the resistance values taken from the map in panel b, which shows a peak at low resistance values and a tail at larger resistance values. We fit this histogram to a log-normal distribution, which accounts for the fact that the resistance  $R$  is positive bounded, using the formula  $Y(R) = \frac{a}{R\sigma\sqrt{2\pi}} \exp\left(-\frac{(\ln R - \mu)^2}{2\sigma^2}\right)$ . From the fitting parameters we can calculate the mode of the distribution according

to  $M = \exp(\mu - \sigma^2)$ . From the fit we find  $\mu = -0.077$  MΩ and  $\sigma = 0.25$  MΩ which gives a resistance  $R(L = 5 \text{ mm}) = (0.87 \pm 0.25)$  MΩ.

The resistance properties of the fabricated films can be extracted through a transfer length measurement. To do this we repeated the previous fabrication four additional times increasing the channel length in steps of 5 mm. Note that given the larger channel length each time we decreased the number of fabricated devices. For each set of resistance values  $R(L)$  we bin the values in a histogram and fit it to the log-normal distribution. Fig. 2d shows the results of this procedure where the resistance is plotted as a function of the channel length. The colored circles correspond to the resistances values of all the devices and the black horizontal and vertical bars represent respectively the distribution mode and standard deviation of each channel length calculated from the fitting parameters. The mode values increase from 0.86 MΩ to 4 MΩ when increasing the channel length from 5 mm to 25 mm and the standard deviation increases as well. From this set of mode values at different lengths we extract the contact resistance  $R_c$  and the sheet resistance  $R_s$  of the film (see inset of Fig. 2d for a circuit diagram) by performing a linear fit to these points. In the fitted linear equation the slope is equal to  $R_s/W$  and the intercept with the vertical axis to  $2R_c$ . The red line in Fig. 2d is the result of such a fit from which we find  $R_s = 0.79$  MΩ  $\square^{-1}$  and  $R_c = 0.13$  MΩ. Finally, using the just found  $R_s$  value and the thickness  $t$  (estimated in Fig. 1d) we

can calculate the resistivity  $\rho$  according to  $\rho = R_{\text{st}}$  and we find  $\rho = 19.7 \text{ } \Omega\text{m}$ . To our knowledge this resistivity is the lowest value reported in literature for  $\text{WS}_2$  films on paper fabricated by dry abrasion or by liquid phase exfoliated inks.<sup>18,21</sup> Compared to the in-plane conductivity of bulk or of single-layer  $\text{WS}_2$  obtained by mechanical exfoliation,<sup>22,23</sup> this resistivity value is still more than three orders of magnitude larger. This suggests that the out-of-plane and the flake-to-flake transport play a significant role in the total resistance of the  $\text{WS}_2$  films on paper. On the other hand,  $R_{\text{C}}$  is comparable to previous reports for  $\text{WS}_2$  films contacted by graphite electrodes suggesting that it does not depend on the film itself but rather on the graphite- $\text{WS}_2$  interface.<sup>18,24,25</sup>

To understand the origin of the resistance distribution and model the transport through the disordered  $\text{WS}_2$  films we propose a random resistor network (RRN) model,<sup>26,27</sup> which we used in a previous article to model the superconducting transport transition in a disordered film of  $\text{NbSe}_2$  on paper.<sup>12</sup> Fig. 3a shows a schematic of the physical devices and a zoomed-in sketch of the  $\text{WS}_2$  film composed of interconnected  $\text{WS}_2$  platelets. Here, one can identify two components to the film resistance, a lower intra-platelet resistance ( $R_{\text{Intra}}$ ) and a larger inter-platelet one ( $R_{\text{Inter}}$ ). A crude model of the film can then be given by a two-dimensional network of  $R_{\text{Intra}}$  and  $R_{\text{Inter}}$  resistances with low valued resistance elements ( $R_{\text{Electrodes}}$ ) at the two sides to simulate the graphite electrodes (and used to apply voltage uniformly to the film). The right panel of Fig. 3a shows an example of a small RRN composed of 36 voltage nodes and 60 resistances.

To model mathematically the RRN we construct a  $N_x \times N_y$  matrix (with  $N_x = 2n_x - 1$  and  $N_y = 2n_y - 1$ , where  $n_x$  and  $n_y$  are the number of voltage nodes across the  $x$  and  $y$  directions), which contains the resistance and the voltage values. The resistance elements occupy the positions identified by the indexes  $r = 1, 3, 5 \dots N_x$  and  $c = 2, 4, 6 \dots N_y - 1$  (for horizontally oriented resistors) or  $r = 2, 4, 6 \dots N_x - 1$  and  $c = 1, 3, 5 \dots N_y$  (for vertically oriented resistors). The voltage nodes are located at the positions  $r = 1, 3, 5 \dots N_x$  and  $c = 1, 3, 5 \dots N_y$ . Note that given  $n_x \times n_y$  voltage nodes, the number of resistors can be calculated according to:  $(2n_x - 1) \times (2n_y - 1) - n_x \times n_y - (n_x - 1) \times (n_y - 1)$ . We populate the matrix with binomial distributed random resistances in the channel and low resistances at the left and right sides. In the case of the left panel of Fig. 3b, a RRN with  $n_x = n_y = 100$ , we choose  $R_{\text{Intra}} = 10^5 \text{ } \Omega$ ,  $R_{\text{Inter}} = 10^{10} \text{ } \Omega$  and  $R_{\text{Electrodes}} = 1 \text{ } \Omega$ . These values for the resistance can be considered as effective values used to reproduce the general physics of the problem and not to simulate the specific film. Notice that in the chosen RRN geometry, the length  $L$  and width  $W$  of the channel are well defined geometrical quantities. To finish the setting-up of the simulation we apply a fixed voltage to the left and right electrodes by assigning the desired voltage values at the right positions (in the showed case  $V_{\text{Left}} = 1 \text{ V}$  and  $V_{\text{Right}} = 0 \text{ V}$  respectively).

To solve for the network unknown voltages and currents we use the Kirchhoff's node law combined to the Ohm's law in matrix form. To account for these two laws we create a new

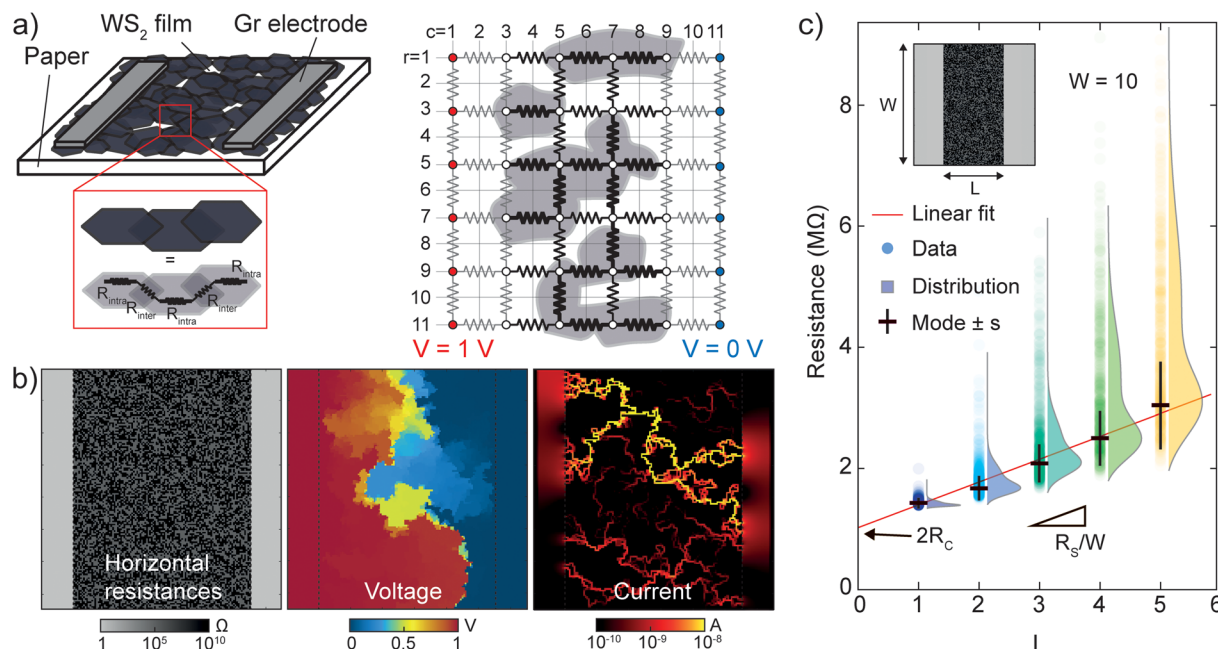

matrix, of size approximately  $n_x^2 \times n_y^2$ , that represents a system of linear equations where the unknowns are the voltages across the network. We then solve for the voltages using the linear equations solver in MATLAB (version R2022b, MathWorks) and then calculate the current across each resistor element. Fig. 3b central and right panels show the results for the voltages and the magnitude of the current flowing through the RRN presented in the left panel. We can see that the voltage is constant in each electrode as expected and that the voltage drop has a step-like behavior, with islands of approximately constant voltage appearing. The logarithmic map of the current shows a filament behavior where few parallel paths contribute mostly to the total current flowing through the RRN, and most of the RRN resistors carry a negligible current. Notice that this behavior is typical of percolative networks of different nature.<sup>28,29</sup> From this current map we find the total current flowing in the RRN (and the total resistance of the network), calculated by summing all the currents flowing through a column of horizontal resistors (*i.e.* summing all the currents with indexes  $r = 1, 3, 5 \dots N_x$  and  $c = N_y/2$ ).

To assess statistically the distribution of the total resistance in a given RRN geometry, we simulate hundreds of randomly generated RRNs and construct the histogram of the total resistance found in each case. To simulate the transfer length discussed in Fig. 2, we generate different RRNs with fixed width  $W = 10$  and varying lengths  $L = 5, 10, 15, 20, 25$  (see the inset of Fig. 3c). For each  $L$  we generate and solve hundreds of RRNs and we plot the results in Fig. 3c as a scatter plot (for the individual resistances) combined with a half violin plot to show the total histogram of each  $L$ . From this graph we can see that the resistances for a given  $L$  show a distribution peaked at lower resistance and with a tail at larger resistance values. This behavior is comparable with the one found from the histograms of the transfer length resistances of Fig. 2c. Similar to the experimental case, we characterize the different distributions by their mode and standard deviation. Interestingly, by increasing  $L$  the mode increases in an approximately linear fashion and the standard deviation also increases, similar to the experimental observations.

Being paper an easily deformable material, one possible application of electrical devices based on films on paper is in strain sensing.<sup>25,30</sup> In the following we discuss the strain sensing capabilities of our devices and show how the RRN model can give some insight into the physical process behind the strain sensing in disordered films. We start by characterizing a  $\text{WS}_2$  drawn channel contacted by graphite drawn electrodes and subjected to uniaxial (compressive or tensile) strain using the apparatus shown in the inset of Fig. 4a. The use of linear micromanipulators allows to finely tune the radius of curvature  $R$  of the device and thus the strain. We calculate the strain using the formula  $\varepsilon = \frac{t}{2R}$ , where  $t$  is the thickness of the device (approximately  $100 \text{ } \mu\text{m}$ , see Fig. 1c). For each value of strain we record the resistance of the device and we plot the results in Fig. 4a. The unstrained device has a resistance of  $R_0 = 2.03 \text{ M}\Omega$ , which decreases for compressive strain and increases for tensile strain. The rate of change in the resistance

**Fig. 3** Random resistance network model. (a) Schematic of the van der Waals film on paper (left) and random resistance network (RRN) composed of low valued resistance elements at the two sides to simulate the electrodes, and a random mixture of medium and large ones to simulate the channel (right). This network is composed by  $6 \times 6 = 36$  voltage nodes and  $5 \times 6 + 5 \times 6 = 60$  horizontal and vertical resistor elements. (b) Left: RRN composed of  $150 \times 150$  resistors. Center: voltage across the RRN calculated with boundary conditions  $V = 1$  V on the far-left side and  $V = 0$  V on the far-right side. Right: current density calculated from the resistance and voltage maps. (c) Transfer length method simulated using RRNs with channel width  $W = 10$  and different channel lengths. The resistance of each RRN is represented by the circles and the distributions of these resistances is shown on the right of the data points as a half-violin plot.

as a function of strain is commonly referred to as gauge factor (GF) which is calculated as  $GF = (R - R_0/R_0)/\epsilon = (\epsilon/R_0)/\epsilon$ .<sup>5,25</sup> Fig. 4b shows  $\Delta R/R_0$  versus epsilon for two different devices based on  $WS_2$  with unstrained resistances respectively  $R_0 = 1.83$  M $\Omega$  (red circles) and  $R_0 = 2$  M $\Omega$  (orange circles). In these two devices the data shows a linear increase with applied strain symmetric for tensile and compressive strain. We find  $GF = 100$  by performing a linear regression to the data. Fig. 4c shows similar measurements performed on a  $MoS_2$  film based device. The devices in this case show a much larger unstrained resistance of  $R_0 = 7$  G $\Omega$  and  $R_0 = 11$  G $\Omega$ , in accordance with previous reports on  $MoS_2$  films on paper fabricated with similar methods.<sup>11</sup> These resistance values are around two orders of magnitude larger than those of large-area  $MoS_2$  films deposited on  $SiO_2/Si$  with Au prepatterned electrodes ( $L = 10$   $\mu m$ ,  $W = 1000$   $\mu m$ ) where square resistances are in the order of 5–50 M $\Omega$   $\square^{-1}$  compared to our  $MoS_2$  film where the film resistance is 1000 M $\Omega$   $\square^{-1}$ .<sup>31</sup> This difference could be due to the different production method of  $MoS_2$  that in ref. 31 comes from mechanically exfoliated flakes from bulk  $MoS_2$  and in our case comes from  $MoS_2$  micronized powder. Interestingly, while the lower  $R_0$  device shows similar slopes both for tensile and compressive strain with a  $GF = 100$ , the larger  $R_0$  device shows a smaller slope for compressive strain in respect to the tensile strain datapoints. In this last device we find  $GF = 100$  for tensile strain and  $GF = 10$  for compressive strain.

In order to gain more insight on the strain sensing properties of disordered films we apply the RRN model. In this

case, to simulate disordered films and apply strain we generate a network of randomly placed squares which we can individually track and displace independently one from the other. The top row of Fig. 4d shows two resistance networks generated in this way, on the left for a larger number (or density) of squares and on the right for a lower number of squares. The central panel in each of the two cases correspond to the unstrained network. The left and right panel of each case correspond respectively to compressive and tensile strained networks. The bottom row shows the calculated current in each case. For the unstrained case we see the usual behavior of RRN where current is carried mostly through a few “filaments” in parallel. The high density network does not show strong change in the number of current paths as a function of strain meaning that also the total resistance does not depend strongly on the strain and thus the gauge factor is small (lower than 10). On the other hand, the low density RRN shows a strong dependency of the current paths on the strain. From the bottom right panel of Fig. 4d it is clear how for compressive strain the network shows a large number of parallel current paths while for tensile strain the current paths are less and carry overall a much lower current. This can give a strong modulation of the total resistance versus strain for tensile strain and larger gauge factors (larger than 10). Fig. 4e summarizes the results from four different simulation performed for increasing RRN densities.

**Fig. 4** Strain sensors based on van der Waals materials on paper. (a) Resistance versus (tensile and compressive) uniaxial strain curves for a WS<sub>2</sub> device. Inset: photograph of the strain setup with superimposed the estimated radius of curvature  $R$ . (b) Percentage change in the device resistance for two different WS<sub>2</sub> devices versus uniaxial strain. (c) Same as (b) for two different MoS<sub>2</sub> devices. (d) RRN network simulations of films with high density (left) and low density (right) under compressive and tensile strain. The lower panels show the calculated current flowing in the networks. (e) Summary of the gauge factor versus uniaxial strain calculated in four different simulations at increasing film density (blue high density and red low density films).

## Conclusions

In conclusion, we demonstrated the fabrication of large-area films of van der Waals semiconductor WS<sub>2</sub> on paper by using a modified dry abrasion method. The resistivity of a film of size  $5 \times 5 \text{ cm}$  and thickness of approximately  $25 \mu\text{m}$  sampled in 81 locations shows a good spatial uniformity demonstrating the good quality of the produced film. By performing transfer length measurements with  $L/W$  ranging from 1 to 5 we extract the sheet resistance and the contact resistance of the films finding  $R$  and  $R_s$ , with  $R_s$  being one order of magnitude lower than previous reports. The disordered nature of the film, composed of a network of interconnected WS<sub>2</sub> platelets, shows up in an asymmetric distribution of resistance values for a certain  $L/W$  geometry. This behavior is consistent with the percolative nature of the WS<sub>2</sub> resistance network as showed by a random resistance network model. We found that in a network composed of two resistances (a smaller one and a larger one, respectively interpreted as an intra-flake and an inter-flake resistance), randomly scattered in a square lattice, the observed distribution of the resistances is similar to the one observed experimentally with a peak at low resistance values and a tail at larger resistance values. Interestingly, both experimentally

and theoretically a lower scattering in the resistance of the film, measured from the standard deviation of the distribution, is observed for devices with smaller  $L/W$ . Finally we discuss the behavior of these devices under applied uniaxial strain and we applied the RRN model to understand the process. The RRN simulations at different film densities show that in the low density limit larger gauge factors can be achieved due to the formation of cracks in the film that can lead to rupture and remodulation of conductive paths.
