Two-dimensional nanomaterials based on rare earth elements for biomedical applications

Mingjun Bai,^a Hao Wan,^a Ying Zhang,^b Siqi Chen,^a Chunyin Lu,^a Xiaohe Liu,^a Gen Chen,^c Ning Zhang^c and Renzhi Ma^d

As a kind of star materials, two-dimensional (2D) nanomaterials have attracted tremendous attention for their unique structures, excellent performance and wide applications. In recent years, layered rare earth-based or doped nanomaterials have become a new important member of the 2D nanomaterial family and have attracted significant interest, especially layered rare earth hydroxides (LREHs) and layered rare earth-doped perovskites with anion-exchangeability and exfoliative properties. In this review, we systematically summarize the synthesis, exfoliation, fabrication and biomedical applications of 2D rare earth nanomaterials. Upon exfoliation, the LREHs and layered rare earth-doped perovskites can be dimensionally reduced to ultrathin nanosheets which feature high anisotropy and flexibility. Subsequent fabrication, especially superlattice assembly, enables rare earth nanomaterials with diverse compositions and structures, which further optimizes or even creates new properties and thus expands the application fields. The latest progress in biomedical applications of the 2D rare earth-based or doped nanomaterials and composites is also reviewed in detail, especially drug delivery and magnetic resonance imaging (MRI). Moreover, at the end of this review, we provide an outlook on the opportunities and challenges of the 2D rare earth-based or doped nanomaterials. We believe this review will promote increasing interest in 2D rare earth materials and provide more insight into the artificial design of other nanomaterials based on rare earth elements for functional applications.

1. Introduction

Two-dimensional (2D) materials are defined as crystalline materials of single- or few-layer atoms or molecules, in which the in-plane interatomic interactions are much stronger than those along the stacking direction.¹ After the exfoliation of layered graphite into graphene, the 2D materials have grown to a large family including the graphene family (*e.g.*, graphene, graphyne, hexagonal boron nitride (hBN), black phosphorene (BP)),^{2–6} Xenes (*e.g.*, borophene, phosphorene, silicene),^{7–10} chalcogenides (*e.g.*, MoS₂, MoSe₂, Sb₂Te₃),^{11–13} MXenes (*e.g.*, Ti₃C₂, Nb₂C, Ta₄C₃),^{14–16} metal–organic frameworks (MOFs),^{17–19} covalent organic frameworks (COFs),^{19–21} 2D oxides (*e.g.*, 2D semiconductor oxides, 2D perovskites),^{22–26} 2D hydroxides (*e.g.*, layered double hydroxides (LDHs), and layered rare earth hydroxides (LREHs)).^{2,27–33} The explosive growth of the 2D family

offers a huge opportunity for the design of crystal structures. The rare earth-based or doped nanomaterials contain a large collection. This review mainly focuses on LREHs, layered rare earth-containing perovskites and their exfoliated ultrathin nanosheets due to their unique structures and fascinating physicochemical properties.

Rare earth-based or doped 2D nanomaterials with versatile energy levels of rare earth/lanthanide (Ln) ions and various active sites are widely applied in diverse fields such as luminescence, sensors, catalysis, *etc.*^{34–39} Due to the spatial localization of 4f electrons within the RE atoms, which induces an unquenched total angular momentum, rare earth-containing nanomaterials exhibit excellent magnetic properties. Among them, rare earth-transition metal nanostructures such as SmCo₅ and Nd₂Fe₁₄B are promising permanent magnets.⁴⁰ In recent years, ultrathin 2D materials (*e.g.*, graphene, MXene, BP, *etc.*) have been reported showing great potential in biomedical fields. For 2D rare earth compounds, in addition to luminescence properties, more and more research studies have been devoted to the biomedical field such as magnetic resonance imaging (MRI), drug delivery, photothermal therapy (PTT) and photodynamic therapy (PDT), especially for Gd³⁺-containing materials, due to the half-filled 4f electron structure, good flexibility and biocompatibility.^{41–47}

Similar to LDHs, LREHs are host-guest compounds with rare earth ions occupying the host layers while anions are in the interlayer gallery. After the first preparation in the 1960s, the LREH family expanded to accommodate nearly all rare earth elements from La to Tm and Y and Lu. Various rare earth elements endow LREHs with color-changeable luminescence.^{32,34,37,48} Recently, *in vivo* upconversion imaging and MRI performances based on upconversion luminescence and magnetic properties have received much attention, especially for Gd³⁺, Yb³⁺ and Nd³⁺ ion-containing host layer LREHs.^{45,49–53} Extensive research has proved that LDHs are good carriers of multiple biomedical active species such as deoxyribonucleic acid (DNA), peptides, proteins, vitamins, *etc.*^{54–56} With similar layered structures, LREHs and other layered rare earth materials are also promising carriers of diverse biomedical drugs, for example, aspirin.^{44,57,58} Moreover, combined with the special luminescence and magnetic properties of RE³⁺, multifunctional drug delivery methods can be realized on the rare earth-containing layered materials, such as targeted drug delivery and real-time monitoring of drug release conditions. Compared with non-layered materials, the interlayer space and rich ion exchangeability of layered rare earth-containing nanomaterials are beneficial to promoting drug loading and release. After exfoliation, the ultra-thin nanosheets expose multiple active sites, ensuring further modification and assembly to facilitate biomedical applications. In addition, unlike common 3D bulk materials, ultra-thin nanosheets are less likely to settle in biological tissues and therefore exhibit higher biocompatibility. The unique layered structure of LREHs enables exfoliation into single or several layers. The ultrathin nanosheets obtained are desirable building blocks to construct artificial superlattice structures due to their large lateral size-to-thickness ratio and high flexibility.^{34,59–61} Furthermore, the hydrophilicity and biocompatibility of the hydroxide nanosheets make them a promising contrast agent for MRI toward tumor vaccination.^{42,43,62}

Though the LREH nanosheets show huge application potential, hydroxyl groups and absorbed water molecules in the rare earth hydroxide nanosheets weaken the photoluminescence properties. Also, the inferior stability of hydroxide nanosheets limits their applications. Therefore, considering the stability, composition and structure variability of nanosheets, more efforts are needed to widen the application potential of rare earth nanosheets.

In addition to LREHs, layered rare earth doped perovskites are another class of 2D rare earth-containing nanomaterials. The diverse compositions and structures of perovskites endow them with various properties and wide applications and have become a target topic in recent years. According to the anion types, the perovskite materials can be divided into two types, namely halide perovskites and oxides. Compared with bulk perovskite, the perovskite nanosheets present a series of advantages, such as higher processability, which is more conducive to the manufacturing of thin films and flexible devices; more active sites, which is more conducive for catalysis; and small size effect and quantum effect, which are better for optical, electrical, and magnetic properties.^{38,63,64} Soft chemistry

Fig. 1 Schematic illustration of the properties and biomedical applications of rare earth nanomaterials.

methods are commonly used for the exfoliation of layered perovskites, that is, dispersing the pretreated layered rare earth perovskite into an organic solution with continuous agitation or ultrasonication. Through this method, diverse perovskite nanosheets were prepared, such as La_{0.90}Eu_{0.05}Nb₂O₇, Eu_{0.56}Ta₂O₇, La_{1-x}Tb_xTa₂O₇, La_{0.95}Eu_{0.05}Nb₂O₇ single perovskite nanosheets and (K_{1.5}Eu_{0.5})Ta₃O₁₀, Gd_{2-x}Eu_xTi₃O₁₀, GdMgWO₆:Eu double perovskite nanosheets. Atomic force microscopy (AFM) results indicate a single-layer structure with lateral size up to 4 nm.^{65–69} Moreover, the layered rare earth-containing perovskite crystal or nanosheet can be applied in photoluminescence, antibacterial activity studies, photocatalysis and bioimaging.^{70–72}

Therefore, with the combined advantages of flexible sheet-like morphology and rich rare earth composition, nanosheets based on rare earth elements and their assemblies are promising materials in many fields, especially in biomedical applications (Fig. 1). To date, there are some excellent reviews on LREHs and/or rare earth-doped oxides focusing on their preparation, crystal structure, exfoliation and photoluminescence properties.^{31,32,73–75} On the other hand, for 2D materials in biomedical applications and/or biosensors, the published reviews mainly focus on C₃N₄, BP, transition metal dichalcogenides (TMDs) and MXene.^{76,77} Few of them have paid sufficient attention to the biomedical applications of 2D rare earth-based or doped nanomaterials. Thus, considering the great potential of emerging 2D rare earth-based or doped nanomaterials, we review the preparation, structural evolution and biomedical applications of 2D nanomaterials based on rare earth elements. The challenges and future perspectives of utilizing these emerging 2D nanomaterials in biomedical fields are also provided.

2. Preparation and structural evolution of 2D rare earth compounds

Various methods have been developed to prepare 2D materials and are mainly divided into two strategies, *i.e.*, “bottom-up” and “top-down” approaches. Molecular beam epitaxy (MBE), chemical vapour deposition (CVD) and pulsed laser deposition (PLD) are typical bottom-up strategies.⁷⁸ Diverse 2D rare earth

materials such as Yb-doped WS_2 , EuC_6 , GdSi_2 and $\text{WS}_2(\text{Er}^{3+})/\text{WSe}_2(\text{Er}^{3+})$ were prepared through this bottom-up method, holding potential for uses in next-generation optoelectronic devices.^{79–82} But silicon or sapphire wafers are needed for the bottom-up processes, limiting the application in biomedical fields. On the other hand, mechanical exfoliation and soft-chemical exfoliation are well-known top-down methods and widely used in the preparation of ultra-thin rare earth-containing 2D nanosheets, especially for LREHs and rare earth-containing perovskites.^{25,33,65,66,68}

2.1 Preparation and exfoliation of LREHs

LREHs with a typical formula of $\text{RE}_2(\text{OH})_{6-m}[\text{A}^{x-}] \cdot \text{H}_2\text{O}$, in which A^{x-} represents intercalated anions such as Cl^- or CO_3^{2-} , have emerged as one of the most important 2D rare earth compounds since their first proposal in 2006.⁸³ Similar to LDHs, the LREHs are composed of positively charged rare earth hydroxide layers and negatively charged interlayer anions. The host layers and guest anions are linked through strong chemical bonds between the RE^{3+} cations and interlayer anions, resulting in anion-exchangeable properties.^{83–87} According to the coordination situation, the LREHs can be divided into two types, namely LREH-I and LREH-II. For the former, one RE^{3+} is coordinated by seven OH^- groups and one H_2O molecule, while for the later one, each RE^{3+} is coordinated by six OH^- groups, two H_2O molecules and one anionic ligand, as shown in Fig. 2.^{31,88} In addition, for LREH-I, the interlayer anions, screened from the direct coordination of RE^{3+} by H_2O molecules, result in a weaker bond energy and thus a more easier interlayer anion-exchange process.³¹

The commonly used method for the synthesis of LREHs is the co-precipitation method. Through this method, researchers have synthesized diverse LREHs which contain almost all RE elements. With the modification of using

hexamethylenetetramine (HMT) or ammonia as the alkali source, Geng *et al.* prepared a series of well-crystallized LREHs with Cl^- or NO_3^- intercalation, and systematically analyzed the morphological and crystal structure (Fig. 3a–e).^{85,88,89,91,92} Through direct synthesis and further ion-exchange processes, researchers expanded the LREHs to Br^- and I^- intercalated counterparts.^{86,93} Though the morphology and crystal structure of LREHs are fully analyzed, the crystal size of the synthesized LREHs is small which is adverse to the following exfoliation process for the preparation of monolayers or few-layer nanosheets. In 2012, Li *et al.* further improved the synthesis process by introducing NH_4NO_3 as a mineralizer, which expanded the LREH crystal up to 300 nm (Fig. 3f).^{90,94} Using sodium dodecyl sulfate (SDS) as a surfactant, Zhong *et al.* prepared DS^- -intercalated LREHs (RE = Y, Tb, Er) with a nanocone morphology (Fig. 3g and h).^{49,95} Therefore, various LREHs were synthesized with diverse morphologies.

As one of the most important features, LREHs exhibit anion-exchange properties. Through uniformly dispersing the as-prepared LREHs with target anions in deionized water under continuous stirring or shaking, LREHs can be topotactically changed to target anion-intercalated counterparts, expanding the LREH family since some functional anionic species are unlikely to intercalate into the interlayer through direct synthetic strategies. There are various interlayer anionic species, including negatively charged inorganic anions (*e.g.*, PO_4^{3-} , CO_3^{2-} , HPO_4^{2-} , ClO_4^- , *etc.*), negatively charged organic anions (*e.g.*, oleic acid, phthalic acid, terephthalic acid, *etc.*), and electrically neutral molecules or polymers (*e.g.*, diclofenac, ibuprofen, naproxen, *etc.*).^{57,86,88,93,96–105} Through anion exchange, the interlayer distance can be adjusted and varies from 0.8 nm to 5.2 nm depending on the anion species. In addition, the anion-exchange property endows LREHs with potential drug delivery properties.^{46,57,58,106–108}

Similar to LDHs, the LREHs can also be exfoliated into nanosheets. In 2009, Lee *et al.* delaminated the as-prepared Cl^- intercalated layered Gd hydroxide (LGDH-Cl), NO_3^- intercalated layered Nd hydroxide (LNdH- NO_3) and NO_3^- intercalated layered La hydroxide (LLaH- NO_3) crystals into corresponding nanosheets in deionized water under sonication conditions (Fig. 4a and b).^{41,98} Transmission electron microscopy (TEM) and AFM analysis results show that the lateral size of the obtained nanosheets is 50–200 nm with a thickness of 2–8 nm. The large thickness indicates that the deionized water may not be a suitable medium for exfoliating the LREHs. Considering the outstanding swelling effect of formamide on LDHs and the similar structure of LREHs to that of LDHs, researchers turned their eyes to formamide. Lee *et al.* dispersed the LGdH- NO_3 crystal in formamide. After 4 days of stirring, a transparent suspension was obtained. AFM results show that the lateral size of the obtained nanosheet is 30–100 nm and the thickness is dominated by two different values (*i.e.*, 0.7 nm and 1.4 nm).¹¹¹ Although the obtained nanosheets are thinner when exfoliated in formamide, they are not unilamellar (*e.g.*, the crystallographic thickness of 0.65 nm). This may be because of the strong binding force between the host layers and interlayer anions, thus the formamide molecule is hard to intercalate into

the guest gallery, resulting in inefficient exfoliation. Moreover, the size of the nanosheets is too small for further assembly and application. To obtain nanosheets of better quality, DS^- anions were introduced into the interlayer gallery of LLeuH through an anion-exchange process, and shaken in formamide for 2 days at

a speed of 170 rpm. After filtration, nanosheets with a lateral size of 500 nm and thickness of 1.6 nm were obtained (Fig. 4c).¹⁰⁹ Through a similar two-step exfoliation method, namely, the combination of anion exchange and exfoliation, Li *et al.* obtained LTmH, LYbH and LYH nanosheets with

a thickness of around 2 nm and a lateral size up to 1.5 μm (Fig. 4d).^{105,110} Moreover, toluene is also used for the exfoliation of oleic acid-intercalated LYH. The as-obtained nanosheets possess a thickness of 1.55 nm with an ultra-large size of up to 20 μm . However, it is difficult to clearly recognize a full nanosheet by either TEM or AFM observations (Fig. 4e).⁹⁴ In addition to the anion exchange method, Yapryntsev *et al.* tried to exfoliate LYH by a rapid expansion of supercritical suspensions, *i.e.*, treating the LYH crystals with supercritical CO_2 resulted in a drastically increased distance. After a following ultrasonication treatment in toluene solvent, a clear suspension was obtained.¹¹² However, the authors did not present any TEM or AFM images to confirm the nanosheets. Considering the excellent exfoliation performance and degradation effect of formamide on DS^- intercalated LDHs, Bai *et al.* modified the two-step exfoliation method and proposed a one-step exfoliation method, *i.e.*, directly exfoliating the as-synthesized DS^- anion intercalated LREHs in formamide under ultrasonication conditions without any anion-exchange processes.^{33,113} This one-step method avoids the possible breakage of the LREH crystals during the long-time anion exchange process. Furthermore, the ultrasonic treatment substantially reduces the exfoliation time within 1 hour, greatly shortening the reaction time with formamide and avoiding degradation. Through this one-step exfoliation method, a series of LREH nanosheets were prepared with a lateral size of up to 1 μm while the thickness was only 1 nm, indicating a monolayer feature (Fig. 4f).^{33,61} This versatile approach achieves the preparation of relatively large LREH monolayers, but also offers great potential for the subsequent construction of various 2D assemblies with rich functionalities.

Although the ion exchange and exfoliation route provides more possibilities for the synthesis of diverse LREHs and nanosheets, there are some disadvantages. For the ion exchange process, it is hard to completely substitute the original intercalated ions with the targeted one, which may affect its properties. Moreover, it usually needs a long time (7 days or even longer) and continuous shaking or sonication to fulfil ion exchange and exfoliation. The strong shear force or ultrasonic waves cause the phase and structure damage of layered materials, resulting in reduced size which further affects the exfoliation effect.¹⁰⁹ As for exfoliation, DS^- anion intercalation and using formamide as the exfoliation solvent have been proven to be an effective method for the preparation of single-layer LREH nanosheets. But the LREHs undergo degradation or even dissolution in formamide for a long time, especially under shear force/ultrasonic waves. As a result, it is hard to obtain large-sized nanosheets. Moreover, the exfoliation yield is still relatively low.^{33,109} In addition, during the exfoliation, there may be some defects such as oxygen vacancy or metal ion vacancy and/or dangling bonds which may affect the energy level.⁶¹ However, a systematic study on these aspects is still lacking.

In addition to exfoliation, ultrathin rare earth hydroxides can be prepared by direct synthesis. Through the hydrothermal method with triethylamine (TEA) as a hydrolysis reagent, Xiao *et al.* prepared a series of Y/Yb/Er-hydroxides in the form of nanoplatelets with a thickness of 10 nm, the hydroxides

exhibited obvious upconversion properties (Fig. 5a–c).⁵⁰ While co-doping Bi^{3+} and Sm^{3+} into the Y-hydroxides followed by the calcination process, $\text{Y}_2\text{O}_3:\text{Bi}^{3+},\text{Sm}^{3+}$ tetragonal nanoplatelets were obtained. As the emission peaks present different changing trends with the temperature changes, the $\text{Y}_2\text{O}_3:\text{Bi}^{3+},\text{Sm}^{3+}$ composite exhibits three kinds of luminescence intensity ratio mode, thus making it a promising temperature sensor with high accuracy (Fig. 5d–f).¹¹⁴ Therefore, various kinds of 2D rare earth hydroxides with diverse compositions have been reported till now, which promote their applications in diverse fields.

2.2 Preparation and exfoliation of layered rare earth-doped perovskites

Perovskites are a large family with various formulae and structures. Layered perovskites are a sub-set with the general composition of $\text{A}_{n-1}\text{B}_n\text{X}_{(3n+1)}$, in which negatively charged host layers and counter cations in the interlayer space demonstrate some peculiar properties like photocatalytic, conductivity, electronic, and biochemical ones.^{72,115–119} Layered rare earth-doped perovskites are commonly classified into two types, *i.e.*, Dion–Jacobson (DJ) type and Ruddlesden–Popper (RP) type with the general formula of $\text{X}[\text{A}_{n-1}\text{B}_n\text{O}_{(3n+1)}]$ or $\text{X}_2[\text{A}_{n-1}\text{B}_n\text{O}_{(3n+1)}]$, respectively, where X and A are alkali or alkali earth elements, and B represents transition metals such as Ti^{4+} , Nb^{5+} or Ta^{5+} ; rare earth elements usually occupy the A site.^{72,117,118}

Layered rare earth-doped perovskites with various compositions are mainly prepared through the solid-state reaction method.^{65,67,120} The exfoliation of layered rare earth-doped perovskites is also a two-step process including ion exchange and exfoliation. Typically, through a replacement of the interlayer alkali metal ion (*e.g.*, K^+ or Rb^+) with H_3O^+ in acid (*e.g.*, HNO_3 or HCl) and the swelling process of perovskite bulk in aqueous TBAOH or TMAOH solution with the help of shaking, the nanosheets are obtained.^{65,121}

Based on the successful preparation of LaNb_2O_7 nanosheets, Ozawa *et al.* first synthesized a Eu^{3+} -doped layered perovskite. After ion exchange and soft chemical exfoliation, $\text{La}_{0.90}\text{Eu}_{0.05}\text{-Nb}_2\text{O}_7$ monolayers with a thickness of 2 nm and a lateral size of 400 nm were finally obtained (Fig. 6a).^{67,121} The photoluminescence analysis shows that there are two types of emissions of Eu^{3+} in the bulk, *i.e.*, the direct excited emission and the host excited emission, whereas only host emission exists for the nanosheets, which can be attributed to the difference of the dimensionality and the confinement of the energy-transfer.⁶⁷ Then, they further studied the role of the Eu^{3+} dopant in the photoluminescence properties of $\text{Eu}_{0.56}\text{Ta}_2\text{O}_7$ nanosheets (Fig. 6b), and found that the emission intensity originating from the host excitation is much larger than that of the direct excitation of Eu^{3+} .⁶⁶ The stronger emission intensity of $\text{La}_{0.90}\text{-Dy}_{0.05}\text{Nb}_2\text{O}_7$ nanosheets than that of the bulk also confirmed that the host excitation is more efficient than the direct excitation.¹²³ Ida *et al.* expanded the layered rare earth-doped perovskite nanosheets to $\text{Gd}_{1.4}\text{Eu}_{0.6}\text{Ti}_3\text{O}_{10}$ (Fig. 6c) and $\text{La}_{0.7}\text{Tb}_{0.3}\text{Ta}_2\text{O}_7$, the nanosheets all have a monolayer feature. Benefiting from the energy transfer within the nanosheets from

the Ti–O network to Gd^{3+} and then to Eu^{3+} , $\text{Gd}_{1.4}\text{Eu}_{0.6}\text{Ti}_3\text{O}_{10}$ nanosheets show a much stronger emission than $\text{La}_{0.90}\text{Eu}_{0.05}\text{-Nb}_2\text{O}_7$ counterparts.⁶⁵ Moreover, they also found that the emission intensity is related to the excitation light and the direction of the magnetic field. Bulk perovskite $\text{HLa}_2\text{Ti}_2\text{TaO}_{10}$ with a similar crystal structure was also prepared and further exfoliated into the corresponding $\text{La}_2\text{Ti}_2\text{TaO}_{10}$ nanosheets with an ultra-high conductivity range from 10^{-9} to 10^{-5} S cm^{-1} .¹¹⁶ Beyond the above down-conversion luminescence nanosheets, up-conversion nanosheets of $\text{Yb}^{3+}/\text{Er}^{3+}$, $\text{Yb}^{3+}/\text{Tm}^{3+}$, and $\text{Tm}^{3+}/\text{Er}^{3+}$ co-doped $\text{K}_2\text{Ln}_2\text{Ti}_3\text{O}_{10}$ perovskites were also prepared, as shown in Fig. 6d.^{122,124,125}

In addition to the above single-layered perovskite, researchers also successfully prepared rare earth-doped double-layered perovskite nanosheets, e.g., $(\text{K}_{1.5}\text{Eu}_{0.5})\text{Ta}_3\text{O}_{10}$, $(\text{K}_{1.5}\text{Tb}_{0.5})\text{Ta}_3\text{O}_{10}$, and $[\text{K}_{1.5}(\text{Tb}_{1-x}\text{Sm}_x)]\text{Ta}_3\text{O}_{10}$ nanosheets (Fig. 6e).^{25,68} Considering the excellent tuneable excitation wavelength and interesting property of cascade energy transfer of double-layered perovskites, researchers designed Eu^{3+} -doped double-layered perovskite $\text{GdMgWO}_6:\text{Eu}$ nanosheets through proton exchange and exfoliation in ethylamine solution (Fig. 6f).^{69,126} Compared with the bulk perovskite, the $\text{GdMgWO}_6:\text{Eu}$ nanosheets showed high concentration quenching of up to 60% of Eu^{3+} and a high quantum yield of 30%.⁶⁹ In general, compared with the bulk phase, the ultrathin nanosheets exhibit enhanced properties in photoluminescence intensity, conductivity and quenching concentration.

2.3 Other rare earth-containing 2D materials

Another attractive 2D material family is rare earth-containing 2D metal–organic frameworks (MOFs). Compared with

traditional 3D MOFs, the 2D MOFs exhibit a larger specific surface area, faster electron transfer and abundant exposed active sites that are accessible, which enable them with improved properties such as electrochemiluminescence (ECL), photocatalysis and sensitivity.^{127,128} With ytterbium as nodes and 4,4',4'',4'''-(21*H*,23*H*-porphine-5,10,15,20-tetrayl) tetrakisbenzoic acid (H_2TCPP) as the ligand in dimethylformamide (DMF) solution, 2D Yb-MOFs were synthesized and exhibited thickness-dependent ECL behavior. In particular, the thinner the 2D Yb-MOFs, the stronger the ECL signals, which was ascribed to the large surface area, better electrochemical conductivity and higher productive ratio of fluorescence quantum yield.¹²⁹ Furthermore, the porphyrin-based 2D Ln-MOFs, especially porphyrin-based 2D Yb-MOF (namely, Yb-TCPP MOF), display outstanding photodynamic activity (Fig. 7a and b).¹³⁰ By coupling the porphyrin-based 2D Yb-TCPP MOF with methylene blue (MB), Jiang *et al.* prepared 2D artificial light-harvesting-system (MB/Yb-TCPP) nanosheets. The MB/Yb-TCPP nanosheets showed efficient photon capture, energy transfer and various active centres, which led to excellent photocatalytic properties (Fig. 7c and d).¹³¹ Moreover, rare earth cations such as Eu^{3+} and Tb^{3+} are also introduced into the 2D Zn(II) MOF to form 2D Ln³⁺-encapsulated functional materials with a tuneable emission color.¹³⁴ With 2,2'-thiodiacetic acid (TDA) as a surfactant, a series of rare earth-based layered MOF can be synthesized, and the layered structures can further be exfoliated into ultrathin nanosheets in EtOH under ultrasonication conditions (Fig. 7e and f).¹³² Through simple mixing of Tb/Eu salts and 5-boronoisophthalic acid (5-bop) in the presence of triethylamine (TEA) at room temperature, Wang *et al.* synthesized three boric acid-functionalized 2D MOF

nanosheets, *i.e.*, Tb-bop, Eu-bop and bimetallic Tb/Eu-bop MOF nanosheets, respectively, expanding the 2D MOF family (Fig. 7g and h).¹³³ Though several 2D MOFs containing rare earths have been synthesized in recent years, the ligands used are quite scarce, resulting in limited availability of rare earth-containing 2D MOFs, which deserve more attention and exploration.

2D rare earth oxyhalides (REOXs) represent another interesting class of rare earth-containing 2D compounds. The CVD method is widely used for the preparation of the REOXs. Through this method, Chen *et al.* successfully synthesized EuOCl with an ultra-narrow linewidth of 1.2 meV at room temperature while Tian *et al.* synthesized DyOCl with strong A-type antiferromagnetism below the Néel temperature T_N of 10 K.^{135,136} Zhang *et al.* designed a facile strategy to prepare a series of 2D LnOCl (Ln = La, Pr, Nd, Sm, Eu, Gd, Tb, Dy) nanoflakes using the molten salt method assisted by the substrate. The lateral size of the prepared ultra-thin nanoplate could reach up to 40 μm with a thickness of only 7.5 nm.¹³⁷ As a gate dielectric, the LnOCl nanoflake exhibited competitive device characteristics of high on/off ratios up to 10^7 and low subthreshold swings down to 77.1 mV dec^{-1} .

2.4 Assembly of rare earth-based or doped nanosheets into functional structures

As one kind of nanosheets showing unique properties, rare earth-based or doped nanosheets can be re-assembled into desirable forms for function exploration. Layer-by-layer (LBL) deposition method is a useful method to fabricate the nanosheets on quartz or silicon wafers. As the LREH nanosheets are positively charged, after introducing the negatively charged poly(sodium-*p*-styrenesulfonate) (PSS) ions as counter ions, the LREH nanosheets can be transferred on the wafer and further LBL assembled to form multilayer films, such as (LGdH:Eu/PSS) $_n$ and (LGdH:Tb/PSS) $_n$ films, where LGdH:Eu represents Eu³⁺ doped LGdH and LGdH:Tb represents Tb³⁺ doped LGdH (Fig. 8a and b).^{60,61} Through self-assembly at the hexane/water interface, Eu(OH)_{2.5}Cl_{0.5}·0.9H₂O and Gd(OH)_{2.5}Cl_{0.5}·0.9H₂O:0.05Eu can be transferred upon a glass wafer.^{138,139} After an annealing treatment, the

hydroxide film can be quasi-topotactically transformed into Gd₂O₃:0.05Eu (Fig. 8c).¹³⁸ The self-assembled film is semi-transparent with a flat surface and strong adhesion, and exhibits high orientation, which is beneficial for enhancement of photoluminescence. This quasi-topotactic transformation and enhanced photoluminescence originating from high orientation were also found in LYH and Y₂O₃ films which were fabricated by spin-coating.¹⁴⁰

Through the LBL deposition method, the negatively charged La_{0.90}Dy_{0.05}Nb₂O₇ nanosheets can be self-assembled with poly-ethylenimine (PEI) as a connector on a quartz, resulting in (PEI/La_{0.90}Dy_{0.05}Nb₂O₇) $_n$ multilayer films (Fig. 9a). Photoluminescence analysis shows that the as-prepared film displayed a blue-light emission with peaks centred at around 480 and 576 nm (Fig. 9b), and it was found that compared with the direct excitation for the bulk structure, the host excitation is in a dominant state in the nanosheet and film.¹²³ Moreover, multilayer upconversion films of alternately assembled Er³⁺/Yb³⁺ co-doped Ln₂Ti₃O₁₀ (Ln₂Ti₃O₁₀:Er³⁺, Yb³⁺) and Tm³⁺/Yb³⁺ co-doped Ln₂Ti₃O₁₀ (Ln₂Ti₃O₁₀:Tm³⁺, Yb³⁺) nanosheet on indium tin oxide (ITO) glass presented a white emission (Fig. 9c).¹²⁵

Assembling the rare earth-containing nanosheets with other 2D nanosheets through the LBL method, superlattice-like nanofilms were fabricated. Ida *et al.* reported a bilayer film composed of Eu(OH)_{3-x} nanosheets and Ti_{1.81}O₄ nanosheets with drastically enhanced luminescence.¹⁴¹ Bai *et al.* further fabricated a series of superlattice films with LREH nanosheets and semiconductive nanosheets, such as (LGdH:Eu/Ti_{0.87}O₂^{0.52-}) $_n$ films, (LGdH:Tb/TaO₃⁻) $_n$ films and (LGdH:Eu/Ti_{0.87}O₂^{0.52-}/LGdH:Tb/TaO₃⁻) $_n$ films and systematically studied the energy transfer process within the superlattice films, in which LGdH:Eu and LGdH:Tb represent Eu³⁺ or Tb³⁺ doped LGdH, respectively (Fig. 10a).⁶¹ When LREH nanosheets were assembled with SiO₂ nanoparticles, LREHs/SiO₂ porous multilayer films were prepared with high transparency (Fig. 10b and c).^{59,142} The emission light color could be tuned by adjusting the composition of the different color light sources. Therefore, the LBL method is a useful way to fabricate multilayer films with

controllable compositions and structures by using ultra-thin nanosheets. In addition, through a block-by-block epitaxial growth of the multistep molten salt method, SmOCl-NdOCl-EuOCl multi-heterostructure and $\text{SmOCl-NdOCl-SmOCl-NdOCl}$ superlattice films were fabricated, that is, growth of the second and subsequent layers by precisely sprinkling the powders beside the existing crystals under the same conditions.¹³⁷

A clean substrate (*e.g.*, quartz glass or silicon wafer) is generally needed for the above-mentioned LBL assembly method, and the rare earth-containing multilayer films assembled by this method are widely used in the luminescence field. As rare earth-doped perovskite nanosheets are negatively charged, they can also be flocculated by positively charged cations to form lamellar structures. This flocculation method endows rare earth-based or doped nanosheets with more properties. Xin *et al.* flocculated negatively charged $\text{Ti}_{0.91}\text{O}_2$ nanosheets with Eu^{3+} or Tb^{3+} ions to form ex- $\text{Ti}_{0.92}\text{O}_2/\text{Eu}$ and ex- $\text{Ti}_{0.92}\text{O}_2/\text{Tb}$ composites, respectively, and found that the

flocculation was in a lamellar structure with a gallery distance of 1.06 nm (Fig. 11a).¹⁴³ The photoluminescence analysis indicates that nonradiative energy transfer from the $\text{Ti}_{0.91}\text{O}_2$ host to Eu^{3+} can take place in this system (Fig. 11b).¹⁴³ Similarly, red- and green-light-emitting Eu^{3+} or Tb^{3+} ion-flocculated TiTaO_5 lamellar aggregates were prepared.¹⁴⁵ Through flocculating $\text{Ca}_2\text{Nb}_3\text{O}_{10}$ nanosheets with Ho^{3+} , Yb^{3+} and Y^{3+} ions, Ozawa *et al.* prepared a new upconversion lamellar material $(\text{Ho}_{0.096}\text{Yb}_{0.23}\text{Y}_{0.164})\text{Ca}_{1.76}\text{Nb}_3\text{O}_{10}$, in which $\text{Ca}_2\text{Nb}_3\text{O}_{10}$ nanosheets were restacked in a parallel manner with three layers (Fig. 11c).¹⁴⁴ While using Ag^+ as the counter cations, Günay *et al.* fabricated an Ag^+ -intercalated $\text{Tm}^{3+}/\text{Er}^{3+}$ co-doped $\text{Ln}_2\text{Ti}_3\text{O}_{10}$ composite, and found that the flocculation exhibited efficient antibacterial and antibiofilm activity but also low cytotoxicity (Fig. 11d).⁷⁰ Compared with the LBL fabrication method, this flocculation method shortens the time largely and can enhance or expand the properties of nanosheets by the introduction of counter ions, but it lost the superlattice-like structures.

Fig. 12 (a) XRD patterns, (b) TEM image and (c) SEM and elemental mapping images of the GdEu/TiO membrane, in which GdEu and TiO represent Eu^{3+} doped LGdH nanosheets and $\text{Ti}_{0.87}\text{O}_2^{0.52-}$ nanosheets, respectively. Adapted from ref. 146. Copyright 2022, John Wiley & Sons, Inc.

Based on electrostatic absorption, Bai *et al.* constructed a self-standing superlattice membrane through the direct assembly of LREH nanosheets and 2D semiconductive oxide counterparts in a face-to-face manner (Fig. 12).³⁴ The emission light color of the (GdEu/TiO)/(GdTb/TaO) membrane can be controlled by adjusting the excitation wavelength numbers, where GdEu and GdTb represent Eu^{3+} or Tb^{3+} doped LGdH nanosheets, respectively, TiO and TaO represent $\text{Ti}_{0.87}\text{O}_2^{0.52-}$ and TaO_3^- nanosheets, respectively. In addition, the self-standing membrane exhibited stable cathode luminescence under continuous electron bombardment. When the LREH nanosheets were assembled with Ti_3C_2 nanosheets, the LREH/MXene hybrid presented excellent photothermic and MRI properties.¹⁴⁶ This re-assembly method of nanosheets will inspire the structural design development of rare earth-based or doped 2D materials with multifunction.

All the above assembly methods of ultrathin rare earth-based or doped nanosheets, especially for the superlattices, inspired new strategies to integrate different nanosheets and promote the design of rare earth nanomaterials towards novel structures and interesting functionalities. Further efforts in the assembly of more functional nanosheets with different compositions/structures are needed to enhance and expand the applications of rare earth nanomaterials.

3. Biomedical applications based on 2D rare earth nanomaterials and composites

The properties of rare earth-containing nanomaterials are largely affected by their structures and doping elements. Tables 1–3 summarize the morphology, rare earth-containing elements and functions of 2D rare earth nanomaterials. It is obvious that the layered structure with interlayer ion exchangeability is beneficial in drug release, especially for LREHs. On the other side, due to the half-filled 4f electrons, the existence of Gd^{3+} endows the nanomaterials with magnetic properties, resulting in their application as MRI agents. Moreover, for ultrathin nanosheets, the abundant active side ensures that it can be modified with other functional nanosheets/groups, thus expanding their application scenarios. This section summarizes the composition, general properties and applications of 2D rare earth nanomaterials.

3.1 Drug delivery

For layered structured nanomaterials, the abundant interlayer space and rich interlayer ion exchangeability greatly promote their drug load and release properties, which provide more ideas for the design of drug delivery carriers.

Through anion exchange or direct synthesis, various drugs, such as diclofenac (dic), ibuprofen (ibu), naproxen (nap), aspartic acid, glutamic acid, palmitic acid, anti-miRNA oligonucleotides and aspirin (ASA), can be intercalated into the gallery of the LREHs.^{46,57,58,106–108} The non-steroidal anti-inflammatory drugs (diclofenac, ibuprofen, and naproxen) can be inserted into LGdH, and the LGdH-drug intercalates are stable in neutral pH and degrade rapidly under acidic conditions.⁵⁷ Different drugs exhibit diverse release times. For example, naproxen-intercalated LREH releases the drug loadings very rapidly (within 1.5 h), and the diclofenac-intercalated one shows sustained release time over 4 h, while the ibuprofen-intercalated counterpart shows a continuous release time of 24 h and the ASA-loaded LREH extends the release time up to 36 h, as shown in Fig. 13a and b.^{57,58} Furthermore, the LREHs-drug composites show good targeted drug delivery properties, high drug loading and low cytotoxicity, enabling the LREHs with potential applications in drug delivery. Gu *et al.* prepared a 5-aminolevulinic acid (5-ALA) intercalating LREH-coated MgFe_2O_4 particles (5-ALA- MgFe_2O_4 @LREH). With the help of magnetic MgFe_2O_4 , the 5-ALA- MgFe_2O_4 @LREH carries drugs efficiently to targeted locations under an external magnetic field.⁴⁵ Recently, Li *et al.* proposed Y/Tb/Gd ternary LREH nanocones with drug delivery and simultaneous MRI properties, as shown in Fig. 13c.⁴⁴ Through anion exchange, ASA can be loaded into the gallery with a delayed release behavior to 48 h (Fig. 13d), which is favorable for sustained therapy. As the intercalation of ASA can enhance the green light emission at the peak of 543 nm, the nanocones can also be utilized as a fluorescence probe to monitor the loading and release process of ASA. Furthermore, the ASA intercalation improves the magnetic properties of the nanocones, which enables an additional application as an MRI contrast agent simultaneously.

In addition to inorganic 2D nanomaterials, rare earth-porphyrin MOF nanosheets can also serve as drug delivery materials. Through the surfactant-assisted solvothermal method, a series of lanthanide-porphyrin MOF nanosheets (denoted as PPF-Ln) with ultrahigh drug loading capacity were

prepared.¹⁴⁷ The results show that the loading capacity of PPF-Gd nanosheets can reach 1515% when the doxorubicin (DOX) concentration is 4 mg mL⁻¹ (Fig. 13e). Also, PPF-Gd nanosheets exhibit pH-responsive biodegradation and persistent drug release performance. As shown in Fig. 13f, in the phosphate buffered saline (PBS) solution (pH = 5.5), about 49% DOX was released over 24 h, while only 15% DOX was released at pH 7.4. The final release percentage reached 72% and 24% at pH 5.5 and 7.4 after 96 h, respectively. Moreover, the *in vivo* results confirm the evident suppression of the tumor growth by the PPF-Gd/DOX system with negligible side effects. Owing to the unique layered structure, these 2D layered rare earth nanomaterials hold controllable drug load and release properties, the release time varies from within 1.5 h to several days depending on the type of drug and environment pH, which enables the 2D rare earth nanomaterials to have promising drug delivery applications in different *in vivo* environments.

Apart from those described above, 2D rare earth nanomaterials can also load and release other therapeutic drugs. The drug delivery applications are summarized in Table 1. Despite the promising commercial prospects, 2D rare earth nanomaterials as drug delivery agents still have some deficiencies. For instance, LREHs as typical hydroxides are stable in neutral and alkaline systems, but are easily decomposed in acidic systems. Thus they are scarcely used in acidic environments such as in the stomach, which greatly limits their application

prospects. Moreover, since LREHs and perovskite host layers are positively and negatively charged, respectively, they exhibit good drug load properties for the negatively and positively charged drugs. However, for those drugs with the same electrical charge or neutral property, their loading capacity needs to be improved.

3.2 Bioimaging

Magnetic resonance imaging, computed tomography (CT), B-scan ultrasonography and X-ray radiography are the most common medical imaging diagnostic technologies. The diverse 4f electron shell endows rare earth-containing nanomaterials with unique magnetic properties. For example, Sc³⁺, Y³⁺, La³⁺ and Lu³⁺ are magnetically inert and are mainly employed as host cations for doping with other ions due to their empty or completely filled 4f electrons.¹⁶³ On the other hand, most rare earth ions are paramagnetic at room temperature due to the unpaired 4f electrons, such as Ce³⁺, Gd³⁺, Tb³⁺ and Eu³⁺, in which Gd³⁺ possesses the largest magnetic moment of all rare earth ions due to the highly symmetric ground state and seven unpaired 4f electrons.¹⁶³⁻¹⁶⁶ Thus, Gd³⁺-containing nanomaterials, with abundant unpaired electrons of the high-spin states of Gd³⁺, exhibit significant magnetic properties and are promising MRI agents for the detection of pathological tissues.^{41,42,108,167}

As shown in Fig. 14a, Gd/Y hydroxide nanosheets show excellent MRI performance with high longitudinal and transverse relativities of r_1 (103 mM⁻¹) and r_2 (372 mM⁻¹) (Fig. 14a).⁴³ When modified with phospholipids, LGdH nanosheets can work as an efficient MRI contrast agent and show a significant signal loss in the T_2 -weighted MRI of the abdomen (Fig. 14b).⁴² The intercalation of some drugs (*e.g.*, diclofenac, ibuprofen, and naproxen) can further enhance the MRI performance of LREHs.⁵⁷ While MRI contrast agents generally show low contrast efficacy for MRI systems with ultrahigh magnetic field higher than 7.0 T, Ce and Tb co-doped LGdH (denoted as LGdH:Ce,Tb) shows excellent negative (T_2) contrast agent efficacy for 7.0 T MRI with a high r_2/r_1 ratio of 48.80, whereas a lower r_2/r_1 ratio of 30.60 for 3.0 T MRI, indicating a high-

Copyright 2020, Oxford University Press.

performance T_2 -weighted contrast agent in ultrahigh-field MRI.⁵² Furthermore, the LGdH:Ce,Tb can also work as a contrast agent in CT and fluorescence bioimaging. In recent years, our team proposed several studies on LREH-based nanomaterials with MRI properties. Though the half-filled 4f electron configuration of Gd³⁺ endows the Gd³⁺-containing nanomaterials with MRI properties, it's negligible for the pure layered Y/Gd hydroxide. Though the intercalation of ASA can enhance the T_1 -weighted *in vitro* MRI performance, the *in vivo* MRI effects are still not obvious enough.⁴⁴ Through the construction of a superlattice of LGdH nanosheets and Ti₃C₂ nanosheets, Bai *et al.* proposed an LGdH/Ti₃C₂ hybrid, which exhibited obvious enhanced *in vitro* and *in vivo* T_1 -weighted MRI effect, as shown in Fig. 14c.¹⁴⁶

Through introducing guests or anion exchange, Gd³⁺ and Gd³⁺-based contrast agents are doped into LDH to improve their MR relaxation.¹⁶⁸ Gd³⁺ and Dy³⁺ co-doped LDH (GdDy-LDH) showed high contrast effect in MRI with $r_1 = 3.49 \text{ mM}^{-1} \text{ s}^{-1}$ and $r_2 = 18.17 \text{ mM}^{-1} \text{ s}^{-1}$.¹⁴⁹ When Gd³⁺ and Cu²⁺ are co-doped in LDH, the GdCu-LDH showed significantly higher longitudinal relativity compared with those solely doped with Gd³⁺ or Cu²⁺ (Gd-LDH or Cu-LDH) due to the synergistic T_1 shortening between adjacent Gd³⁺ and Cu²⁺ in the LDH host layers.¹⁵⁰ Through ion exchange, Xu *et al.* prepared Gd-dtpa (dtpa = diethylene triamine pentaacetate) intercalated Mg₂Al-Cl-LDH (LDH-Gd(dtpa)).^{151,152} Compared to Gd(dtpa) free LDH, the LDH-Gd(dtpa) displayed 4 times increase in longitudinal proton relaxation and a 12 times increase in transverse proton relaxation.¹⁵¹ Guan *et al.* developed a supramolecular nanomaterial

(FITC/FA-DOX/Gd-LDH) *via* co-intercalation of folic acid (FA) and DOX into the Gd-LDH, followed by adsorption of fluorescein isothiocyanate (FITC), FITC/FA-DOX/Gd-LDH exhibited excellent T_1 -weighted MRI and fluorescence dual-mode imaging activity.¹⁵⁵ Through adding gold nanoclusters (AuNCs) and Chlorin e6 (Ce6) to the Gd-LDH, Mei *et al.* synthesized Ce6&AuNCs/Gd-LDH. Both *in vitro* and *in vivo* results confirmed that the Ce6&AuNCs/Gd-LDH showed MRI and fluorescence dual-mode imaging activity.¹⁵⁶

Other than inorganic 2D materials, rare earth-based 2D MOFs show promising applications in the bioimaging field.^{169,170} The PPF-Gd nanosheets exhibit an obviously enhanced T_1 -weight MR signal with a transverse relativity of $10.04 \text{ mM}^{-1} \text{ s}^{-1}$.¹⁴⁷ As shown in Fig. 14d and e, for both intravenous injection and subcutaneous injection, the *in vivo* T_1 -weighted MRI signal is detected and significantly higher than that before injection. Moreover, the PPF-Gd nanosheets show obvious fluorescence imaging properties following subcutaneous injection after 72 h.

As summarized in Table 2, 2D rare earth nanomaterials can also work as CT imaging and NIR imaging agents in addition to MRI. Through reverse micelle preparation of LDH and Gd(OH)₃, Jung *et al.* synthesized Gd/MgGa-LDH hybrids, which exhibited CT and MR dual-modal imaging performance, due to the high X-ray attenuation coefficient and paramagnetic properties of Gd³⁺ in Gd(OH)₃.¹⁵⁷ Mei *et al.* prepared Gd³⁺ and Yb³⁺ co-doped LDH (Gd&Yb-LDH) monolayer nanosheets. The experiments on the *in vivo* metabolic pathway indicated that *in vivo* tri-mode (MR, CT and near-infrared fluorescence (NIRF)) imaging was

(f) *In vivo* MR and (g) CT imaging of nude mice bearing HeLa tumors at different time points after intravenous injection of SN38&ICG/Gd&Yb-LDH. (h) *In vivo* fluorescence imaging and drug bio-distribution for nude mice bearing HeLa tumors at different time points after intravenous injection of PBS, SN38&ICG/Gd&Yb-LDH and SN38&ICG, respectively, together with *ex vivo* imaging of ICG in the tumour and five different organs collected from mice sacrificed at 24 h, in which SN38&ICG/Gd&Yb-LDH represents a chemotherapeutic drug (SN38) and indocyanine green (ICG) co-modified Gd^{3+} and Yb^{3+} co-doped LDH. Adapted from ref. 148. Copyright 2018, the Royal Society of Chemistry.

achieved (Fig. 14f–h), enabling a non-invasive visualization of cancer cell distribution with deep spatial resolution and high sensitivity.¹⁴⁸ The Gd&Yb-LDH monolayers exhibited ultrahigh loading content of a chemotherapeutic drug (SN38) up to 925%. Furthermore, SN38&ICG/Gd&Yb-LDH was prepared by further modifying Gd&Yb-LDH with SN38 and ICG. As shown in Fig. 14f and g, after intravenous injection of SN38&ICG/Gd&Yb-LDH, the tumor site of nude mouse displayed a gradually enhanced MRI and CT imaging signal due to the enhanced permeability and retention (EPR) effects and preferential accumulation, respectively. As shown in Fig. 14h, after the injection of SN38&ICG and SN38&ICG/Gd&Yb-LDH for 2 h, significant NIRF signals were observed throughout the whole body. For the injection of SN38&ICG/Gd&Yb-LDH, the signal remained after 24 h while it was rather weak for SN38&ICG after 6 h.

Thus, both the inorganic and organic Gd³⁺-containing 2D nanomaterials exhibit high potential in bioimaging applications. Although extensive work has been conducted on the magnetic property modulation and MRI applications of 2D rare earth nanomaterials, it mainly focuses on Gd³⁺-containing materials. Other RE-based nanomaterials have been rarely explored, which needs more study.

3.3 Tumor therapy

On account of biocompatibility and low toxicity, the applications of 2D rare earth nanomaterials in other biochemical fields beyond drug delivery and MRI contrast agents have also been explored recently, especially tumor therapy.

For instance, poly(ethylene glycol) (PEG) modified LGdH (PLGdH) presents superior X-ray deposition and tumor penetrability. Moreover, after further encapsulation of physcion (Phy), the Phy-modified PLGdH (Phy@PLGdH) can further amplify PLGdH-sensitized room temperature mediated oxidative stress and DNA damage, and synergistically induce the potent immunogenic death, resulting in highly active tumor inhibition in radiation therapy (RT) (Fig. 15a).⁶² In addition, Gd-based porphyrin paddlewheel framework (PPF-Gd) MOF showed significantly high *in vitro* and *in vivo* tumor inhibition performance, as illustrated in Fig. 15b and c. After subcutaneous injection, the doxorubicin (DOX) modified PPF-Gd (PPF-Gd/DOX) exhibited a greatly enhanced inhibition efficacy to the tumor growth.¹⁴⁷ Meanwhile, the weight of mice was slightly increased during the treatment in the PPF-Gd/DOX group, making it an excellent chemotherapy agent candidate in cancer therapy with enhanced therapeutic efficiency and low toxic side effects.

Though RT and thermotherapy are widely used in tumor therapy, they are harmful to biological tissues. Compared with these harmful treatments, PTT treatment has gained increasing attention due to its deep penetration and low tissue damage. For photothermal therapy, the LGdH/Ti₃C₂ hybrid exhibited an enhanced photothermal effect under 2 W cm⁻² irradiation for 10 min, in which the temperature surpassed 60.4 °C (Fig. 15d).¹⁴⁶ The above-mentioned SN38&ICG/Gd&Yb-LDH demonstrated excellent PTT properties. After the injection of 3 min, the temperature of the nude mice tumor site increased to

51 °C, and the dynamic tumor growth experiment also confirmed the benefit of SN38&ICG/Gd&Yb-LDH to *in vivo* photothermal therapy.¹⁴⁸

Other than traditional phototherapy and chemotherapy, 2D rare earth nanomaterials were also used in photocatalytic therapy (PCT), photodynamic therapy (PDT) and chemodynamic therapy (CDT).^{171,172} Zhang *et al.* synthesized Ce and S co-doped Bi₂O₃ (BOSC) nanosheets with enhanced PCT under near-infrared light irradiation. The introduction of Ce promotes the generation of reactive oxygen species (ROS), which enhances light absorption, introduces oxygen vacancies, reduces bandgap, and facilitates charge separation. The Ce doping also modifies the band position and Fermi level of BOSC, resulting in increased band bending at the solid-liquid interface, enabling a cascade reaction of ROS.^{159,160} On the other hand, Wang *et al.* prepared AFGd-LDH through surface modification of Gd-LDH with atorvastatin (ATO) and ferritin heavy subunit (FTH). Both *in vitro* and *in vivo* experiments verified that the AFGd-LDH shows outstanding MRI performance and alleviates brain reperfusion injury issue due to the excellent ROS scavenging efficiency.¹⁵³

Moreover, PDT has become a promising cancer treatment approach with superior advantages.¹⁶¹ Liu *et al.* synthesized a tumor target agent through modifying NaYF₄:Yb,Tm@NaGdF₄, folic acid (FA), carboxymethyl triphenylphosphine (TPP) on graphene oxide quantum dots, in which the upconversion nanoparticles serve as a transducer of excitation light.¹⁷³ Both *in vitro* and *in vivo* experiments show that the synthesized nanomaterials exhibited significantly enhanced subcellular targeting and PDT efficacy for cancer therapy.

To further improve the treatment efficiency of tumor cells, researchers have designed 2D rare earth nanomaterials with multiple treatment pathways. Wang *et al.* designed Ce-doped CuAl-LDH (denoted as CAC-LDH) nanosheets and further loaded them with indocyanine green (ICG) to synthesize ICG/CAC-LDH.¹⁵⁸ The synthesized ICG/CAC-LDH could induce intracellular glutathione (GSH) depletion and reduce Cu²⁺ and Ce⁴⁺ to Cu⁺ and Ce³⁺, respectively, and further decompose H₂O₂ to cytotoxic ·OH through the Fenton reaction. The obviously enhanced absorption at 808 nm and efficient NIR light-to-heat conversion enable the ICG/CAC-LDH with photothermal efficiency and further increase the Fenton reaction rate. Thus, the ICG/CAC-LDH showed remarkable dual-model PTT/CDT efficacy against HepG2 cancer cells. Furthermore, ICG/CAC-LDH can also work as an MRI and photoacoustic imaging (PAI) agent. Moreover, triple-model combined therapy, so-called chemo/PTT/PDT, can be achieved by co-modification of DOX, ICG and Gd³⁺ on MgAl-LDH (denoted as DOX&ICG/MLDH).¹⁶² Jia *et al.* synthesized UCSP-FeMn-LDH through modifying FeMn-LDH with mesoporous silica and Ce6 co-coated NaGdF₄:Yb,Er@NaGdF₄:Yb (UCSP). The UCSP-FeMn-LDH showed excellent oxygen-elevated PDT, enhanced PTT and CDT synergistic therapy (Fig. 15e) and real-time monitoring of therapeutic effect *via* feasible CT imaging and T₁/T₂-weighted MRI.¹⁵⁴

In addition to tumor therapy, 2D rare earth nanomaterials can also work in other biomedical applications. The Ag⁺-

modified Tm³⁺/Er³⁺ co-doped K₂La₂Ti₃O₁₀ layered compound demonstrates efficient antibacterial and antibiofilm activity (Fig. 15f and g).^{70,122} Moreover, 2D MOFs with rare earth ions as nodes (MOF-Ln), such as MOF-La, also show some interesting properties in biomedical applications. Wang *et al.* found that the fluorescence of negatively charged fluorescein (FAM)-labelled single-stranded DNA (ssDNA) was partially quenched

by MOF-Ln nanosheets, while that of positively charged tetramethyl rhodamine (TAMRA)-labelled ssDNA showed the same quenching and recovery properties on MOF-Ln nanosheets. Thus the MOF-Ln can be used as a two-color sensing platform for intracellular detection in living cells (Fig. 15h).¹³²

The summary of 2D rare earth nanomaterials for tumor therapy applications is listed in Table 3. The *in vitro* and *in vivo*

experiments verified that 2D rare earth-containing nanomaterials have low cytotoxicity and great biocompatibility.^{43,44,62,153} For example, Phy@LGdH showed no obvious cytotoxicity in CT26 tumor cells and the BOSC showed no significant inhibition of 4T1 mouse breast cancer cells after 48 h of incubation, while the LTbH showed no significant cytotoxicity on Caco-2, HEK 293 cell line, HeLa, fibroblast and rhabdomyosarcoma cancer cell lines.^{46,62,148,159} However, only limited experiments on *in vivo* metabolic pathways have been carried out. More attention in this regard is needed in future clinical applications. Therefore, with the combined advantages of high biocompatibility, low toxicity and the unique biochemical properties of 2D rare earth nanomaterials and composites, further investigations of more 2D rare earth nanomaterials in biomedicine fields, especially in *in vivo* applications, are highly desired.

4. Conclusions

In summary, this work provides an overview of the recent progress in the design, preparation and biomedical applications of 2D nanomaterials based on rare earth elements. In particular, focus on the exfoliation of LREHs and rare earth-doped layered perovskites is presented. Through exfoliation, bulk layered LREHs or rare earth-doped perovskites can be dimensionally reduced into ultrathin nanosheets, which promotes further assembly and multifunctional applications. Artificial superlattice assembly is an effective method to enhance the properties of rare earth-based or rare earth-containing nanosheets. Moreover, the application fields can be expanded with integration with other functional counter nanosheets. Progress in diverse biomedical applications (*e.g.*, drug delivery, MRI, cancer therapy, *etc.*) implies that the 2D rare earth nanomaterials have great potential in health-related field applications. Although significant breakthroughs have been made in these fields, some limitations and challenges still exist. Herein, based on the current progress, several prospects and opportunities for the development of 2D nanomaterials based on rare earth are proposed.

(i) It is desirable to expand the family of rare earth-based or doped nanosheets. Diverse-high-quality nanosheets based on rare earth elements with tuneable composition are essential for further research, although a variety of rare earth nanosheets such as LREHs and rare earth-doped perovskite nanosheets have been proposed. Compared with the large class of similar LDHs and perovskites, the class of rare earth-based or doped nanosheets is still limited. Thus, the design and preparation of new 2D nanomaterials based on rare earth elements are of great importance.

(ii) Further studies on the exfoliation process and in-depth understanding of the mechanism are urgent. High quality (*i.e.*, high crystallinity, tuneable lateral size and ultrathin thickness) of rare earth-based or doped nanosheets is vital to promote the assembly and further applications. Although great breakthroughs have been made in the preparation of rare earth-based or doped nanosheets recently, the yield is very low. Furthermore, the nanosheets are unstable in the exfoliation

solution, that is, the nanosheets are easily restacked to form flocculations and/or degrade in the solution upon long time storage. Thus, more research should focus on the improvement of exfoliation yield and structural stability, such as selecting a more efficient exfoliation solvent and/or surface modification on the nanosheets. Therefore, further studies and improvements in the exfoliation process are needed to propose basic principles and key factors which determine the exfoliation efficiency and nanosheet quality.

(iii) More attempts at superlattice assembly of rare earth-containing nanosheets and other functional nanosheets are expected. Molecular-scale assembly enables construction of functional nanostructures based on 2D rare earth nanomaterials with diverse compositions and structures, and is an important method to improve their properties, especially for rare earth-based or rare earth-containing nanosheets. It is proved that for superlattice-like assembly, the suitable pairing (combination) of rare earth-based or doped nanosheets with other functional nanosheets can significantly enhance the original properties (*e.g.*, photoluminescence properties) or even create new properties (*e.g.*, photothermal properties). Thus, more attempts on the superlattice assembly of rare earth-containing nanosheets and other functional nanosheets (*e.g.*, MXenes, TMDs, oxides, *etc.*) may spawn new interesting functional materials.

(iv) Expansion and acceleration on applications of 2D nanomaterials based on rare earth elements. 2D rare earth-based or doped nanomaterials are mainly applied to drug delivery and bioimaging, and have demonstrated excellent performance and promising application prospects in diverse biomedicine fields. Further investigations of rare earth nanomaterials in other frontier biomedical fields such as cancer treatment agents (*e.g.*, photothermal therapy, photodynamic therapy, *etc.*), biosensors, theragnostic agents, tissue engineering and regenerative agents are highly expected.

Data availability

No primary research results, software or code has been included and no new data were generated or analysed as part of this review.

Author contributions

M. B. and R. M. conceived the idea. H. W., X. L. and R. M. supervised the project. The manuscript was written through the contribution of all authors. All authors have approved the final version of the manuscript.
