Borylative transition metal-free couplings of vinyl iodides with various nucleophiles, alkenes or alkynes†

Gesa Seidler, ‡ Max Schwenzer, ‡ Florian Clausen, Constantin G. Daniliuc ‡ and Armido Studer ‡*

Alkyl boronic esters are highly valuable compounds in organic chemistry and related fields due to their good stability and highly versatile reactivity. In this edge article, stereoselective borylative couplings of vinyl iodides with various nucleophiles, alkenes or alkynes is reported. These coupling reactions proceed through stereospecific hydroboration and subsequent stereospecific 1,2-metallate rearrangement. The cascades utilize readily available reagents and proceed without the need of a transition metal catalyst.

Introduction

Alkyl and aryl boronic esters are highly valuable building blocks in organic synthesis due to their stability and versatile reactivity.¹ Various reactions have been developed that allow the transformation of the boronic ester moiety into a variety of other functional groups, in many cases in a stereoselective manner.^{2–6} Moreover, boronates can be protodeboronated^{7–10} or be used as nucleophiles in C–C bond forming reactions, for example in the highly valuable Suzuki–Miyaura cross coupling.^{11–13} In addition, boron containing organic compounds can also be found in medicinal chemistry or materials science.¹⁴ As a result, organic chemists are greatly interested in advancing novel reactions that facilitate the preparation of boronic esters or their chemical modification while preserving the valuable boron containing moiety.^{5,6,15} In this regard, hydroboration reactions^{16,17} and 1,2-metallate rearrangements such as the Matteson reaction^{18–20} have been established. Both reactions are highly stereospecific with the hydroboration proceeding through a concerted *syn*-addition of a B–H compound to a double bond¹⁶ and the Matteson reaction comprising the rearrangement of a readily generated boron ate complex resulting in the substitution of an anionic leaving group in the α -position of an alkyl boronic ester (Scheme 1A). This substitution occurs with inversion of the stereogenic center next to the boron atom.^{20,21}

We opted to combine these two highly valuable reactions with the aim of devising a practical procedure that facilitates the

direct generation of substituted alkyl boronic esters from vinyl iodides and organometallic nucleophiles (Scheme 1B). Initial regioselective hydroboration of an alkenyl iodide with HBCl₂ and subsequent treatment with pinacol (pinH₂) should lead to the corresponding α -iodoalkyl pinacol boronic ester. Coupling with an organometallic reagent would provide through its boron ate complex the targeted alkyl boronic ester with complete diastereoselectivity. HBCl₂ was chosen as the hydroboration reagent due to its increased reactivity.

‡ These authors contributed equally.

Further, HBCl_2 unveils an additional reaction pathway subsequent to the initial hydroboration. Instead of esterifying the intermediate α -iodoalkylchloroborane with pinacol, we also intended to selectively mono-reduce this dichloroborane. This reduction would yield an alkylchloroborane, primed for a subsequent hydroboration reaction with a second alkene or alkyne (Scheme 1C). Boron ate complex formation should then be achieved by simple treatment with deprotonated pinacol and a 1,2-metallate rearrangement should deliver the coupling product with high diastereoselectivity, retaining the valuable boron moiety in the final compound. To our knowledge, boron ate complex formation using such a mild strategy not requiring a reactive organometallic species has not been reported to date.²² Of note, new C–R, C–B and C–H bonds are formed in both sequences and two stereocenters are constructed. The high diastereoselectivity is inherited from the stereospecificity both of the hydroboration and the subsequent 1,2-metallate rearrangement step. The relative configuration of the new stereocenters will be set by the alkene geometry of the starting vinyl iodide, which is directly accessible from a ketone or an alkyne. Both reductive coupling reactions proceed in the absence of any transition metal catalyst, utilize readily available reagents and can be conducted in one-pot only requiring a single purification step at the very end of the sequence.

Results and discussion

We commenced the investigations by first addressing the stepwise coupling of vinyl iodides with organometallic compounds (see Scheme 1B). The hydroboration of halogen substituted alkenes has turned out to be challenging for organic chemists in the past and is scarcely reported. Often, a dehalogenated product is obtained^{23,24} or the α -halogen bearing targeted boron compounds readily decompose.²⁵ An additional challenge is the regioselectivity of the hydroboration reaction. To our knowledge, the only practical hydroboration procedure for haloalkenes was reported in 1994 by Deadman utilizing catecholborane and proceeding either in the presence of a rhodium catalyst or catalyst-free at high temperatures.^{26,27} However, these rather inconvenient conditions seemed unsuitable for our envisioned cascades, in particular considering the borylative vinyl iodide/alkene coupling proposed in Scheme 1C. As discussed above, HBCl_2 which can be readily formed *in situ* from boron trichloride and triethylsilane seemed to be a promising alternative.²⁸ The vinyl iodide **1a** directly accessible from acetophenone *via* boron-Wittig reaction/iodinolysis^{29,30} (one-pot, see ESI†) was selected as the test substrate for our initial experiments (Scheme 2).

Hydroboration with HBCl_2 proceeded smoothly in CH_2Cl_2 (0 °C, 30 min to room temperature for 30 min or several hours at –78 °C). The resulting dichloroalkylborane was then directly treated with pinacol to provide the corresponding α -iodoboronic ester **2a**, which was isolated in 95% yield by distillation. The structure and relative configuration of an analogue of **2a** was confirmed by single-crystal X-ray diffraction analysis (see ESI†). It should be mentioned that the order of addition of the hydroboration components is essential for the success of the

Scheme 2 Optimization of the hydroboration and 1,2-metallate rearrangement.

transformation. BCl_3 needs to be placed in the reaction flask first followed by addition of a solution containing iodoalkene and triethylsilane. Of note, hydroboration of vinyl chlorides and bromides under these conditions did not work well. While the reaction with the chloride or bromide analogues of vinyl iodide **1a** did not lead to any product formation, a modest yield was obtained at full conversion using β -bromostyrene. In contrast, hydroboration of the iodoalkene **1b** proceeded well (**2b**, 90%) even on gram-scale (81%), demonstrating the robustness of the protocol.

Typically, 1,2-metallate rearrangements involving α -halo boronic esters are accomplished by initiating the formation of the boron ate complex at low temperatures. Subsequently, the reaction mixture is allowed to gradually reach room temperature, promoting the 1,2-migration process. In some cases, this is conducted in the presence of a Lewis acid.³¹ Et_2O and THF are the typically employed solvents. α -Iodoboronate **2a** was selected as the test substrate in combination with PhLi as the coupling partner. In THF or Et_2O , the targeted **3ba** was formed as a minor product and side reactions were observed, which we attribute to a lithium iodine exchange on substrate **2a** and subsequent coupling of the lithiated boronate with unreacted starting material **2a** (see ESI†). However, using dimethyl sulfide (DMS) as the solvent, the undesired side reaction could be fully suppressed and the boronic ester **3ba** could be obtained in high efficiency. Due to observed instability of **3ba** during purification on silica gel, the boronic ester was oxidized to give the benzylic alcohol **4ba** in 90% isolated yield with excellent diastereoselectivity. The same sequence was also realized with PhMgBr, and the benzylic boronic ester **3ba** could be isolated in 95% yield. Subsequent investigations revealed that the reaction with PhMgBr is also compatible with THF or Et_2O as solvents. Additionally, benzylic boronic esters can be more conveniently isolated through chromatography on NaOAc-deactivated silica gel, resulting in only negligible losses in yield (see ESI†). Driven by the consistently high yields achieved at each stage, we considered carrying out the transformation as a one-pot process. For this variation, isolation of intermediate **2** is replaced by a solvent exchange and an excess of the organometallic reagent is used in the following rearrangement step. Preliminary outcomes of this one-pot procedure were found to be quite satisfying with a yield of 87% for boronic ester **3ba**. We

consider the one-pot process to be particularly advantageous in scenarios where the organometallic reagent is inexpensive or when rapid access to the boronic ester is desired. On the other hand, the concomitantly developed and scalable two-step sequence might be most suitable for diversification originating from a single parent vinyl iodide or for reactions that are sensitive to an excess of reagent.

The transformation of vinyl iodide **1a** into various substituted boronic esters was subsequently examined using a range of diversely hybridized nucleophiles, predominantly carbon-centered (Scheme 3). Alkyl Grignard reagents are tolerated, and reaction with MeMgBr in Et₂O yielded the alkyl boronic ester **3aa** in 76% yield. The corresponding alcohol **4aa** could be isolated in 72% yield by the same one-pot approach,

appended with an additional oxidation step. Similar yields were noted for the ethyl, benzyl, cyclopropyl or cyclobutyl Grignard reagents (**3ab–3ae**). Treatment with AllylMgBr allowed the synthesis of the homoallylic boronic ester **3af** (82%).

Homoallylic and protected propargylic Grignard reagents were also well tolerated, providing the boronic esters **3ag** (88%) and **3ah** (94%, see ESI† for its X-ray structure).§ We also investigated the incorporation of more complex alkyl groups.

Consequently, the boronic ester **3ai**, which contains a silyl ether group, was produced. Additionally, the β-cyano boronic ester **3aj** and the 1,1,2-tris(boronate) **3ak** were synthesized from stabilized alkyl lithium reagents, achieving moderate yields when using THF as the solvent.

Scheme 3 Scope of the one-pot coupling of vinyl iodides with organometallic compounds. All reactions were run on a 0.25 mmol scale using 1.1 equiv. of BCl₃, Et₃SiH and pinH₂ respectively in CH₂Cl₂ (0.1 M) at 0 °C (30 min) to r.t. (30 min). For information on the nucleophile stoichiometry (usually 1.5–3.0 equiv.) and reaction times of the Matteson step (usually 1 h) see ESI.† Products were obtained in diastereomeric ratios > 20 : 1 if not noted otherwise. ^aGrignard reagent used. ^bOrganolithium reagent used. ^cTHF as solvent. ^dEt₂O as solvent. ^eDMS as solvent. ^fOverall yield when running the sequence stepwise with isolation of the α-iodoboronic ester **2a**. ^g1.0 equiv. BCl₃, pinH₂ and Et₃SiH. ^hHydrolysis with HCl in H₂O/THF after the reaction. ⁱNucleophile = KSCN (2.0 equiv.), DMF, 60 °C, 4 h.

Aryl Grignard compounds with F, SiMe₃ (see ESI† for its X-ray structure),§ SMe and NMe₂ substituents in the *para* position are suitable reagents to afford the benzylic boronic esters **3bb–3be** in 64–82% yields. Lithiated heteroarenes derived from thiophene and furan provided the boronic esters **3bf** and **3bg** in 60% and 56% yield, respectively. The sterically more hindered *ortho*-methyl phenyllithium worked very well to give **3bh** in excellent 92% yield. Likewise, a *meta*-anisole moiety could be introduced (**3bi**, 65%). Aryllithium reagents bearing CF₃-substituents also worked, as evidenced by the synthesis of **3bj** with an 84% yield in just one hour. In contrast, using the corresponding ArMgI species necessitated a prolonged reaction time (overnight) and more reagent (3.0 equiv.) giving a lower yield of 60%. Subsequently, we examined the applicability of the protocol to coupling reactions involving Grignard reagents that carry more delicate and synthetically valuable functional groups, such as carbonyls. A ketal may be used as a protecting group for this purpose and acetophenone **3bk** (66%) could be isolated after deprotection. Certain carbonyl containing aryl Grignard reagents can be formed at reduced temperatures through the reaction of the corresponding aryl iodides with ¹PrMgBr,³² which allowed their use for the synthesis of the morpholine benzamide **3bl** (53%). Along these lines, the methyl benzoate **3bm** (44%, see ESI† for its X-ray structure)§ and the benzonitrile **3bn** (79%) were successfully prepared.

The utilization of vinyl magnesium bromide enabled the preparation of allylboronic ester **3ca** (60%) and the corresponding allylic alcohol **4ca** (53%). Running the cascade in two steps with a stoichiometric amount of the Grignard reagent improved the overall yield for alcohol **4ca** to 90%. Vinyl lithium reagents, readily generated from vinyl halides, could also be employed to the coupling of vinyl iodide **1a** in DMS, providing trisubstituted (**3cb**, 74%; **3cc**, 64%, *E:Z* = 1:7) and even tetrasubstituted (**3cd**, 32%) allylboronic esters,³³ which are commonly employed in the allylboration of carbonyls³⁴ or in radical chemistry.^{35,36} Lastly, a more complex scaffold derived from (+)-citronellal could be introduced in good yield (**3ce**, 82%).

The coupling could also be achieved with alkynyllithium reagents (in Et₂O or THF) that are relatively less basic, enabling the isolation of propargylic boronic esters (**3da**, 62%; **3db**, 50%), and an enyne could be coupled (**4dc**, 49%). Phenylacetylene and (*p*-bromophenyl)acetylene yielded the propargylic alcohols **4dd** (46%) and **4de** (35%).

Next, a brief exploration of the vinyl iodide coupling component was undertaken. Vinyl iodides derived from aldehydes took part in the cascade reaction. This resulted in the preparation of 1,1,2-tris(boronate) **3ak'** (90%), along with α -arylated boronic esters **3bo'** (45%) and **3bp'** (46%). Additionally, the incorporation of a scaffold originating from (+)-citronellal was accomplished while retaining the *E*-geometry from the vinyl iodide **3cf** (66%).

The viability of incorporating non-carbon-based nucleophiles into the protocol was investigated in short. Notably, selective introduction of deuterium was achieved using LiDBEt₃,³⁷ resulting in the formation of α -monodeuterated alkyl boronic ester **3e** with a 52% yield and an excellent degree of

monodeuteration (98%). Coupling with the N-centered nucleophile LiHMDS, followed by derivatization with TsCl,³⁸ enabled the isolation of sulfonamide-protected aminoboronic acid **3f** in 33% yield. Even the heteroatom-centered, weakly nucleophilic potassium thiocyanate³⁹ was applicable under more rigorous reaction conditions, yielding the α -borylated thiocyanate **3g**.

Our investigations were then continued by addressing the challenging transition metal-free stereoselective borylative vinyl iodide/alkene coupling sequence suggested in Scheme 1C. Hydroboration with *in situ* generated HBCl₂ was conducted under the above optimized conditions in dichloromethane. The intermediate alkyldichloroborane was then treated with a mixture containing an additional portion of Et₃SiH and the second alkene component, leading to the corresponding chloroborane that engages in a renewed hydroboration reaction. Boron ate complex formation could be achieved by treatment of the intermediate dialkylchloroborane with a THF solution of monodeprotonated pinacol (pinHLi) at –78 °C. The reaction mixture was then allowed to slowly warm to room temperature to induce the final 1,2-metallate rearrangement. The clean formation of both the alkyldichloroborane and the dialkylchloroborane throughout this sequence could be verified by NMR analysis under inert conditions (see ESI†).

Studies on the compatibility of different alkenes for this reaction sequence were conducted using vinyl iodide **1a** as the coupling partner (Scheme 4). Different styrene derivatives proved to be suitable and the boronic esters **5aa–5ad** were obtained in moderate to very good yields (54–87%) with complete diastereoselectivity. The expected relative configuration of the stereocenters was confirmed by single-crystal X-ray diffraction of product **5aa**.§ Considering aliphatic alkenes, both 1,2- and 1,1-disubstituted congeners could be employed in the reaction. While boronic ester **5ae** was again obtained as a single diastereomer in a good yield (61%), the coupling product **5af** was isolated as a mixture of the two diastereomers (75%). We assume a partial epimerization of the intermediate boronate complex to be the cause for this diminished diastereoselectivity. The use of different monosubstituted aliphatic alkenes allowed the introduction of a cyclohexyl group (**5ag**, 83%), a silane (**5ah**, 67%) and an ether moiety (**5ai**, 55%) into the coupling products. Notably, a tetrasubstituted alkene was found to be an eligible coupling partner, albeit reaction occurred with lower efficiency (**5aj**, 41%). The reaction with vinylferrocene led to iron complex **5ak** (54%), again as a mixture of diastereomers. However, recrystallization provided crystals of the expected major diastereoisomer.§ Importantly, alkynes were also tolerated as coupling partners and through that approach, the allylic boronic esters **6aa** and **6ab** were successfully prepared in 52% and 25% yield, respectively. We attribute the reduced yield of product **6ab** to steric repulsion of the coupling partners during the second hydroboration step.

We then investigated the scope with respect to the vinyl iodide component by using indene as the coupling partner. Methyl- and iodo-substituted styrene derivatives were well tolerated and the boronic esters **5ba** and **5ca** were obtained in good yields (64%, 67%). In case of the methyl derivative, the reaction had to be conducted at lower temperature in order to

Scheme 4 Scope of the borylative vinyl iodide–alkene/alkyne coupling reaction. All reactions were run on a 0.25 mmol scale using 1.1 equiv. of BCl_3 and Et_3SiH in CH_2Cl_2 (0.13 M) at 0°C (30 min) to r.t. The second hydroboration step was run with Et_3SiH (1.1 equiv.) and alkene/alkyne (1.0 equiv.) in CH_2Cl_2 (0.13 M) overnight. For details on the use of pinHLi and the rearrangement step see ESI.† Products were obtained in diastereomeric ratios $> 20 : 1$ if not noted otherwise. ^aBoth hydroborations were carried out at -78°C . ^bRecrystallization from Et_2O . For details see ESI.†

ensure a high diastereoselectivity. The CF_3 -, TMS- and fluoro-substituted vinyl iodides gave the corresponding boronic esters in good yields; however, a poor diastereoselectivity resulted even upon running these cascades at -78°C (5da–5fa). Notably, recrystallization of these solid compounds led to improved diastereomeric ratios, as demonstrated for the boronic esters 5da–5fa. Low diastereoselectivity was also observed for the reaction of vinyl iodide (*Z*)-1a and the product 5aa was formed along with the expected *anti*-substituted boronic ester 5a*a. The vinyl iodides derived from 2-indanone, benzaldehyde and heptyne provided the corresponding boronic esters 5ga–5ia in good yields (59–84%).

We also envisioned that our borylative protocols would facilitate practical stereoselective deuteration by substituting Et_3SiH with Et_3SiD , aiming to prepare β -deuterated and/or γ -deuterated boronic esters (Scheme 5). Consequently, when we conducted a coupling reaction with β -iodostyrene 1b and PhMgBr using deuterated silane under standard conditions, we were delighted to achieve a 55% yield of boronic ester 7a, with an excellent 99% incorporation of deuterium. Additionally, the coupling reaction between vinyl iodide and a second alkene offers the possibility of monodeuteration at two distinct positions in the product, as well as the formation of a bisdeuterated product. The site-selective incorporation of deuterium at these various positions was showcased in the coupling of vinyl iodide 1a with vinyl

cyclohexane. These reactions displayed remarkable efficiency, yielding a mono-D-incorporation of 98% for β -deuterated 7b, 99% for γ -deuterated 7c, and a bisdeuteration degree of 97% for boronic ester 7d. Since deuteration during the second hydroboration step introduces an additional stereocenter in the product, we anticipate that compounds 7c and 7d exist as a mixture of diastereomers. However, NMR analysis could not discern between different isomers.

Scheme 5 Application of Et_3SiD for D-labeling. ^a Et_3SiH is substituted with Et_3SiD (1.1 equiv.) only in the first hydroboration step. ^b Et_3SiH is substituted with Et_3SiD (1.1 equiv.) only in the second hydroboration step.

Conclusions

In summary, we developed two methods that allow the formation of a broad range of substituted boronic esters by the coupling of vinyl iodides with either organometallic reagents, alkenes or alkynes. Reactions proceed with good to complete diastereoselectivity in the absence of a transition metal and can be conducted as one-pot processes. These cascades comprise stereospecific hydroborations, or optionally deuteroborations, and 1,2-metallate rearrangements. Both processes utilize simple starting materials and stereoselectively lead to rather complex product structures, plenty of which are not accessible by established hydroboration/oxidation sequences from alkenes. We are confident these methods will find applications in organic synthesis and related fields.

Data availability

The data that support the findings of this study are available in the ESI.†
