## Two-step insertion/release of electrolytic cations in redox-active hydrogen-bonding nanoporous coordination crystals<sup>†</sup>

Makoto Tadokoro, 💿 \*ª Ryota Nishimura,ª Hajime Kamebuchi,<sup>b</sup> Fumiya Kobayashi, 💿 ª Jun Miyazaki 💿 <sup>c</sup> and Masa-aki Haga 回 <sup>d</sup>

Solid-state cyclic voltammetry (CV) of redox-active H-bonding  $\{[Ru^{III}(Hbim)_3]\}_n$  (1) 1-D nanoporous crystals was performed using single crystals in MeCN solutions containing seven electrolyte cations with different effective ionic radii (EIRs). Two cations must be included to every nanochannel unit in  $\{[Ru^{III}Ru^{II}]^{2-}\}$  reductive states by a two-step and multi-electron transfer reaction through the  $\{[Ru^{III}Ru^{II}]^{-}\}$  mixed-valency state. This study is the first to use solid-state CV to determine the EIR limitation of cations confinable in these crystals.

Self-organising materials such as metal–organic frameworks (MOFs), covalent organic frameworks (COFs), and hydrogen-bonded (H-bonded) organic frameworks (HOFs) have attracted attention over the past decade as functional nanoporous materials.<sup>1</sup> These materials have robust and regular crystalline nanochannel spaces created by molecular designs and can store and separate gases such as  $CO_2$ ,  $O_2$ , and  $CH_4$ ;<sup>2</sup> hence, they are useful for the insertion/release of active small molecules for a catalytic reaction.<sup>3</sup> In addition, MOFs contain central transition-metal ions with both redox-active<sup>4</sup> and magnetic<sup>5</sup> behaviours. Therefore, they can be used to construct nanoporous frameworks.

Recently, several MOF-based conductors that utilise intermolecular charge-transfer interactions between metal ions and redox-active ligands have been developed.<sup>6</sup> Their conductive mechanisms involve electron flow through the spaces of porous frameworks or conjugated  $\pi$ -electron ligand systems. For example, Prussian blue (PB) ([ $\{Fe^{II}-CN-Fe^{III}-CN\}M^+$ ]<sub>n</sub>), a conductive MOF discovered more than 300 years ago, has the mixed-valency states of  $Fe^{2+}/Fe^{3+}$  bridged by  $CN^{-}$   $\pi$ -conjugated ligands.<sup>7</sup> The PB crystals exhibit a blue colour owing to the optical charge-transfer transition from Fe<sup>2+</sup> to Fe<sup>3+</sup>. Furthermore, PB demonstrates semiconductive behaviour. Alkali and alkaline earth metal ions can be inserted into and released from the PB lattice spaces through electrochemical redox reactions induced by solid-state cyclic voltammetry (CV).<sup>8</sup> Solid-state CV with electrolyte salts containing Rb<sup>+</sup>, Cs<sup>+</sup>, or NH4<sup>+</sup> revealed that the metal (M<sup>+</sup>) ions can be reversibly inserted into and released from three-dimensional vacant PB lattices more than 10<sup>3</sup> times. However, for Li<sup>+</sup>, Na<sup>+</sup>, or Ba<sup>2+</sup> with a large hydrate radius or +2 valence state, the observed current value decreased for every sweep, indicating the decomposition of the PB lattice. Owing to their ion and electron conductivities, such electron-conductive MOFs have wide applications in information transmission systems<sup>9</sup> and supercapacitors.10

The crystal of  $\{[Ru^{III}(Hbim)_3]\}_n$  (1)  $(=[\{Ru^{III}Ru^{III}\}_n]_n$ , where  $Hbim^{-} = 2,2'-biimidazolate monoanion),^{11}$  entirely connected by only H-bonds of Ru<sup>III</sup> complexes [Ru<sup>III</sup>(Hbim)<sub>3</sub>], is a self-organized quasi-one-dimensional (1-D) nanoporous crystal. All the  $\pi$ -electron interactions between the metal complexes in  $\{[Ru^{III}(Hbim)_3]\}_n$  are disrupted by H-bonds connected through only  $\sigma$ -orbital bonding interactions. The other intermolecular interactions are only weak van der Waals interactions. Fig. 1a shows the solid-state CV curve of 1 with a large reversible redox current when several single crystals of 1 were placed on the surface of a Pt working electrode ( $\phi = 1.5 \text{ mm}$ ) covered with only a membrane filter ( $\phi = 0.3 \mu m$ ) (Fig. S1, ESI<sup>†</sup>). This is attributed to the solid-state proton-coupled electron transfer (S-PCET) between Ru<sup>II</sup> and Ru<sup>III</sup> complexes in 1. A previous study has synthesised the mixed-valency crystals of {[Ru<sup>II</sup>(H<sub>2</sub>bim)(Hbim)<sub>2</sub>]- $[Ru^{III}(bim)(Hbim)_2]$  (K(BnOMe)<sub>6</sub>) $_n$  (2) (=  $[{Ru^{II}Ru^{III}}_n]_n$ ) and reported the corresponding DC conductivity to be  $8.01 \times 10^{-6}$  S cm<sup>-1</sup> (277 K), which indicated the semiconductive behaviour<sup>11</sup> (Fig. S2, ESI<sup>†</sup>). The aforementioned study was the first to report that H-bonded protons (H<sup>+</sup>) contribute to the electrical conductivity of a crystal through S-PCET between valence states in the Ru<sup>II</sup> and Ru<sup>III</sup> complexes.

**Fig. 1** (a) Solid-state CV of the single crystals of 1 in MeCN with  ${}^{n}Bu_{4}NPF_{6}$  as the electrolyte salt. The velocities were changed from 10 to 500 mV s<sup>-1</sup>. (b) Down view along the *c* axis showing the 1-D nanochannel unit. (c) View parallel to the *ab* plane showing the 2-D honeycomb sheet structure formed by H-bonds between the [Ru<sup>III</sup>(Hbim)<sub>3</sub>] of **1**.

We have previously reported that crystal 1 is reversibly reduced and oxidized on the electrode interface by solid-state CV and shows a two-step and multi-electron transfer reaction  $([{Ru^{III}Ru^{III}}_{0}]_{n} \rightleftharpoons [{Ru^{II}Ru^{III}}_{n}]_{n} \rightleftharpoons [{Ru^{II}Ru^{II}}_{0}]_{n}]_{n}$ in 1 flows internally via a series of sequential S-PCET reactions until the reduced state of  $[{Ru^{II}Ru^{II}}^{2-}]_n$  is reached. As 1 is completely reduced, up to two electrolytic cations must be inserted into each of the vacant channel unit of the 1-D nanochannel due to charge compensation. However, owing to the size limitation of the channel pore ( $\sim 2$  nm) in 1, the insertion of two cations may be incomplete, depending on the size, shape, and characteristics of the cations. In this study, we theoretically calculated the effective ionic radius (EIRs) for each cation. Then, we employed solid-state CV to investigate the insertion/release reactions of seven different counter-cations, varying in size, shape, and characteristics, for the porous channel with a diameter of  $\sim 2$  nm of **1**. This study is the first to use solid-state CV measurements of single crystals to discover the size limitation of electrolyte cations that can be confined to nanoporous crystals formed from redox-active Hbonding metal complexes via the S-PCET reaction.

Fig. 1b and c show the structure of a nanoporous single crystal of 1, in which the H-bonded Ru<sup>III</sup> complexes ([Ru<sup>III</sup>(Hbim)<sub>3</sub>]) are linked only by intermolecular H-bonds and have the reversible one-step and one-electron transfer for the redox activity of Ru<sup>3+</sup>/Ru<sup>2+</sup> in MeCN solution. According to singlecrystal X-ray structural analysis, 1 is constructed by the stacking of the repeating units of 2-D honeycomb sheet structures (Fig. S3, ESI<sup> $\dagger$ </sup>), in which two  $\Delta$  and  $\Lambda$  optical isomers of [Ru<sup>III</sup>(Hbim)<sub>3</sub>] alternately form a triad with complementary two-point H-bonds. The hexagonal cavities in the honeycomb sheets are stacked to give large 1-D nanochannels of  $\sim$ 2 nm width. The side walls of the 1-D nanochannels are formed by the alternative stacking of the  $\Delta$  and  $\Lambda$  isomers of  $[Ru^{III}(Hbim)_3] (Ru^{3+} \cdots Ru^{3+} = 7.777(6) \text{ Å})$ to afford a woven ribbon structure. The solid-state CV measurements of the single crystals of 1 show a two-step and multielectron transfer reaction of  $\{[Ru^{III}Ru^{III}]^0\}_n \Leftrightarrow \{[Ru^{II}Ru^{III}]^-\}_n \Leftrightarrow$  ${[Ru^{II}Ru^{II}]^{2-}}_{n}$   ${(E_{1/2}^{1} = -0.61 \text{ V}, E_{1/2}^{2} = -0.92 \text{ V}, \nu s. \text{ Ag/Ag}^{+} \text{ in MeCN}}$ with 0.1 M <sup>n</sup>Bu<sub>4</sub>NPF<sub>6</sub>). Before deprotonation, the mononuclear complex [Ru<sup>II</sup>(H<sub>2</sub>bim)<sub>3</sub>](PF<sub>6</sub>)<sub>2</sub> exhibited only a reversible one-step and one-electron transfer of  $[Ru^{II}(H_2bim)_3]^{2+} \Leftrightarrow [Ru^{III}(H_2bim)_3]^{3+}$ 

 $(E_{1/2} = 0.33 \text{ V} \text{ vs. Ag/Ag}^+$  in MeCN with 0.1 M <sup>*n*</sup>Bu<sub>4</sub>NPF<sub>6</sub>), as measured by solution CV. (Fig. S4, ESI<sup>†</sup>). Additionally, the solidstate CV measurements revealed that both Ru<sup>II</sup> and Ru<sup>III</sup> states coexist on the crystal interfaces because exactly half of the [Ru<sup>III</sup>(Hbim)<sub>3</sub>] complexes were reduced to [Ru<sup>II</sup>(Hbim)<sub>3</sub>]<sup>-</sup> in the electric double layer on the electrode surface (Fig. S5, ESI<sup>†</sup>). The {[Ru<sup>II</sup>Ru<sup>III</sup>]<sup>-</sup>}<sub>*n*</sub> mixed-valency state in **1** was reversible. Hence, a rapid PT must be facilitated after the electron transfer (ET) from the electrode surface.

During the reductive reaction of a Ru<sup>III</sup> complex to Ru<sup>II</sup> one for 1, one H<sup>+</sup> moves through one of the three H-bonds from [Ru<sup>III</sup>(Hbim)<sub>3</sub>] to the adjacent  $[Ru^{II}(Hbim)_3]^-$ , forming  $[Ru^{III}(bim)(Hbim)_2]^-$  and  $[Ru^{II}(H_2bim)(Hbim)_2]^0$ , respectively. Thus, the macroscopic mixedvalency state of { $[Ru^{II}Ru^{III}]^{-}$  is stabilised as { $[Ru^{II}(H_2bim)(Hbim)_2]$  $[Ru^{III}(bim)(Hbim)_2]^-$ , (Fig. S6, ESI<sup>+</sup>). During the redox reaction, electrolytic cations move into and out of the electrolyte solution through the opening gates of nanochannels of 1 owing to charge compensation. This suggests that ET is a rate-determining step for a diffusion process of the electrolytic cations to the inside crystal. Before the redox reaction of  $\mathbf{1}$ ,  $^{n}\mathrm{Bu}_{4}\mathrm{N}^{+}$  cations do not enter the void spaces in the hexagonal nanochannels, containing the solvent molecules because of the neutral repeating units of  $\{[Ru^{III}Ru^{III}]_{n}^{0}\}_{n}$ However, in the mixed-valency state of  $\{[Ru^{II}Ru^{III}]^{-}\}_n$ , half of the Ru<sup>III</sup> complexes are reduced to Ru<sup>II</sup> ones by electrons. Consequently, one  ${}^{n}Bu_{4}N^{+}$  is inserted to each nanochannel unit of 1 to compensate for the -1 charge in the mixed-valency state. In addition, the { $[Ru^{II}Ru^{III}]^{-}$ }<sub>n</sub> state is reduced to { $[Ru^{II}Ru^{II}]^{2-}$ }<sub>n</sub> by electrons, generating the -2 charge in each nanochannel unit. As a result, two <sup>n</sup>Bu<sub>4</sub>N<sup>+</sup> are inserted into each of the nanochannel unit for charge compensation. As 1 reversibly undergoes a two-electron redox reaction in each nanochannel unit on a solid-state CV set-up, two <sup>n</sup>Bu<sub>4</sub>N<sup>+</sup> would move into and out of each nanochannel unit. However, for electrolyte salts containing large bulky cations, the wavy shapes of the redox peaks in the solid-state CV measurement would change depending on the capture/release mechanism for their cations to the nanoporous crystal of 1. Therefore, in this study, we have investigated the peak changes in the solid-state CV curves of seven electrolyte salts with cations of different sizes, shapes, and characteristics.

Table 1 presents the EIRs<sup>12</sup> of seven counter-cations containing the electrolyte salts used in solid-state CV measurements. The EIRs were calculated based on the geometry optimization for each of the seven cations in the gas phase and PCM (polarizable continuum model) condition for MeCN solvation by using the B3LYP/6-311+G(d) basis set included in the Gaussian 16 software package.<sup>13</sup> The temperature was set at 298.15 K for every calculation. The EIRs are optimized between the center of N atoms and the terminal H atoms of C atoms in the all-*trans* conformation of various NR<sub>4</sub><sup>+</sup> ions, and between the center of a P atom and H atom on the 4-position of a phenyl ring in PPh<sub>4</sub><sup>+</sup>, whose initial geometry (or structure) is referred from the 3-D conformer shown in PubChem<sup>14</sup> (Fig. S7, ESI<sup>+</sup>).

The seven counter-cations, which exist as electrolyte salts with Br<sup>-</sup> anions, were used in the solid-state CV measurements as 0.1 M MeCN solution. The cations were found to have a wide range of sizes and characteristics, ranging from a smaller  ${}^{n}\text{Pr}_4\text{N}^+$  (~4.75 Å) to a larger  ${}^{n}\text{Oct}_4\text{N}^+$  (~11.17 Å), and a softer R<sub>4</sub>N<sup>+</sup> (R = *n*-propyl ( ${}^{n}\text{Pr}$ ), *n*-butyl ( ${}^{n}\text{Bu}$ ) (~6.05 Å), *n*-pentyl ( ${}^{n}\text{Pen}$ )

Table 1 Effective ionic radii of electrolytic cations

<sup>*a*</sup> We performed the geometry optimization for those molecules in the PCM condition (solvent: Acetonitrile) using the B3LYP/6-311+G(d) basis set included in the Gaussian 16 software package.<sup>12</sup> The temperature was set at 298.15 K every calculation.

 $(\sim 7.32 \text{ Å})$ , *n*-hexyl (<sup>*n*</sup>Hex) ( $\sim 8.61 \text{ Å}$ ), *n*-heptyl (<sup>*n*</sup>Hep) ( $\sim 9.88 \text{ Å}$ ), and *n*-octyl (<sup>*n*</sup>Oct)) to harder  $Ph_4P^+$  (~5.69 Å). The solid-state CV measurements were conducted until two cations are inserted/ released in each 1-D nanochannel unit of 1 during the redox reaction of  $\{[Ru^{III}Ru^{III}]^0\}_n \Leftrightarrow \{[Ru^{II}Ru^{III}]^-\}_n \Leftrightarrow \{[Ru^{II}Ru^{III}]^2-\}_n\}$ . As PPh<sub>4</sub>Br exhibited a different trend, we compared the primary  $(E_{1/2}^{1})$ and secondary  $(E_{1/2}^2)$  potentials of the solid-state CV redox reactions of **1** in MeCN. Notably,  ${}^{n}Pr_{4}N^{+}$  ( $E_{1/2}^{1} = -0.66$  V,  $E_{1/2}^{2} = -0.93$  V),  $^{n}\text{Bu}_{4}\text{N}^{+}$  ( $E_{1/2}^{1}$  = -0.61 V,  $E_{1/2}^{2}$  = -0.92 V), and  $^{n}\text{Pen}_{4}\text{N}^{+}$  ( $E_{1/2}^{1}$  = -0.64 V,  $E_{1/2}^2 = -0.97$  V) demonstrated reversible two-step and multielectron transfer processes with similar current areas and shapes for  $E_{1/2}^1$  and  $E_{1/2}^2$  through the {[Ru<sup>II</sup>Ru<sup>III</sup>]<sup>-</sup>}<sub>n</sub> mixed-valency state. The results suggest that three cations with a smaller EIR than that of  $^{n}\text{Hex}_{4}N^{+}$  can be reversibly inserted into and released from each 1-D nanochannel unit of 1 in a sequential manner owing to charge compensation (Fig. 2a). In contrast, three cations with EIRs larger than that of "Pen<sub>4</sub>N<sup>+</sup>, that is "Hex<sub>4</sub>N<sup>+</sup> ( $E_{1/2}^1 = -0.65 \text{ V}, E_{1/2}^2 = -1.11 \text{ V}$ ), <sup>*n*</sup>Hep<sub>4</sub>N<sup>+</sup> ( $E_{1/2}^1 = -0.66$  V,  $E_{1/2}^2 = -1.09$  V), and <sup>*n*</sup>Oct<sub>4</sub>N<sup>+</sup> ( $E_{1/2}^1 = -0.66$ V,  $E_{1/2}^2 = -0.97$  V), showed almost no changes in their redox potentials for  $E_{1/2}^1$  and  $E_{1/2}^2$ . Nevertheless, the secondary redox waves of  ${}^{n}\text{Hex}_{4}N^{+}$ ,  ${}^{n}\text{Hep}_{4}N^{+}$ , and  ${}^{n}\text{Oct}_{4}N^{+}$  were sharper, and the current areas gradually decreased (Fig. 2b). To investigate whether the electrolytic anions of <sup>n</sup>Bu<sub>4</sub>NX influence the redox reactions, we performed solid-state CV measurements of 1 in four electrolyte salts containing different anions (X<sup>-</sup> = PF<sub>6</sub><sup>-</sup>, Br<sup>-</sup>, BF<sub>4</sub><sup>-</sup>, and  $\text{ClO}_4^-$ ). The four CV curves of 1 in  $^n\text{Bu}_4\text{NPF}_6$  ( $E_{1/2}^1 = -0.61$  V,  $E_{1/2}^2 = -0.92 \text{ V}$ , <sup>*n*</sup>Bu<sub>4</sub>NBr ( $E_{1/2}^1 = -0.66 \text{ V}$ ,  $E_{1/2}^2 = -0.89 \text{ V}$ ), <sup>*n*</sup>Bu<sub>4</sub>NBF<sub>4</sub>  $(E_{1/2}^1 = -0.67 \text{ V}, E_{1/2}^2 = -0.95 \text{ V})$ , and  ${}^n\text{Bu}_4\text{NClO}_4$   $(E_{1/2}^1 = -0.66 \text{ V},$  $E_{1/2}^2 = -0.95$  V) were almost comparable. This indicates that the changes in the  $E_{1/2}^1$  and  $E_{1/2}^2$  redox reactions of **1** were influenced only by the electrolytic cations.

Fig. 2 shows the solid-state CV curves of 1 in MeCN solutions of <sup>*n*</sup>Pen<sub>4</sub>NBr and <sup>*n*</sup>Oct<sub>4</sub>NBr. The secondary oxidation peak  $E_a^2$  in the CV curve of 1 in "Pen<sub>4</sub>NBr showed the largest half-width potential  $\Delta E_a^2$ (HW) (442 mV), whereas that of **1** in <sup>*n*</sup>Oct<sub>4</sub>NBr was

Fig. 2 Solid-state CV images of 1 in MeCN solutions of (a) <sup>n</sup>Pen<sub>4</sub>NBr and (b) <sup>n</sup>Oct<sub>4</sub>NBr electrolyte salts. The velocity was changed from 0.01 to 0.5 V s<sup>-</sup> (vs. Ag/Ag<sup>+</sup>, WE: glassy carbon, RE: Pt wire).

52 mV, which is nearly 1/10th of the current area. The ratio of the current area of the primary reduction peak  $E_c^1$  ( $C_1$ ) to that of the secondary oxidation peak  $E_a^2(C_2)$  (*i.e.*  $C_2/C_1$ ) decreased from 1.37 to 0.30, which is the EIR region between <sup>*n*</sup>Pen<sub>4</sub>N<sup>+</sup> (~7.32 Å) and <sup>*n*</sup>Hex<sub>4</sub>N<sup>+</sup> (~8.61 Å). The line graphs of  $\Delta E_{2}^{2}$ (HW) in Fig. 3a also show the separation between <sup>*n*</sup>Pen<sub>4</sub>N<sup>+</sup> and <sup>*n*</sup>Hex<sub>4</sub>N<sup>+</sup>, which highlights the significance of EIRs of the R<sub>4</sub>N<sup>+</sup> cations. In the case of the three cations smaller than <sup>*n*</sup>Hex<sub>4</sub>N<sup>+</sup>, the  $C_2/C_1$  values were greater than 1.0, and the  $\Delta E_a^2$ (HW) values were ~400 mV on average. In contrast, for three cations larger than <sup>*n*</sup>Pen<sub>4</sub>N<sup>+</sup>, the  $C_2/C_1$  approximately decreased to ~0.35, and the  $\Delta E_{a}^{2}$ (HW) decreased by ~70 mV on average. This is because the two larger cations cannot be accommodated in the 1-D nanochannel unit of **1** in the  $\{[Ru^{II}Ru^{II}]^{2-}\}_n$  reduction state; however, the secondary cations can be partially inserted into or incompletely adsorbed onto the crystal surface of 1. Furthermore, the current values in the secondary redox waves partially decreased during the reduction of the mixed-valency  ${[Ru^{II}Ru^{II}]^-}_n$  state to the reduced { $[Ru^{II}Ru^{II}]^{2-}$ }, state because only a few larger secondary cations could be completely inserted into the nanochannel units. During the  $E_a^2$  oxidation reaction, the partially inserted cations were immediately released during the partial oxidation of the  $\{[Ru^{II}Ru^{II}]^{2-}\}_n$  states to the  $\{[Ru^{II}Ru^{III}]^{-}\}_n$  state. Generally, as  $\Delta E_a^2$ (HW) on the CV curve becomes sharper, the redox reaction occurs faster. For example, for the largest cation  $^{n}Oct_{4}N^{+}$ , the secondary cation in the  $\{[Ru^{II}Ru^{II}]^{2-}\}_{n}$  state was incompletely adsorbed on the crystal surface of 1 or partially trapped in the 1-D nanochannel units. Therefore, these cations were rapidly released immediately after the partial oxidation of  $\{[Ru^{II}Ru^{II}]^{2-}\}_n$  to  $\{[Ru^{II}Ru^{III}]^{-}\}_n$ . Fig. 3b shows the  $C_2/C_1$  and  $\Delta E_a^2$ (HW) values of the four electrolyte salts of <sup>n</sup>Bu<sub>4</sub>N<sup>+</sup> with different anions (Br<sup>-</sup>, ClO<sub>4</sub><sup>-</sup>, PF<sub>6</sub><sup>-</sup>, and BF<sub>4</sub><sup>-</sup>). Every  $C_2/C_1$  value was greater than 1.0, and the  $\Delta E_{a}^{2}$ (HW) was ~400 mV on average, indicating that changes in the CV curves were solely caused by the cations.

**Fig. 3** Ratios of the current areas of the primary reduction peaks  $E_c^1(C_1)$  to those of the secondary oxidation peaks  $E_a^2$  ( $C_2$ ) of the solid-state CV curves as bar graphs and the corresponding half-width potentials  $\Delta E_a^2$ (HW) as line graphs of (a) **1** in six electrolyte salts with  $R_4N^+$  cations of different EIRs and (b) **1** in four electrolyte salts with different  $X^-$  anions of  ${}^{n}Bu_4N^+$ 

Fig. 4 Semi-differential solid-state CV curve of 1 measured in MeCN solution with the Ph₄PBr electrolyte salt.

Unlike other  $R_4 N^+$  electrolytic cations,  $Ph_4 P^+$  contains four rigid phenyl groups bonded to a phosphorous (P) atom, has a spherical shape as a whole, and is one of the cations with the smaller EIR ( $\sim$  5.69 Å) among the seven cations with a relatively large molecular weight ( $M_W$  = 339.40). The semi-differential solidstate CV curve  $(E_{1/2}^1 = -0.62 \text{ V}, E_{1/2}^2 = -0.89 \text{ V})$  in the MeCN solution containing PPh<sub>4</sub>Br resembled the characteristic CV curve in solution with the three larger  $NR_4^+$  cations compared to  $^nPen_4N^+$ one (Fig. 4). The semi-differential representation excludes a diffuse component from the solid-state CV curve. In the  $\{[Ru^{III}Ru^{III}]^0\}_n$ state of 1, each 1-D nanochannel unit is initially filled with only MeCN; however, the primary Ph<sub>4</sub>P<sup>+</sup> cation is inserted into each nanochannel unit through  $E_{\rm c}^1$  reduction. Nevertheless, the secondary  $Ph_4P^+$  cation cannot be completely accommodated in the nanochannel unit during the subsequent  $E_{c}^{2}$  reduction. Accordingly, the line shape of the oxidation  $E_a^2$  narrowed ( $\Delta E_a^2$ (HW) = 80 mV), and the  $C_2/C_1$  value was 0.16. This value is comparable to that of the larger  ${}^{n}\text{Hex}_{4}\text{N}^{+}$  (EIR = ~ 8.61 Å), even though PPh<sub>4</sub><sup>+</sup> is much smaller (EIR =  $\sim 5.69$  Å). This observation could be attributed to the flexible and deformable alkyl chains of  $R_4N^+$ , which, unlike  $Ph_4P^+$ , has a rigid spherical structure. Therefore, although the EIR is relatively small, two  $Ph_4P^+$  cations cannot be completely accommodated in one 1-D nanochannel unit. A previous study reported that the energy density and power capacity of supercapacitor materials, comprising nanoporous carbons, depended on the uptake quantities of NEt<sub>4</sub><sup>+</sup> cations. The amount of NEt<sub>4</sub><sup>+</sup> cations with four ethyl chains anomalously increased in the nanopores with the size-distribution of less than  $\sim 1$  nm; this was attributed to desolvation and deformation of electrolytic NEt<sub>4</sub><sup>+</sup> cations.<sup>15</sup> However, compared to NR4<sup>+</sup> with long alkyl chains, PPh4<sup>+</sup> cations are rigid and cannot be deformed; therefore, despite its small EIR,  $PPh_4^+$ behaves similarly to  $^{n}$ Hex<sub>4</sub>N<sup>+</sup>, whose EIR is ~3 Å larger.

In summary, <sup>n</sup>Pr<sub>4</sub>N<sup>+</sup>, <sup>n</sup>Bu<sub>4</sub>N<sup>+</sup>, and <sup>n</sup>Pen<sub>4</sub>N<sup>+</sup> cations were completely inserted as two cations into each 1-D nanochannel unit of 1 after the reduction of 1 to  ${[Ru^{II}Ru^{II}]^{2-}}_n$ . In contrast, only one larger  ${}^{n}\text{Hex}_{4}\text{N}^{+}$ ,  ${}^{n}\text{Hep}_{4}\text{N}^{+}$ , and  ${}^{n}\text{Oct}_{4}\text{N}^{+}$  cation and the smaller but rigid PPh4<sup>+</sup> cation could be completely inserted into each 1-D nanochannel unit in the mixed-valency state of  $\{[Ru^{II}Ru^{III}]^{-}\}_{n}$ while the other secondary cations were only partially inserted into the remaining space of the 1-D nanochannel units. This resulted in a smaller and sharper secondary oxidation peak of  $E_a^2$ . While two PPh<sub>4</sub><sup>+</sup> cations were restricted in each nanochannel unit owing to their rigid structure, two <sup>n</sup>Pen<sub>4</sub>N<sup>+</sup> cations with flexible, long alkyl chains were not restricted. This finding has implications
