1913Study of multimodal light emissions from Pr³⁺/Yb³⁺
doped NaLa(MoO₄)₂ phosphors for optoelectronic
devices and plant-growth applications†Sonali Tomar,^a Neeraj Kumar Mishra,^{b,c} Vaibhav Chauhan,^d Kaushal Kumar^b
and C. Shivakumara^{*a}

Recent advancements in materials design have driven the scientific community to explore phosphor materials for multifunctional applications. This study presents the multimodal light emission (downshifting – DS, quantum cutting – QC, and upconversion – UC) from Pr³⁺/Yb³⁺ activated NaLa(MoO₄)₂ phosphors for multifunctional applications. Under blue (449 nm) and NIR (980 nm) excitation, co-doped phosphors emit visible light through DS and UC processes caused by different f–f transitions of Pr³⁺ ions. Additionally, when the co-doped samples are excited with blue light, they emit a near-infrared (NIR) light band ranging from 900 to 1050 nm. This is caused by the f–f transition of Yb³⁺ resulting from energy transfer from a single Pr³⁺ ion to a pair of Yb³⁺ ions through the QC process. Concurrently, in-depth investigations were conducted to understand the concentration and thermal quenching mechanism. Firstly, the applicability of phosphors in optical thermometry using the luminescence intensity ratio (LIR) technique was explored, with the maximum relative sensitivity of 0.41% K^{−1} (448 K). A phosphor-coated LED (pc-LED) was constructed by coupling NaLa_{0.97}Pr_{0.03}(MoO₄)₂ with a blue LED chip (InGaN). Furthermore, based on the observed optical properties of the prepared phosphor, its application in improving the photovoltaic performance of solar cells and indoor plant applications is systematically discussed.

1. Introduction

In the current era of materials science, functional materials are continually explored to address the increasing human demands in areas such as energy, health, environment, indoor agriculture, and technology.^{1–5} Some of these materials, known as multifunctional materials, possess unique properties that enable us to extract multiple functions from them. Any multifunctional material that can be produced through a cost-effective and environment-friendly process brings certain additional advantages, such as scalability, enhanced sustainability and reduced production cost. The advancement in the development of phosphors for multifunctional applications like solid-state lighting, luminescent solar concentrators (LSC), and luminescent thermometers using various luminescence phenomena such as downconversion (DC), quantum cutting (QC), and upconversion (UC) is highly beneficial.^{6–9} Lanthanide (Ln) doped molybdate phosphors have garnered significant attention for the aforementioned multifunctional applications due to their high luminescence efficiency, ease of synthesis, and high thermal and chemical stability. As we know, the optical transitions in Ln³⁺ occur due to the 4f orbitals, which are effectively shielded from their local environment by the fully occupied 5s and 5p outer orbitals.¹⁰

See DOI: <https://doi.org/10.1039/d4dt02532f>

However, direct excitation into the 4f level results in low luminescence efficiency due to the low absorption cross-section of lanthanide ions. This efficiency can be improved by utilizing sensitization processes, typically achieved through either charge transfer band (CTB) excitation or energy transfer (ET) processes. Various researchers have explored different molybdate-based host sensitized phosphors such as $\text{Y}_2\text{MoO}_6\text{:Sm}^{3+}$,¹¹ $\text{SrMoO}_4\text{:Ln}^{3+}$ ($\text{Ln}^{3+} = \text{Eu}^{3+}$, Tb^{3+} , or Dy^{3+}),¹² $\text{CaMoO}_4\text{:Eu}^{3+}$,¹¹ $\text{NaYb}(\text{MoO}_4)_2\text{:Yb}^{3+}$, $\text{Tm}^{3+}/\text{Er}^{3+}/\text{Ho}^{3+}$,¹³ and $\text{KbAY}(\text{MoO}_4)_3\text{:Ln}^{3+}$ ($\text{Ln}^{3+} = \text{Sm}^{3+}$, Tb^{3+} , Eu^{3+} , $\text{Tb}^{3+}/\text{Sm}^{3+}$, or $\text{Tb}^{3+}/\text{Eu}^{3+}$)¹⁴ to achieve efficient light emission. In the studies discussed above, efficient light emission was achieved only through a single mode. But in this present work, we have explored spectral conversion from $\text{NaLa}(\text{MoO}_4)_2\text{:Pr}^{3+}$, Yb^{3+} phosphors through different modes, such as QC, DC, and UC, which are desirable for applications such as LSC, LEDs and luminescence thermometry.

Generally, for a silicon solar cell, a quantum cutting technique utilizing Ln^{3+} -doped phosphors was proposed to better exploit the solar spectrum ranging from 350 to 550 nm, to improve the quantum efficiency ($>100\%$), and to prevent lattice thermalization.¹⁵ Among different Ln^{3+} ions, trivalent Yb^{3+} is an optimal candidate for QC emitters in Si-based photovoltaic cells. Yb^{3+} has a single state at around $10\,000\text{ cm}^{-1}$ (1.24 eV), matching the silicon band-gap energy (1.12 eV).¹⁶ Thus, the IR emission of Yb^{3+} ions is efficiently absorbed by the Si solar cells without significant thermalization losses.¹⁷ The selection of an appropriate donor ion capable of absorbing high-energy photons and transferring its energy to at least two Yb^{3+} ions is a complex task. Few Ln^{3+} ions, such as Tb^{3+} ,¹⁸ Er^{3+} ,¹⁹ Tm^{3+} ,²⁰ Pr^{3+} ,²¹ and Nd^{3+} ,²² have been considered for visible to near-IR QC with Yb^{3+} ions. Two consecutive energy transfers can occur from one donor to two Yb^{3+} ions when using Nd^{3+} , Er^{3+} , or Pr^{3+} as donors. In this scenario, the QC mechanism is a true two-step process, whereas the simultaneous excitation of two Yb^{3+} ions by Tb^{3+} donors occurs *via* a single cooperative energy transfer. Two-step processes are inherently more efficient because they rely on direct donor-acceptor energy transfers, which are 4 to 5 orders of magnitude more effective than second-order cooperative mechanisms. Among the mentioned co-dopants, $\text{Pr}^{3+}\text{-Yb}^{3+}$ is often regarded as a particularly promising pair for QC. The Pr^{3+} ion is one of the ideal candidates for energy transfer to neighbouring Yb^{3+} ions due to its energy level matching conditions. The metastable $^3\text{P}_0$ level is located at approximately $20\,000\text{ cm}^{-1}$, and the $^1\text{G}_4$ level is at around $10\,000\text{ cm}^{-1}$, enabling a QC mechanism based on two resonant energy transfers: $\text{Pr}^{3+} (^3\text{P}_0 \rightarrow ^1\text{G}_4)$ to $\text{Yb}^{3+} (^2\text{F}_{7/2} \rightarrow ^2\text{F}_{5/2})$ and $\text{Pr}^{3+} (^1\text{G}_4 \rightarrow ^3\text{H}_4)$ to $\text{Yb}^{3+} (^2\text{F}_{7/2} \rightarrow ^2\text{F}_{5/2})$.^{17,23} Additionally, unlike other co-dopants, such as $\text{Er}^{3+}\text{-Yb}^{3+}$ or $\text{Nd}^{3+}\text{-Yb}^{3+}$, the energy gap between the $^3\text{P}_0$ and $^1\text{G}_4$ levels and their immediate lower energy levels ($^1\text{D}_2$ and $^3\text{F}_4$, respectively) is sufficiently large to mitigate the negative impact of multiphonon relaxation. Multiphonon transitions can be effectively neglected in the $\text{Pr}^{3+}\text{-Yb}^{3+}$ system when utilizing low phonon energy host materials, such as molybdates.^{24,25}

Another important application we have focused on is the fabrication of phosphor-coated light-emitting devices (pc-LEDs), which are especially suitable for plant growth appli-

cations. Indoor agriculture utilizing pc-LEDs as a light source has emerged as a prominent avenue for future agricultural advancement due to the notable advantages it offers. The light environment is crucial as a primary energy source in plant cultivation and development. However, not all sunlight is absorbed by plants. The essential light requirements for plant growth are distributed in the blue (400 to 500 nm), red (600 to 690 nm), and far-red (720 to 740 nm) regions, which correspond to phototropic processes, photosynthesis, and photomorphogenesis, respectively.^{26,27} It is possible to enhance the yield and characteristics of various crops by controlling the spectral composition to optimise plant growth in phytotron chambers or greenhouses. In these controlled environments, artificial lighting by pc-LEDs provides specific wavelengths and spectra that match with plant photoreceptors, thereby influencing plants at different growth stages and improving the efficiency of light utilization.²⁸ Traditional gas discharge lamps (GDLs) are commonly used as light sources in greenhouses, but they are suboptimal for plant lighting due to the mismatch between their emission spectra and the absorption spectra of chlorophylls and carotenoids.²⁹ The pc-LEDs may offer a versatile alternative to other horticultural light sources because they can be engineered to produce specific spectral compositions that elicit desirable plant responses. Moreover, pc-LEDs generally exhibit high efficiency, long lifetimes, environmental friendliness, compact size, and durability, making them ideal for plant cultivation.³⁰ The observed emission bands from the electric transitions of Pr^{3+} overlap with the absorption spectra of chlorophyll-a, chlorophyll-b, and phytochrome, making it an ideal candidate for plant growth applications. In this article, we have fabricated a pc-LED by coating the prepared samples over commercially available blue LED chips (InGaN using the doctor blade technique). The good thermal stability of the fabricated pc-LED is supported by temperature-dependent photoluminescence (PL) analysis.

On analyzing the temperature-dependent emission spectra, it was evident that the prepared phosphor samples can also be used for contactless optical thermometry purposes. Conventional contact-based thermometry is impractical in numerous nano-level applications, including diagnostics. Exploring the optical thermometry capabilities of phosphors offers certain advantages, such as their operation in harsh environments, non-contact nature, fast response, high sensitivity, zero interference with electrical signals, and accuracy. These luminescent thermometers find application in determining the temperature of various systems, such as gas centrifuges, running jet turbines, and chemical reaction vessels. In this paper, we have adopted the luminescence intensity ratio (LIR) technique to determine the sensitivity of the proposed luminescent thermometers.

2. Experimental section

2.1. Material synthesis

Pr^{3+} -doped and $\text{Pr}^{3+}/\text{Yb}^{3+}$ -codoped $\text{NaLa}(\text{MoO}_4)_2$ (NLMO) phosphors were synthesized through a conventional solid-state reac-

tion method using heat treatment at 750 °C for 4 h. The compositions have been represented by the formulas $\text{NaLa}_{1-x}\text{Pr}_x(\text{MoO}_4)_2$ and $\text{NaLa}_{0.97-y}\text{Pr}_{0.03}\text{Yb}_y(\text{MoO}_4)_2$, where x and y can take values of $(0.00 \leq x \leq 0.11)$ and $(0.00 \leq y \leq 0.14)$. The raw materials utilized in the present study consist of analytical-grade lanthanum oxide (La_2O_3 , 99.9%, Loba Chemicals) that has been pre-heated at 800 °C for 6 h. Sodium carbonate (Na_2CO_3 , 99%, Merck), molybdenum trioxide (MoO_3 , 99.5%, Chemie Pvt. Ltd), praseodymium oxide (Pr_6O_{11} , 99.9%, Sisco Research Laboratories Pvt. Ltd), and ytterbium oxide (Yb_2O_3 , 99.9%, Sigma-Aldrich Chemicals) were measured in stoichiometric quantities according to their respective chemical formulae. After that, the powder was ground meticulously in an agate mortar, and then the obtained mixture was transferred into a ceramic crucible and exposed to the muffle furnace at 750 °C for 4 h. Finally, the furnace was cooled to ambient temperature. The obtained cooled mixture was crushed again for a few minutes to get a fine and homogeneous powder sample.

2.2. Characterization

X-ray powder diffraction (XRD) studies were performed using a Bruker D-8 Advanced powder diffractometer. The diffractometer was programmed at 40 kV and 30 mA, utilizing Cu K α radiation. The scanning rate was set at 3.8° min⁻¹, with a 0.02 step size and a 2 θ range of 10 to 80°. The structural parameters for each phosphor were identified using the FullProf Suite-

2000 software and the Rietveld refinement approach. The FTIR spectra were recorded on a PerkinElmer Frontier spectrometer, with KBr pellets as a reference. The experiment utilized a PerkinElmer Lambda 750 spectrophotometer to obtain diffuse reflectance spectra (DRS). Al K (1486.6 eV) was used as the X-ray source to perform the X-ray photoelectron spectroscopy (XPS) measurements. A Jobin Yvon spectrofluorometer (Fluoromax, Horiba) was used to record the excitation and emission spectra with a 450 W xenon lamp as the excitation source. The emission spectra resulting from the upconversion were measured using a CCD-based spectrometer (Avantes, ULS2048×64) with continuous wave (CW) stimulation from a 980 nm laser. All measurements were conducted at ambient temperature. Temperature-dependent photoluminescence (TDPL) is measured in an Ocean optics spectrophotometer (model: FLAME-S-XRI-ES) and household heating assembly.

3. Results and discussion

3.1. XRD

The XRD patterns were used to analyze the crystal structure and impact of dopants on the crystal lattice. Fig. 1(a) illustrates the XRD patterns of $\text{NaLa}_{1-x}\text{Pr}_x(\text{MoO}_4)_2$ ($0.00 \leq x \leq 0.11$) phosphors. The diffraction peaks of all prepared compounds matched perfectly with the JCPDS file no. 85-1751,³¹ indicating the absence of a secondary phase or impurities from the pre-

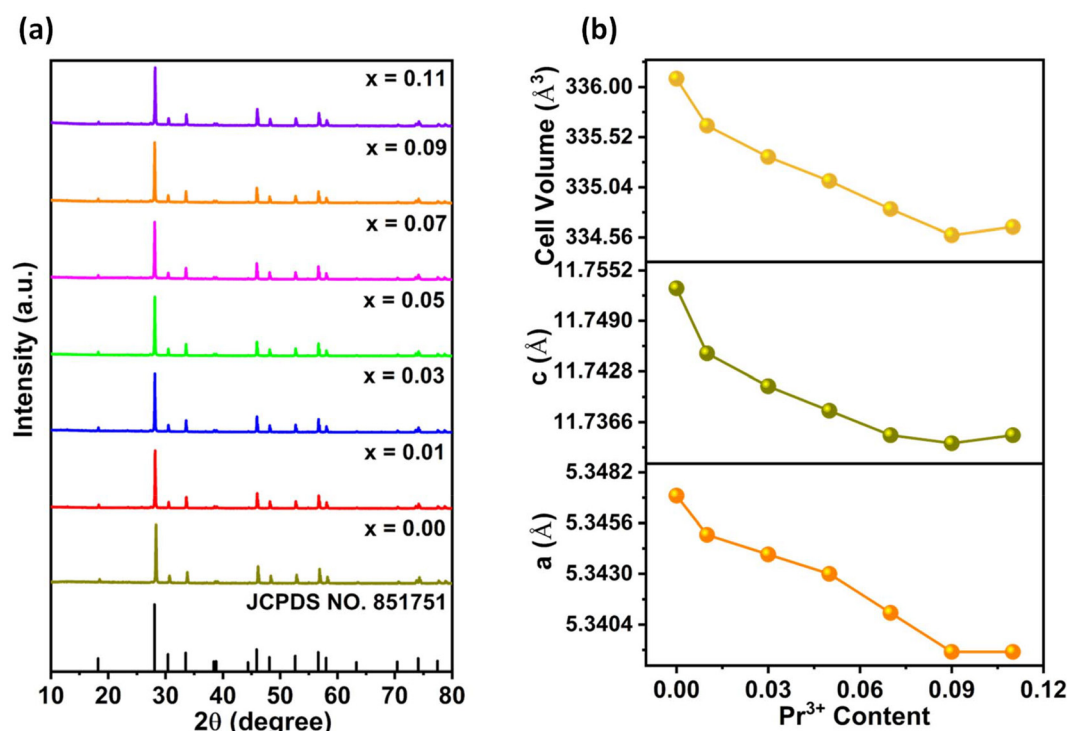

Fig. 1 (a) XRD patterns of $\text{NaLa}_{1-x}\text{Pr}_x(\text{MoO}_4)_2$ ($0.00 \leq x \leq 0.11$) phosphors and (b) unit cell volume and lattice parameter variations in $\text{NaLa}_{1-x}\text{Pr}_x(\text{MoO}_4)_2$.

cursors. This suggests the formation of single-phase compounds when Pr^{3+} is substituted on the La^{3+} site in the NLMO system. Additionally, the following equation was used to calculate the difference in radii between the substituted ion (Pr^{3+}) and the host cation (La^{3+}) in the NLMO system:

$$R_r = \frac{R_h(\text{CN}) - R_d(\text{CN})}{R_h(\text{CN})} \times 100 \quad (1)$$

R_d , R_h , and R_r represent the dopant radius, host cation radius, and percentage difference between R_d and R_h , respectively, and CN stands for coordination number. The radius percentage difference was determined to be 2.93% when larger La^{3+} (CN = 8, $R_h = 1.160 \text{ \AA}$) ions were replaced by smaller Pr^{3+} (CN = 8, $R_d = 1.126 \text{ \AA}$) ions in an NLMO system. The permissible percentage difference in the ionic radius between the host and substitute ions must not exceed 30%.³² This result suggests that the doped Pr^{3+} ions were successfully incorporated into the La^{3+} site in the NLMO host matrix.

To enhance the clarity of the crystal structure, a Rietveld refinement study was performed on pure and doped Pr^{3+} NLMO phosphors. The studies were conducted using the FullProf Suite-2000 program. Fig. S1† shows the refinement results of (a) NLMO, (b) $\text{NaLa}_{0.97}\text{Pr}_{0.03}(\text{MoO}_4)_2$ and (c) $\text{NaLa}_{0.94}\text{Pr}_{0.03}\text{Yb}_{0.03}(\text{MoO}_4)_2$. The observed and calculated profiles exhibit a notable concurrence, suggesting a significant level of refinement accuracy. The detailed analysis of lattice parameters and unit cell volume for $\text{NaLa}_{1-x}\text{Pr}_x(\text{MoO}_4)_2$ obtained from the Rietveld refinement is presented in Table S1.† The refinement analysis manifests that all compounds are crystallized in the scheelite-type tetragonal structure with space group $I_{41/a}$ (no. 88). The unit cell volume and cell parameters (a and c) of the pure NLMO sample decrease as the concentration of Pr^{3+} dopant increases up to 11 mol%. This is primarily due to the smaller ionic radius of the Pr^{3+} ion (1.126 Å, CN = 8) compared to the La^{3+} ion (1.160 Å, CN = 8) in the scheelite-type tetragonal NLMO system. Fig. 1(b) illustrates the variations in the volume of the unit cell and the cell parameters with respect to the concentration of Pr^{3+} ions. Tables S2 and S3† show the Rietveld refined structural parameters for $\text{NaLa}_{0.97}\text{Pr}_{0.03}(\text{MoO}_4)_2$ and $\text{NaLa}_{0.94}\text{Pr}_{0.03}\text{Yb}_{0.03}(\text{MoO}_4)_2$ compounds respectively.

Furthermore, the VESTA program was used to model the crystal structure of the $\text{NaLa}_{0.97}\text{Pr}_{0.03}(\text{MoO}_4)_2$ phosphor by considering the coordination of atoms and lattice parameters, as shown in Fig. S1(d).† In the NLMO compound, $\text{Na}^+/\text{La}^{3+}$ ions are coordinated by eight O^{2-} ions to form $(\text{Na/La})\text{O}_8$ dodecahedra, while each Mo^{6+} ion is coordinated by four O^{2-} ions, resulting in MoO_4 tetrahedra. These MoO_4 tetrahedra and $(\text{Na/La})\text{O}_8$ dodecahedra are connected *via* shared oxygen atoms, which contribute to the stability of the entire structure. In this system, Pr^{3+} ions are substituted at the La^{3+} ion sites. Similarly, the XRD patterns of $\text{NaLa}_{0.97-y}\text{Pr}_{0.03}\text{Yb}_y(\text{MoO}_4)_2$ co-doped phosphors, shown in Fig. S1(e),† match well with the JCPDS File no. 85-1751, confirming a high level of crystallinity. The absence of impurity diffraction peaks indicates that the

incorporation of Yb^{3+} and Pr^{3+} ions on La^{3+} sites as co-dopants had no impact on the crystal lattice of the host material. As a result, it may be concluded that all produced phosphors maintain a pure tetragonal phase.

3.2. XPS

XPS analysis was performed to ascertain the oxidation states of the components present in the $\text{NaLa}_{0.92}\text{Pr}_{0.03}\text{Yb}_{0.05}(\text{MoO}_4)_2$ phosphor. Fig. S2(a)† displays the survey scan of the $\text{NaLa}_{0.92}\text{Pr}_{0.03}\text{Yb}_{0.05}(\text{MoO}_4)_2$ phosphor within the binding energy range of 0–1200 eV. These identifications are based on the National Institute of Standard Technology (NIST) XPS database.³³ The survey spectrum confirms the presence of C 1s due to carbon absorption from the surrounding environment onto the sample's surface.^{34,35} Fig. S2(b–g)† illustrate the detailed XPS spectra of Na (1s), La (3d), Pr (3d), Yb (4d), Mo (3d), and O (1s) respectively. The XPS data undergo charge correction for all elements based on the C 1s peak at approximately 284.6 eV. The Na 1s spectrum exhibits one prominent peak at 1071.3 eV due to the 1s state of the Na^+ ion shown in Fig. S2(b).†³⁶ Fig. S2(c)† displays the 3d electronic state of La, which exhibits two peaks at 851.7 eV and 835.15 eV. These peaks correspond to the ejection of electrons from the $3d_{3/2}$ and $3d_{5/2}$ states of La^{3+} ions, respectively.³⁶ In order to verify the oxidation state of the dopant Pr, the 3d state is analyzed. In Fig. S2(d),† we observe the characteristic peaks of Pr $3d_{5/2}$ and Pr $3d_{3/2}$ at binding energies of 933.94 and 955.2 eV, respectively, providing evidence that the Pr ion is in the +3 oxidation state. Fig. S2(e)† illustrates the XPS spectra of Yb 4d states, exhibiting a band centred at around 196.1 eV and 186.08 eV, which correspond to the $4d_{3/2}$ and $4d_{5/2}$ energy levels of Yb^{3+} , respectively.^{37,38} These core-level XPS spectra validate the +3 oxidation state of ytterbium. Fig. S2(f)† displays the Mo 3d XPS spectra, with peaks at around 235.7 eV and 232.4 eV. The detected Mo peaks originate from the $3d_{3/2}$ and $3d_{5/2}$ core energy levels, confirming that Mo has a +6 oxidation state.³⁹ The O 1s signal, seen in Fig. S2(g),† has a central energy of approximately 530.5 eV.³⁹

3.3. Fourier transform infrared (FTIR) analysis

The FTIR technique is used to identify the functional groups through the characteristic transmission patterns recorded in a range of 380 to 1000 cm^{-1} , as illustrated in Fig. S3(a and b)† for $\text{NaLa}_{1-x}\text{Pr}_x(\text{MoO}_4)_2$ and $\text{NaLa}_{0.97-y}\text{Pr}_{0.03}\text{Yb}_y(\text{MoO}_4)_2$, respectively. The peak observed at 408 cm^{-1} in the $\text{NaLa}_{1-x}\text{Pr}_x(\text{MoO}_4)_2$ and $\text{NaLa}_{0.97-y}\text{Pr}_{0.03}\text{Yb}_y(\text{MoO}_4)_2$ compounds corresponds to the anti-symmetric bending of bonds inside the $[\text{MoO}_4]^{2-}$ cluster. On the other hand, the stretching vibrations of O–Mo–O in the MoO_4^{2-} tetrahedron are clarified by the presence of two separate peaks at 710 and 908 cm^{-1} . The bands observed at 846, and 734 cm^{-1} correspond to the anti-symmetric stretching modes that arise from the Mo–O stretching vibration in the MoO_4^{2-} tetrahedral structure. Introducing Pr^{3+} ions does not influence the positions and characteristics of distinct vibrational bands.

3.4. DRS spectra

Fig. S4(a and b)† demonstrate the DRS and Kubelka–Munk plots of $\text{NaLa}(\text{MoO}_4)_2$, $\text{NaLa}_{0.97}\text{Pr}_{0.03}(\text{MoO}_4)_2$ and $\text{NaLa}_{0.86}\text{Pr}_{0.03}\text{Yb}_{0.11}(\text{MoO}_4)_2$ phosphors, respectively. The DRS spectra of doped and co-doped samples exhibit several absorption peaks at 449, 468, 486, 602, and 1030 nm due to the characteristic f–f transitions of Pr^{3+} and Yb^{3+} ions. The transitions corresponding to the distinctive absorptions of Pr^{3+} ions are $^3\text{H}_4 \rightarrow ^3\text{P}_2$ (449 nm), $^3\text{H}_4 \rightarrow ^3\text{P}_1$ (468 nm), $^3\text{H}_4 \rightarrow ^3\text{P}_0$ (487 nm), $^3\text{H}_4 \rightarrow ^1\text{D}_2$ (602 nm), and $^3\text{H}_4 \rightarrow ^1\text{G}_4$ (1030 nm). The other band at 976 nm corresponds to the transition of Yb^{3+} ions from the ground state $^2\text{F}_{7/2}$ to the excited state $^2\text{F}_{5/2}$.

Eqn (2) and (3) refer to the Kubelka–Munk equation and Tauc equation, respectively, which are commonly used in the field to determine the optical band gap of materials using their reflectance spectra:^{40,41}

$$F(R_{\infty}) = \frac{(1 - R_{\infty})^2}{2R_{\infty}} = \frac{K}{S} \quad (2)$$

$$\alpha h\nu = K(h\nu - E_g)^n \quad (3)$$

The comprehensive theory and significance of the employed symbols were addressed in our previous article.³⁹ The Kubelka–Munk plot of the aforementioned phosphors is shown in Fig. S4(b).† The observed optical band gaps of $\text{NaLa}(\text{MoO}_4)_2$, $\text{NaLa}_{0.97}\text{Pr}_{0.03}(\text{MoO}_4)_2$ and $\text{NaLa}_{0.86}\text{Pr}_{0.03}\text{Yb}_{0.11}(\text{MoO}_4)_2$ phosphors are 3.83 eV, 3.63 eV and 3.76 eV, respectively. The observed decrease in the optical band gap of doped and co-doped samples suggests that the formation of new electronic states below the conduction band in the doped and co-doped materials is due to an increase in charge carrier concentration.¹¹

4. Multimodal light emission studies

Multimodal luminescence refers to the emission of light through different processes, including downshift (DS), quantum cutting (QC), and upconversion (UC). This phenomenon has gained considerable interest because of its extensive applications in display technologies, multimodal imaging, and optical thermometry, and for improving the performance of photovoltaic cells, among others. However, complete coverage of all luminescence types from Ln^{3+} doped single host matrices is still lacking in the existing literature. The emission of light *via* the aforementioned processes is contingent on certain processes, which will be explained in the following sections that specifically examine luminescence through different modes.

4.1. Downshifting (DS) emission

The material's photoluminescence properties can be determined by examining its excitation spectra, emission spectra, and luminescence lifetime. Fig. 2(a) represents the photoluminescence (PL) excitation spectra of NLMO phosphors activated with Pr^{3+} , measured at a 647 nm emission wavelength.

The spectra exhibit distinctive absorption peaks of Pr^{3+} at 449, 468, and 486 nm, caused by 4f–4f electronic transitions from the $^3\text{H}_4$ (ground state) to $^3\text{P}_2$, $^3\text{P}_1$, and $^3\text{P}_0$ multiplet states of Pr^{3+} ions, respectively, which is well aligned with the UV-Vis diffuse reflectance spectra, as shown in Fig. S4(a).† The samples were excited using the most intense characteristic excitation peak at 449 nm of Pr^{3+} ions. The intense excitation bands in the blue region support the utilization of NMLO: Pr^{3+} phosphors in developing InGaN (blue) LED-excited pc-LEDs. Additionally, the InGaN chip that emits blue light can serve a dual function, acting as both an excitation source for NMLO: Pr^{3+} phosphors and a supplementary source of blue light. Fig. 2(b) shows the photoluminescence (PL) emission spectra of NLMO with different concentrations of Pr^{3+} ions, excited at 449 nm. The emission peaks of Pr^{3+} ions are observed at specific wavelengths: one cyan emission peak at 486 nm ($^3\text{P}_0 \rightarrow ^3\text{H}_4$), two green emission peaks at 530 nm ($^3\text{P}_1 \rightarrow ^3\text{H}_5$) and 556 nm ($^3\text{P}_0 \rightarrow ^3\text{H}_5$), several low-intensity red emission peaks at 602 nm ($^1\text{D}_2 \rightarrow ^3\text{H}_4$), 688 nm ($^3\text{P}_1 \rightarrow ^3\text{F}_3$), and 731 nm ($^3\text{P}_0 \rightarrow ^3\text{F}_4$) and two strong red emission peaks at 618 nm ($^3\text{P}_0 \rightarrow ^3\text{H}_6$) and 647 nm ($^3\text{P}_0 \rightarrow ^3\text{F}_2$) of Pr^{3+} ions.^{23,42} The emission peaks at 486 and 647 nm exhibit greater intensity than all other peaks under excitation at both wavelengths due to the significant population of the $^3\text{P}_0$ excited state. Furthermore, the hypersensitive $^3\text{P}_0 \rightarrow ^3\text{F}_2$ transition of Pr^{3+} ($\Delta S = 0$, $\Delta J = 2$; S = spin angular momentum, and J = total angular momentum) is responsible for the emission at 647 nm.⁴³ This transition is a forced electric dipole transition, and it is strongly influenced by the field environment around the Pr^{3+} ions. The observed emission bands under a suitable excitation wavelength could be understood through the schematic energy level diagram displayed in Fig. 5(d).

The concentration of activator ions influences the luminescence intensity of the material. To achieve the maximum intensity, it is necessary to incorporate an appropriate quantity of activator ions. Fig. 2(c) shows that the emission intensity initially increases as the concentration of Pr^{3+} ions increases, reaching its optimum value at 3 mol% and then reducing with a further increase in concentration. The initial rise in intensity as a function of Pr^{3+} concentration is due to the increased quantity of favourable luminescent sites. Nevertheless, the reduction in intensity beyond the optimal value results from the concentration quenching phenomenon. When the number of activator ions (Pr^{3+} ions) in the host lattice exceeds a certain threshold, their distance from each other reduces, and some of the Pr^{3+} ions start to occupy the interstitial sites instead of the lattice sites of La^{3+} . The Pr^{3+} ions in the interstitial positions serve as luminescence quenchers, absorbing the photons that would otherwise be emitted as light and releasing the energy through non-radiative multiphonon emissions. The energy transfer process involved in concentration quenching can be understood by calculating the critical energy transfer distance (R_c).⁴⁴

$$R_c = 2 \left[\frac{3V}{4\pi x_c n} \right]^{\frac{1}{3}} \quad (4)$$

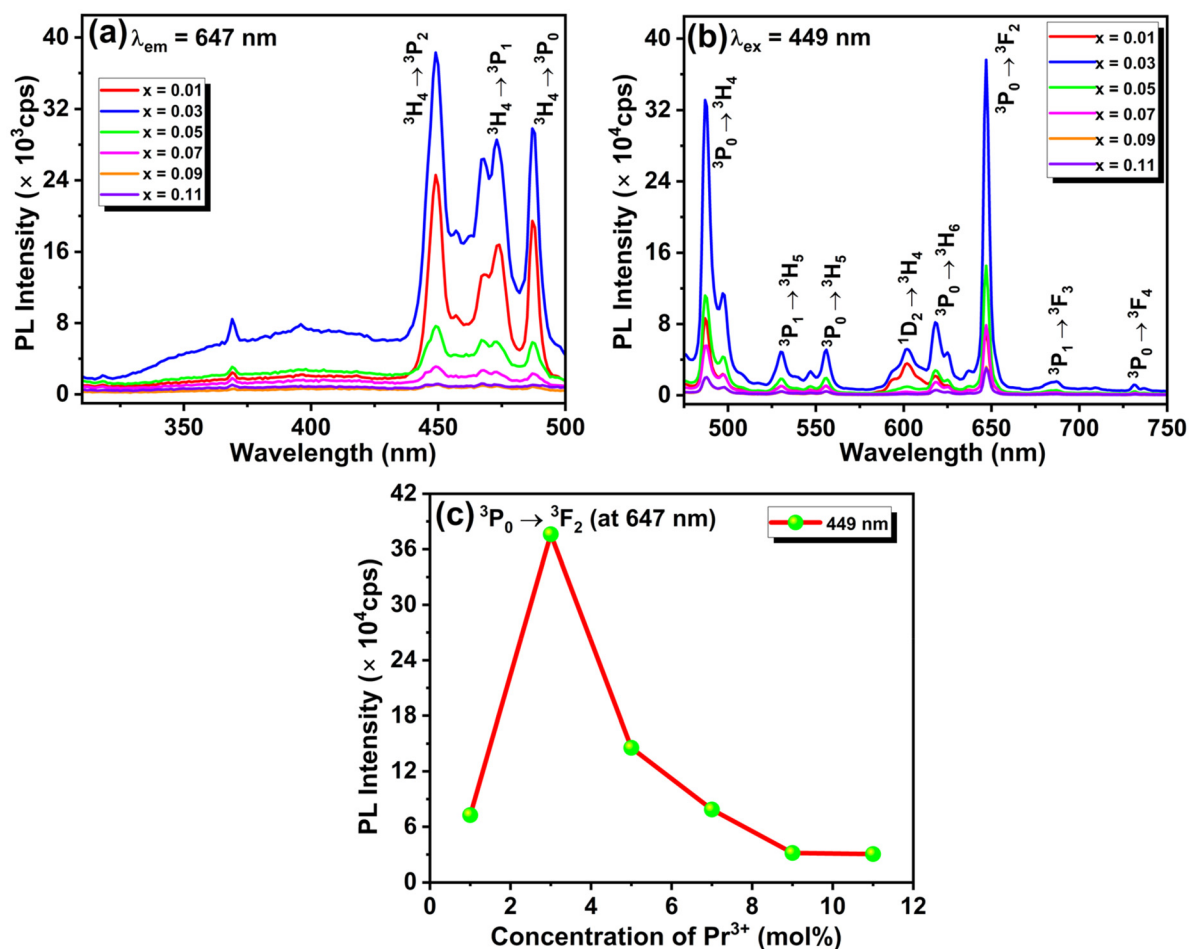

Fig. 2 (a) Excitation spectra of NaLa_{0.97}Pr_{0.03}(MoO₄)₂ phosphors monitored at 647 nm emission wavelength, (b) emission spectrum of NaLa_{0.97}Pr_{0.03}(MoO₄)₂ phosphors monitored at $\lambda_{\text{ex}} = 449$ nm, and (c) variation of the emission intensity with the percentage of NaLa_{0.97}Pr_{0.03}(MoO₄)₂ ($0.01 \leq x \leq 0.11$) phosphors monitored at $\lambda_{\text{ex}} = 449$ nm.

Where V , x_c , and n stand for the volume of a unit cell at the optimum concentration, n is the number of possible doping sites in the unit cell, and x_c signifies the optimum doping concentration, respectively. V , x_c , and n for the material are 335.33 Å³, 0.03, and 2, respectively. Based on eqn (4), if R_c is below 5 Å, luminescence is quenched due to exchange interactions. If R_c is above 5 Å, luminescence is quenched because of electric-multipole interactions. In the present scenario, the R_c value is 22.02 Å, above the threshold of 5 Å, indicating that electric-multipole interaction is the reason behind concentration quenching. But this electric-multipolar interaction consists of several types like dipole-dipole (d-d), dipole-quadrupole (d-q), and quadrupole-quadrupole (q-q) interactions. To know the particular type of multipolar interactions involved in the luminescence quenching, Dexter and Van's theory was used for multipolar interaction, which is represented by the following equation:⁴⁰

$$\frac{I}{x} = K \left[1 + \beta(x)^{\frac{Q}{3}} \right]^{-1} \quad (5)$$

The PL emission intensity and corresponding doping concentration are denoted by I and x , respectively. In contrast, β and k represent the constants for the given host lattices. The interaction type between rare-earth ions is represented by Q , where $Q = 6, 8$, and 10 correspond to dipole-dipole (d-d), dipole-quadrupole (d-q), and quadrupole-quadrupole (q-q) interactions, respectively. Fig. S5† depicts the logarithmic plot of I/x vs. x for NaLa_{1-x}Pr_x(MoO₄)₂ phosphors at an excitation wavelength of 449 nm. The plot of $\log(I/x)$ vs. $\log(x)$ is found to be relatively linear, with a slope of -3.05 and a value of Q is obtained around 9.15 by using eqn (5), which is approaching the minimal Q value of 10. Therefore, it is confirmed that the interaction involved in concentration quenching is quadrupole-quadrupole (q-q) interaction in NaLa_{1-x}Pr_x(MoO₄)₂ phosphors.

4.2. Quantum cutting (QC) emission

In the QC phenomenon, typically, higher energy photons get converted into two or more lower energy photons through an energy transfer pathway. It was first observed in YF₃:Pr³⁺ (ref.

45) in 1974 and has since been extensively studied in several fluoride-based host materials like $\text{KY}_3\text{F}_{10}:\text{Pr}^{3+}/\text{Yb}^{3+}$,⁴⁶ $\text{YOF}:\text{Pr}^{3+}/\text{Yb}^{3+}$,¹⁷ $\text{NaYF}_4:\text{Pr}^{3+}/\text{Yb}^{3+}$,⁴⁷ $\text{Ba}_4\text{Y}_3\text{F}_{17}:\text{Pr}^{3+}/\text{Yb}^{3+}$,⁴⁸ *etc.* As fluoride materials have relatively low phonon energy ($\sim 420\text{ cm}^{-1}$), which helps in reducing the non-radiative transition *via* multiphonon emission and, therefore, favours efficient energy transfer and high fluorescence quantum yield. However, the high toxicity and low chemical stability of fluoride-based materials hinder their applicability.⁶ To overcome this problem, oxide-based host materials are used due to their non-toxicity, chemical stability, ease of synthesis, and strong absorption in the n-UV region. Considering this criterion, researchers have recently used oxide-based host phosphors with QC emission as coating materials to improve the photovoltaic performance of c-Si solar cells.¹⁹ Fig. 3(a and b) show the emission spectra of $\text{NaLa}_{0.97-y}\text{Pr}_{0.03}\text{Yb}_y(\text{MoO}_4)_2$ samples excited at 325 nm recorded in the visible (400 nm–800 nm) and near-infrared (800–1050 nm) regions, respectively. Fig. 3(a) shows different visible emission bands related to the various f–f transitions of Pr^{3+} ions, as mentioned in the above section of downshifting emission studies. Fig. 3(b) indicates the NIR emission spectra, which contain emission bands at around 982 nm ($^3\text{P}_0 \rightarrow ^1\text{G}_4$),

1016 nm ($^1\text{D}_2 \rightarrow ^3\text{F}_4$), and 976 nm ($^2\text{F}_{5/2} \rightarrow ^2\text{F}_{7/2}$) related to the electronic transitions of Pr^{3+} and Yb^{3+} ions, respectively.⁴⁹ Specifically, the emission bands of Pr^{3+} and Yb^{3+} ions in the NIR region are appealing for solar cell applications because they align with the most efficient region of c-Si solar cells. From Fig. 3(b), it is clear that as the concentration of Yb^{3+} increases, the emission intensity of the Pr^{3+} peak at 647 nm ($^3\text{P}_0 \rightarrow ^3\text{F}_2$) gradually attenuates in the visible region, while in the NIR region the emission intensity of the band at 976 nm observed due to the $^2\text{F}_{5/2} \rightarrow ^2\text{F}_{7/2}$ transition of Yb^{3+} increases up to 3 mol% of Yb^{3+} . However, it eventually decreases due to concentration quenching caused by non-radiative energy transfer (ET) between neighbouring Yb^{3+} ions. The observed NIR emission band of Yb^{3+} ($^2\text{F}_{5/2} \rightarrow ^2\text{F}_{7/2}$) can only be achieved upon 325 nm ($22\,690\text{ cm}^{-1}$) excitation through energy transfer (ET) from Pr^{3+} , as Yb^{3+} does not have an electronic state above $10\,240\text{ cm}^{-1}$. Energy transfer (ET) from Pr^{3+} to Yb^{3+} can occur *via* two pathways. The energy level diagram could explain the different pathways to achieve NIR emissions and energy transfer from Pr^{3+} to Yb^{3+} ions, as shown in Fig. 5(d).

To get a deeper insight into the optical process involved in QC emission, the authors measured the power-dependent

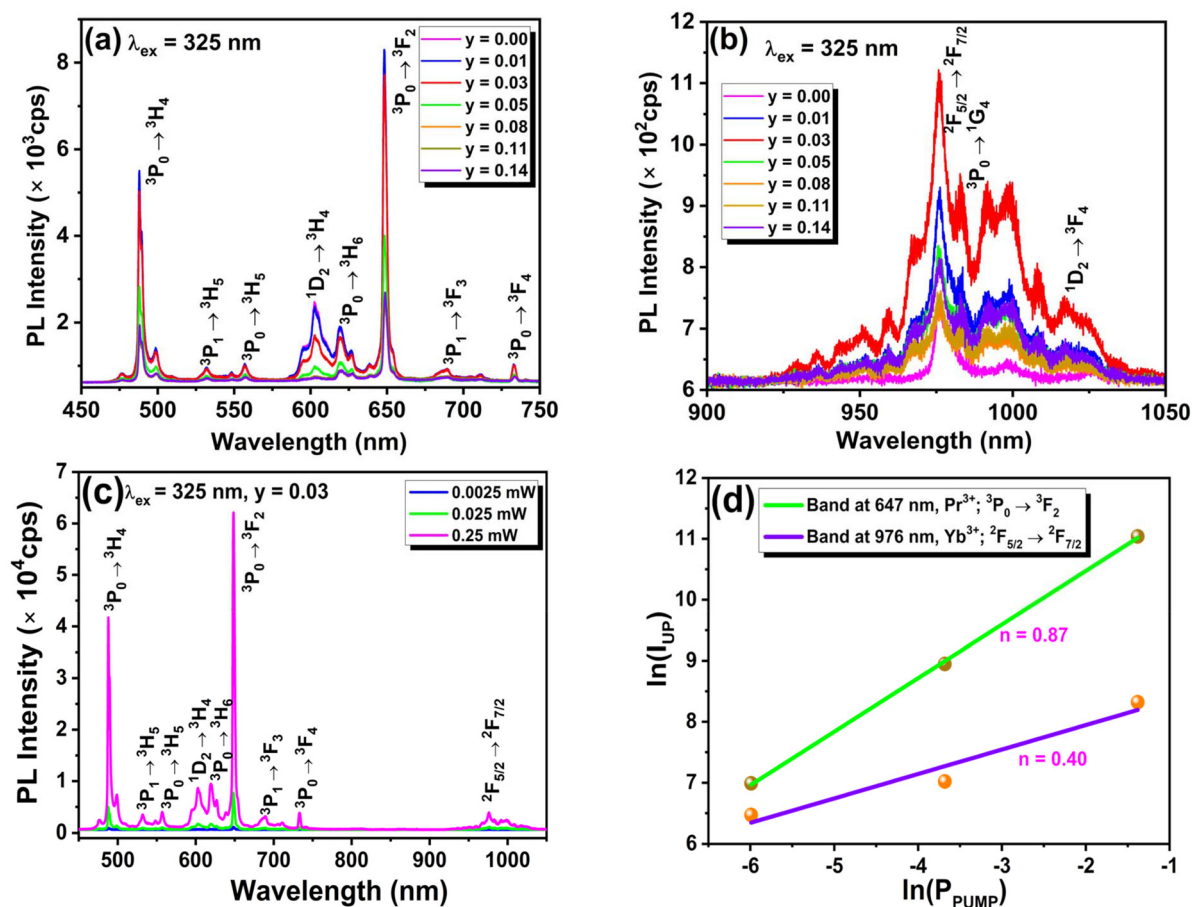

Fig. 3 (a and b) Concentration-dependent emission spectra of $\text{NaLa}_{0.97-y}\text{Pr}_{0.03}\text{Yb}_y(\text{MoO}_4)_2$ phosphors ($0.00 \leq y \leq 0.14$) upon 325 nm laser excitation, in the visible and NIR regions, respectively, and (c and d) power-dependent QC emission spectra and the \ln – \ln plot of intensity vs. the pump plot of $\text{NaLa}_{0.94}\text{Pr}_{0.03}\text{Yb}_{0.03}(\text{MoO}_4)_2$ samples, respectively.

emission spectra of the $\text{NaLa}_{0.94}\text{Pr}_{0.03}\text{Yb}_{0.03}(\text{MoO}_4)_2$ sample in the visible-NIR range using 325 nm laser excitation. Furthermore, this power-dependent emission data were analyzed by monitoring the emission intensities of the 647 nm: $^3\text{P}_0 \rightarrow ^3\text{F}_2$ (Pr^{3+}) and 976 nm: $^2\text{F}_{5/2} \rightarrow ^2\text{F}_{7/2}$ (Yb^{3+}) bands with the applied excitation power, as displayed in Fig. 3(c). The $\ln(I)$ vs. $\ln(P)$ plots for the emission bands at 647 nm and 976 nm are illustrated in Fig. 3(d). From the plot, it is evident that the emission band related directly to the excited Pr^{3+} ions shows a higher response with the applied power compared to the emission band associated with the indirectly excited Yb^{3+} ions. This may be due to the fact that only a few of the excited Pr^{3+} ions participate in transferring their energy to nearby Yb^{3+} for the NIR emission. The variations of these emission bands within the low-power region follow the following relationship:⁶

$$I \propto P^n \quad (6)$$

where I signifies the emission intensity, P is the excitation power, and n refers to the number of photons required for light emission under specific processes. In the present case, the observed value of n , *i.e.*, the slope value for the $\ln(I)$ vs. $\ln(P)$ for the visible emission, is $n = 0.87 \approx 1.0$, and for the NIR emission, it is $n = 0.40 \approx 0.5$. Thus, it is clear that the observed visible emission is through the linear optical process, and the observed NIR emission is through the non-linear optical process. Additionally, it supports the assumption of conversion of one high-energy photon into two low-energy photons

for the QC process. Similar types of observations have been reported by other researchers in $\text{KYb}(\text{WO}_4)_2:\text{Tb}^{3+}$,⁵⁰ $\text{Ca}_{12}\text{Al}_{14}\text{O}_{33}:\text{Yb}^{3+}/\text{Eu}^{3+}$ oxide⁵¹ based phosphor materials.

4.3. Decay kinetics and quantum cutting efficiency

The decay kinetic studies of the samples were performed to quantitatively estimate the energy transfer and internal quantum cutting efficiency from Pr^{3+} to Yb^{3+} ions. The decay times of Pr^{3+} doped NLMO and $\text{Pr}^{3+}/\text{Yb}^{3+}$ co-doped NLMO samples were recorded for the most intense emission band, *i.e.*, for 647 nm of Pr^{3+} by fixing the excitation wavelength at 447 nm. In both cases, the observed experimental data were fitted with the single exponential function as mentioned below:³⁹

$$I = I_0 \exp\left(\frac{-t}{\tau}\right) \quad (7)$$

The decay emission intensities at any time t and time 0 are denoted as I and I_0 , respectively. τ is the decay time, which could be obtained by fitting the data in eqn (7). Fig. 4(a and b) display the decay time profile of Pr^{3+} and $\text{Pr}^{3+}/\text{Yb}^{3+}$ doped NLMO samples, respectively. From the decay time profile, it is clear that the observed maximum decay time in single Pr^{3+} doped NLMO samples is the maximum in the optimized sample, *i.e.*, for 3 mol% of Pr^{3+} , and it was around 6.52 μs . Whereas the decay time in the case of co-doped samples in

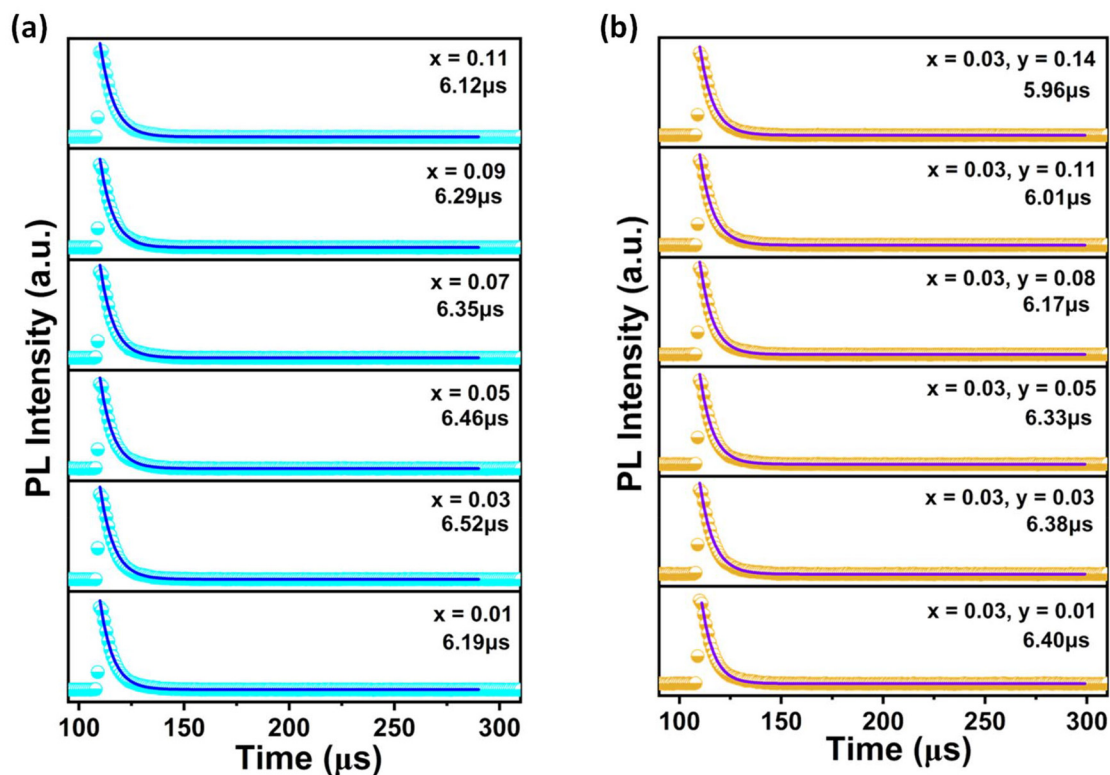

Fig. 4 Decay time profile of (a) $\text{NaLa}_{1-x}\text{Pr}_x(\text{MoO}_4)_2$ ($0.01 \leq x \leq 0.11$) and (b) $\text{NaLa}_{0.97-y}\text{Pr}_{0.03}\text{Yb}_y(\text{MoO}_4)_2$ ($0.01 \leq y \leq 0.14$) samples, recorded by fixing emission at 647 nm and excitation at 447 nm.

which the amount of Pr^{3+} was fixed at 3 mol% and the amount of Yb^{3+} was varied from 1 to 14 mol%, decreases continuously with increasing the amount of Yb^{3+} , as mentioned in Table S4.† This decrement in the decay time of Pr^{3+} may be due to the fact that some of the excited Pr^{3+} ions transfer their energy to the nearby Yb^{3+} for QC emission. It is important to mention that the PL emission in the visible region follows a similar trend to that seen in the decay time with the increasing amount of Yb^{3+} . Thus, in this type of system, energy transfer from Pr^{3+} to Yb^{3+} ions can be assumed through the cooperative energy transfer (CET) channel and the energy transfer efficiency (η_{ETE}) can be calculated using the following relationship:⁶

$$\eta_{\text{ETE}} = 1 - \frac{\tau_{\text{Pr}^{3+}/\text{Yb}^{3+}}}{\tau_{\text{Pr}^{3+}}} \quad (8)$$

where the decay times of $\text{Pr}^{3+}/\text{Yb}^{3+}$ and Pr^{3+} -doped samples are denoted as $\tau_{\text{Pr}^{3+}/\text{Yb}^{3+}}$ and $\tau_{\text{Pr}^{3+}}$, respectively. The determination of the internal quantum efficiency (η_{QE}) for various quantities of Yb^{3+} can be achieved by utilizing the provided energy transfer efficiency values and applying the following relationship:^{6,19}

$$\eta_{\text{QE}} = \eta_{\text{Pr}}(1 - \eta_{\text{ETE}}) + 2\eta_{\text{ETE}} \quad (9)$$

In the aforementioned relationship, the initial component represents the visible photons emitted by Pr^{3+} ions, while the subsequent term refers to the near-infrared (NIR) photons emitted by Yb^{3+} ions. In this context, η_{Pr} represents the quantum efficiency of Pr^{3+} , and it can be taken as equal to 1 in an ideal case when the probability of non-radiative transition is zero, *i.e.*, for maximum possible efficiency. Table S4† represents the variations in calculated parameters η_{ETE} and η_{QE} with the amount of Yb^{3+} ions. In the present case, the maximum possible quantum-cutting efficiency (η_{QE}) is for the samples having compositions $\text{NaLa}_{0.83}\text{Pr}_{0.03}\text{Yb}_{0.14}(\text{MoO}_4)_2$ and it was around 109%. This indicates that when 100 photons of 449 nm radiation are absorbed by the sample having compositions $\text{NaLa}_{0.83}\text{Pr}_{0.03}\text{Yb}_{0.14}(\text{MoO}_4)_2$, then it will generate 18 photons with NIR-region wavelengths (900–1100 nm) and 91 photons with visible-region energy (emission of Pr^{3+}).

4.4. Upconversion (UC) emission

The UC emission studies of $\text{Yb}^{3+}/\text{Pr}^{3+}$ co-doped samples were performed using an NIR 980 nm laser excitation source. In UC emission studies, the amount of Pr^{3+} was fixed at 3 mol% as it was optimized in the DS emission study, and then the amount of Yb^{3+} was varied from 1 to 14 mol%, as displayed in Fig. 5(a). The presence of Yb^{3+} in the $\text{NaLa}_{0.97}\text{Pr}_{0.03}(\text{MoO}_4)_2$ phosphor is essential to achieve the UC emission, as no energy level in Pr^{3+} corresponds to the 980 nm excitation wavelength. Under 980 nm laser excitation, Yb^{3+} ions absorb energy and transfer their energy to nearby Pr^{3+} ions for visible UC emission. The observed UC emission exhibits similar emission bands as observed in the DS emission study due to various f–f transitions of Pr^{3+} ions. Initially, the strength of observed UC emission bands increases with the amount of Yb^{3+} , and it reaches a

maximum of 11 mol% of Yb^{3+} and then declines because of concentration quenching.

Further, the power-dependent UC emission spectra were recorded to know the number of photons involved in the observed UC emission band, as shown in Fig. 5(b). On analyzing the power-dependent UC emission spectra using eqn (6), it was found that two NIR photons are required to get the most prominent 647 and 486 nm visible UC emission bands from Pr^{3+} ions shown in Fig. 5(c). A schematic energy level diagram was drawn, as illustrated in Fig. 5(d), to explain the observed UC emission in the present system. For details, one may refer to the work of Balaji S. *et al.*⁵²

5. Thermal stability

The phosphor's thermal stability is significant for its use in lighting and display device applications. Fig. 6(a) shows the temperature-dependent emission spectra of $\text{NaLa}_{0.97}\text{Pr}_{0.03}(\text{MoO}_4)_2$ phosphors monitored at a 449 nm excitation wavelength with temperatures ranging from 298 K to 448 K. From Fig. 6(a), it is clear that upon increasing the temperature, the emission intensity of each peak decreases with a different rate without losing its spectrum pattern, owing to the thermal quenching phenomenon. Fig. 6(b) illustrates the relationship between normalized intensity variations with rising temperature for four major peaks of the Pr^{3+} ion. The temperature-dependent change in the relative integrated intensity of the 647 nm emission band maintained approximately 41% of its maximum value at 423 K, as shown in Fig. 6(c).

Furthermore, the activation energy (ΔE_a) obtained from the analysis of temperature-dependent emission spectra is an important thermal quenching parameter and was calculated by the Arrhenius equation given below:¹¹

$$\ln\left(\frac{I_0}{I_T} - 1\right) = \ln A - \frac{\Delta E}{kT} \quad (10)$$

where I_0 and I_T signify the emission intensity at 0 K temperature and at any temperature T , respectively. $\ln A$ is the constant frequency factor, k denotes the Boltzmann constant (8.629×10^{-5} eV K^{-1}), T is the temperature and activation energy is defined by ΔE_a . In this case, the value of activation energy for the 647 nm band was obtained by linearly fitting $\ln\left(\frac{I_0}{I_T} - 1\right)$ vs. $1/kT$, and it is found to be 0.44 eV and is represented by the slope of the fitted line, as shown in Fig. 6(d). The obtained high value of ΔE_a indicates that the phosphor has good thermal stability. The obtained value of ΔE_a was around 0.44 eV, which is relatively higher than that of the others previously reported for Pr^{3+} doped phosphors.^{43,53–56}

6. Applications

6.1. Optical thermometry

To shed some light on optical thermometry properties, the fluorescence-based temperature sensing technique utilizes the

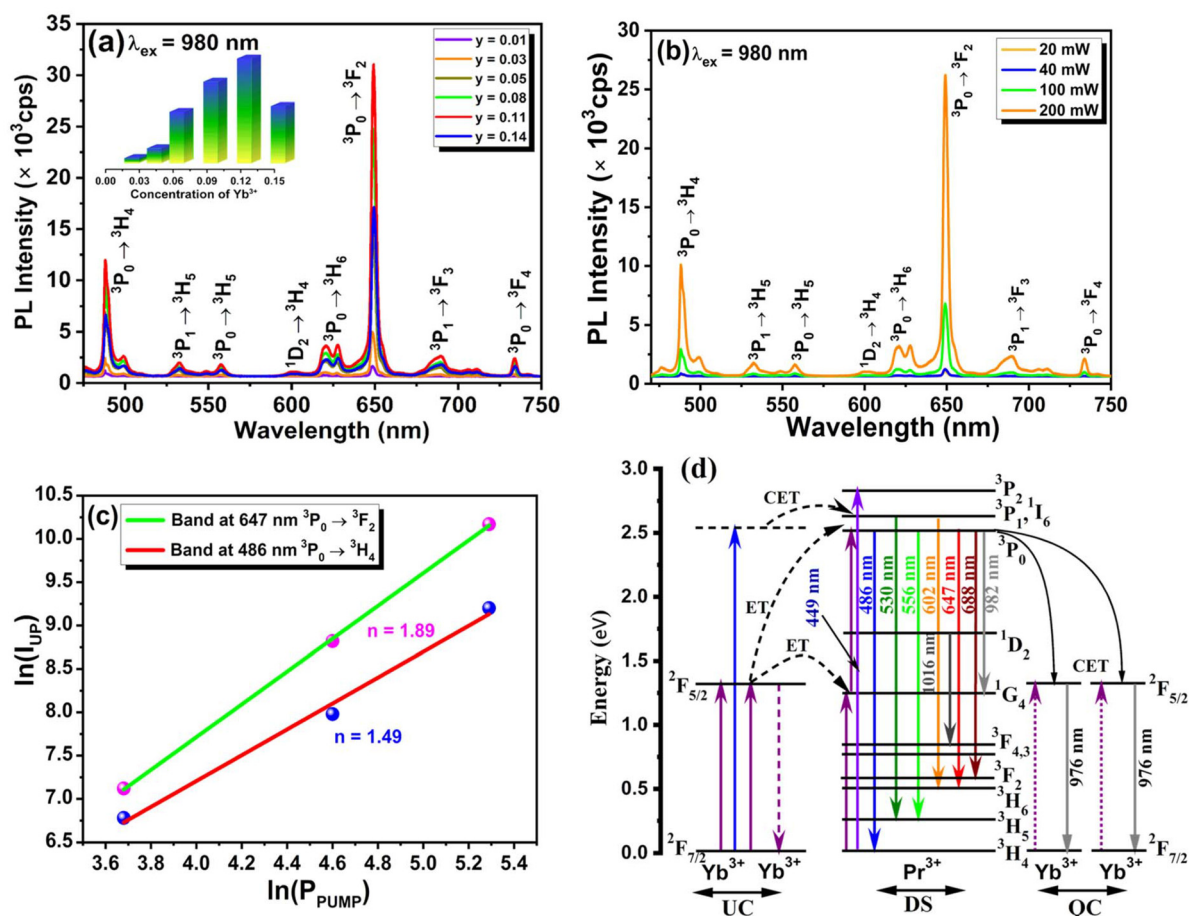

Fig. 5 (a) Concentration-dependent UC emission spectra of $\text{NaLa}_{0.97-y}\text{Pr}_{0.03}\text{Yb}_y(\text{MoO}_4)_2$ phosphors ($0.01 \leq y \leq 0.14$) under 980 nm laser excitation, (b) power-dependent UC emission spectra of $\text{NaLa}_{0.86}\text{Pr}_{0.03}\text{Yb}_{0.11}(\text{MoO}_4)_2$ phosphors, (c) \ln – \ln plot of intensity vs. pump power for $\text{NaLa}_{0.86}\text{Pr}_{0.03}\text{Yb}_{0.11}(\text{MoO}_4)_2$ phosphors, and (d) schematic partial energy level diagram of $\text{Pr}^{3+}/\text{Yb}^{3+}$ ions to explain the observed emission bands under different excitation wavelengths.

temperature-sensitive fluorescence characteristics of luminescent materials, presenting various advantages over conventional methods such as thermocouple detectors. This method demonstrates robust functionality even in environments characterized by intense electromagnetic interference, electrical sparks, and corrosive conditions. This technique has two primary modalities: one that relies on the measurement of fluorescence lifetime and the other that depends on the measurement of luminescence intensity ratio (LIR). Fluorescence lifetime-based temperature evaluation faces limitations, particularly with the thermalized energy levels that are usually used. However, the FIR technique provides an alternate solution. The majority of energy level pairs associated with rare earth ions remain non-thermalized, and the FIR ratio of these pairs exhibits temperature-dependent behaviour. However, it is difficult to populate these non-thermalized energy levels *via* thermal excitation because of significant differences in energy levels. While FIR technology traditionally depends on transitions between thermally coupled levels (TCLs), its effectiveness in temperature

measurement is constrained by notable restrictions.⁵⁷ Therefore, a polynomial function can accurately represent the temperature-dependent FIR emissions of non-thermally connected levels (NTCLs).

The following equation can be utilized to determine their LIR relationship:⁵⁸

$$\text{LIR} = A + BT + CT^2 + DT^3 \quad (11)$$

here, A , B , C and D are constants that can be determined by fitting the LIR to the temperature data. The luminescence ratios were derived from the integrated values of the luminescence peaks.

Additionally, the absolute S_a and relative S_r temperature sensitivities, which are crucial parameters for temperature measurement, can be calculated using the following equations:⁵⁹

$$S_a = \left| \frac{d(\text{LIR})}{dT} \right| = B + 2CT + 3DT^2 \quad (12)$$

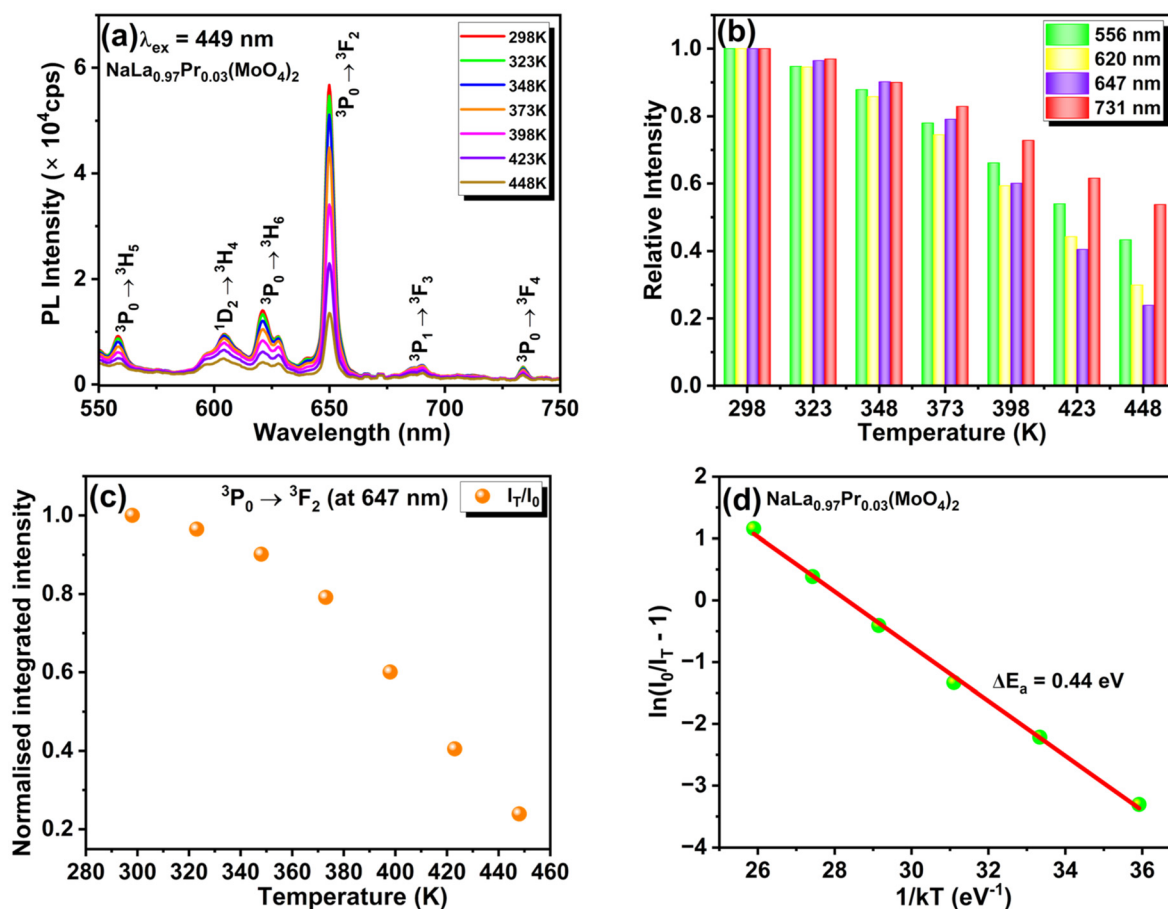

Fig. 6 (a) Temperature-dependent emission spectra of $\text{NaLa}_{0.97}\text{Pr}_{0.03}(\text{MoO}_4)_2$ phosphors excited at 449 nm. (b) Bar diagram representing the normalized intensity variation as a function of temperature for four major peaks of Pr^{3+} , (c) normalized integral intensity variation as a function of temperature, and (d) the $\ln(I_0/I_T - 1)$ vs. $1/kT$ plot for the determination of activation energy.

and

$$S_r = \frac{1}{\text{LIR}} \times \left| \frac{d(\text{LIR})}{dT} \right| = \left| \frac{B + 2CT + 3DT^2}{A + BT + CT^2 + DT^3} \right| \quad (13)$$

The values of S_a and S_r can be evaluated by using eqn (12) and (13), respectively, based on the various non-thermally coupled (NTCL) energy levels. Fig. 7(a–d) illustrate the changes in LIR and sensitivity parameters S_a and S_r as the temperature varies from 298 to 448 K in the Pr^{3+} doped samples. Table 1 provides an overview of the estimated maximum sensitivity parameters for both cases. It is evident from the table that the Pr^{3+} doped NLMO sample exhibits the highest relative sensitivity for the chosen pair of NTCLs I_{620}/I_{647} . The obtained sensitivity parameters were also compared with the sensing parameters observed in other Pr^{3+} doped phosphor samples, as presented in Table 1. Based on the analysis, it can be concluded that the prepared sample holds promise for use in contactless optical temperature sensing applications.

To ascertain the commercial viability of the prepared samples as temperature-sensitive probe materials, it is imperative to assess not only the relative and absolute sensitivity parameters but also repeatability and uncertainty (ΔT). In this

work, the I_{602}/I_{620} sample showed the highest absolute sensitivity values and was then examined for repeatability and uncertainty measurements. Fig. 7(e) depicts the cyclic repeatability of LIR (I_{602}/I_{620}) during several measurement cycles and temperature fluctuations.

The temperature uncertainty (ΔT) can be calculated using the following equation:^{64,65}

$$\Delta T = \frac{1}{S_r} \frac{\Delta \text{LIR}}{\text{LIR}} \quad (14)$$

The standard deviation in the LIR value is denoted as ΔLIR . Fig. 7(f) illustrates the uncertainty in the temperature measurement of the $\text{NaLa}_{0.97}\text{Pr}_{0.03}(\text{MoO}_4)_2$ phosphor for I_{602}/I_{620} . The temperature uncertainty falls within a range of 0.3–1.3 K. The low uncertainty value validates the appropriateness of the produced phosphor for temperature-sensing applications. Another essential parameter on which the above parameters can rely is percentage repeatability (R), and it can be expressed as⁶⁶

$$R = \left| 1 - \frac{\max(\Delta_m - \Delta_i)}{\Delta_m} \right| \times 100 \quad (15)$$

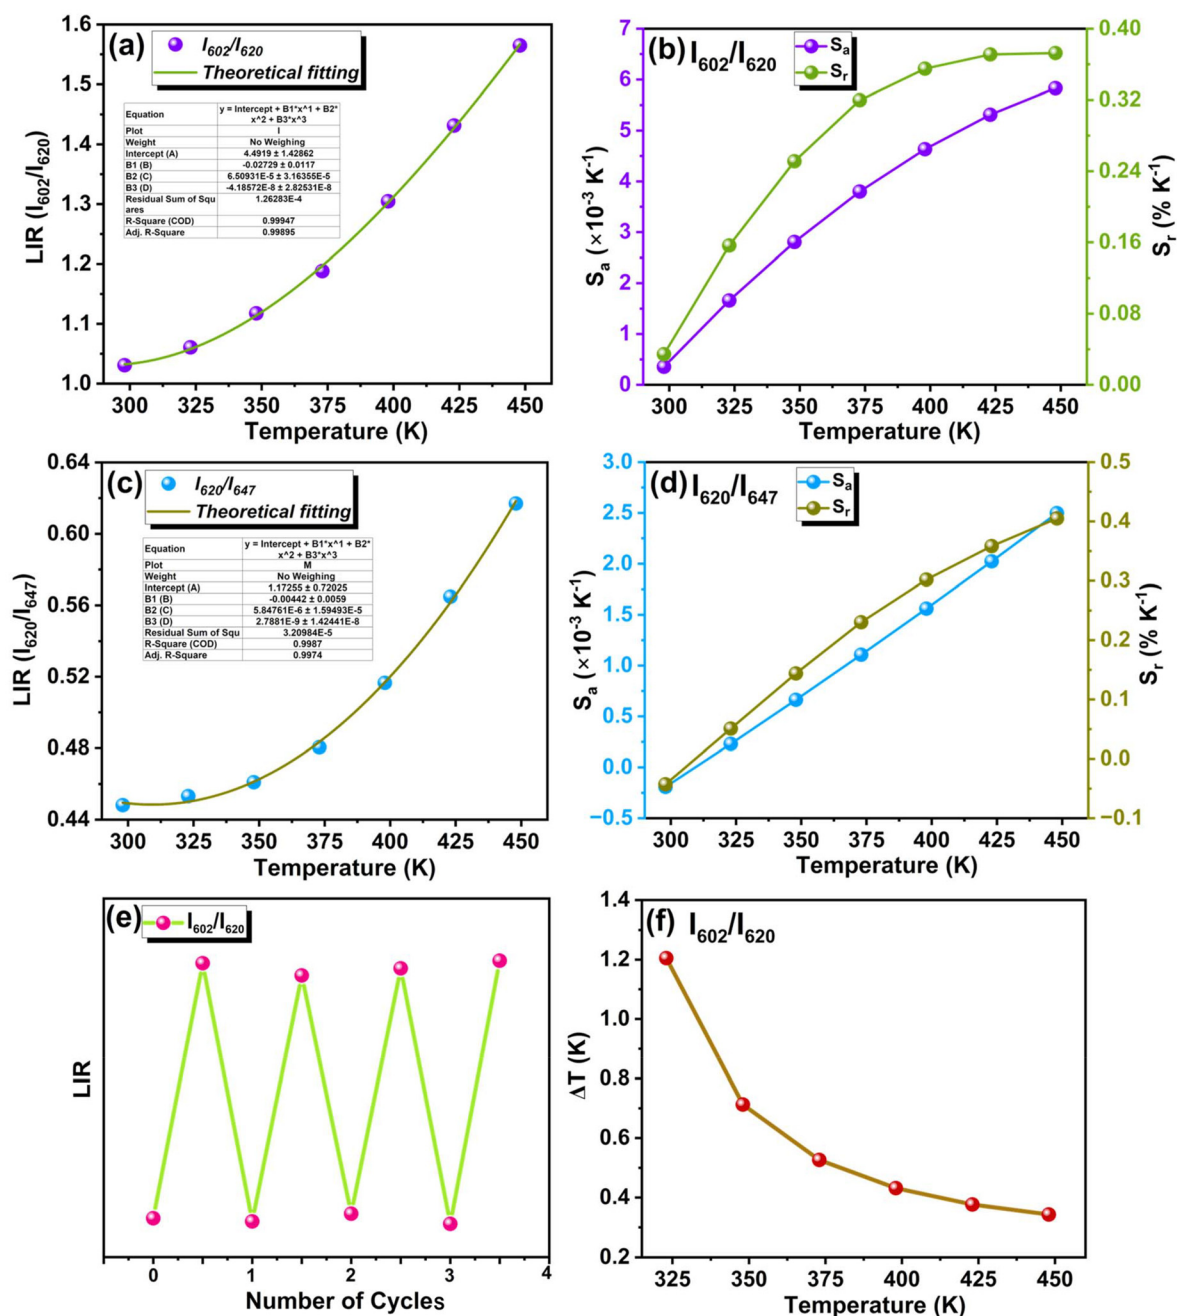

Fig. 7 LIR variation with T for NaLa_{0.97}Pr_{0.03}(MoO₄)₂ phosphors in the temperature range of 298 to 448 K under a 449 nm excitation wavelength for (a) I_{602}/I_{620} and (c) I_{620}/I_{647} . The dependence of absolute sensitivity (S_a) and relative sensitivity (S_r) on temperature for (b) I_{602}/I_{620} and (d) I_{620}/I_{647} for NTCL, (e) repeatability measurement, and (f) uncertainty measurement at variable temperatures.

Table 1 The maximal values of sensitivity parameters (S_a and S_r) in different types of Pr³⁺ doped samples

Sample	LIR (NTCLs)	S_a -Maximum ($\times 10^{-3}$ K ⁻¹) (at temperature)	S_r -Maximum (% K ⁻¹) (at temperature)	Ref.
NLMO:Pr ³⁺	I_{602}/I_{620}	5.8 (448 K)	0.37 (448 K)	This work
NLMO:Pr ³⁺	I_{620}/I_{647}	2.5 (448 K)	0.41 (448 K)	This work
Sr ₃ Sc ₂ Ge ₃ O ₁₂ :Pr ³⁺	—	—	0.32 (650 K)	60
NaSrGd(MoO ₄) ₃ :Pr ³⁺	I_{530}/I_{619}	1.5 (290 K)	0.52 (290 K)	61
LaMgNbO ₃ :Pr ³⁺	I_{492}/I_{619}	32.1 (523 K)	0.71 (473 K)	62
YF ₃ :Pr ³⁺	I_{700}/I_{723}	—	0.57 (293 K)	63

where Δ_m indicates the mean LIR values for four cycles and Δ_i is the LIR value in four repeated radiation cycles. The variation of LIR values in four consecutive cycles is shown in Fig. 7(e). In the present case, estimated values of R within the temperature range of 298 to 448 K are more than 98, so it can be said that the sample exhibits good thermal repeatability.

6.2. Fabrication of pc-LED and plant growth

To test the practical use of the prepared phosphor in a phosphor-coated LED (pc-LED) device, the pc-LED device was developed by combining a commercially available blue LED (InGaN) chip with the chosen $\text{NaLa}_{0.97}\text{Pr}_{0.03}(\text{MoO}_4)_2$ phosphor. The selected phosphor and epoxy resin (product name: CLEARRESIN) were mixed in a 1:10 wt% ratio and blended thoroughly using ultrasonication. Once the mixing was complete, a smooth layer of paste was carefully applied to the blue LED chip using the doctor blade technique. The developed pc-LED was then placed in an oven at 60 °C for 3 h to allow the paste to dry.⁵⁹ In this case, a blue LED was selected because its emission was approximately in the 430–440 nm range and aligned with one of the prominent excitation bands observed through the $^3\text{H}_4 \rightarrow ^3\text{P}_2$ transition of Pr^{3+} ions. The emission spectra of the developed pc-LED device as a function of applied voltage are recorded and displayed in Fig. 8(a). The observed emission spectra of pc-LED include an emission band at around 440 nm attributed to the leakage of the used LED chip and emission bands resulting from various f-f transitions of Pr^{3+} in the visible region. The strength of the emission bands increases with the increase in the applied voltage, which indicates the voltage stability of the developed pc-LED. This increase in intensity does not disrupt the band pattern, indicating the stability of the developed pc-LED under varying voltage conditions. Furthermore, to demonstrate the applicability of the developed pc-LED in plant growth, the observed emission spectrum of the developed pc-LED was compared with the absorption spectra of chlorophylls (a,b) and phyto-

chrome, as shown in Fig. 8(b). Here, it is to be noted that chlorophylls (a,b) and phytochrome are the compounds found in plants that are responsible for plant growth. From the comparison, it is clear that the observed emissions in the blue region and red regions of the developed pc-LED fall in the prominent absorption regions of chlorophyll and phytochrome, respectively. Thus, such a pc-LED could be used as a light source for indoor plant applications. Similarly, other researchers have also suggested the use of Eu^{3+} , Sm^{3+} , and Mn^{4+} doped red colour-emitting phosphor-based pc-LEDs for indoor plant applications.^{67–69} But the advantage of the presented pc-LED is that it utilizes blue and red emission to cover the absorption of chlorophyll as well as phytochrome.

6.3. c-Si solar cells

The spectral range of 900–1100 nm is found to be the most effective for the operation of c-Si solar cells. However, these cells have limited responsiveness towards shorter wavelengths (300–500 nm) due to thermal losses. It is worth noting that solar irradiation is abundant in this range. Therefore, materials that can capture solar energy in the 300–500 nm range and convert it into near-infrared (NIR) emissions falling within the 900–1100 nm range are ideal for use as coatings on c-Si solar cells to enhance the photovoltaic performances.⁵⁹ Fig. 9(a) shows a comparison of the normalized spectral irradiance of solar radiation (derived from ASTM G-173-03), the spectral response curve of c-Si solar cells, and the excitation/emission spectrum of a $\text{NaLa}_{0.94}\text{Pr}_{0.03}\text{Yb}_{0.03}(\text{MoO}_4)_2$ sample. This comparison highlights the ability of the prepared $\text{Yb}^{3+}/\text{Pr}^{3+}$ co-doped NLMO sample to harness solar energy in the 300–450 nm range and convert it into NIR emissions within the 900–1100 nm band. The emission spectrum of the prepared sample aligns with the most efficient region of c-Si solar cells, indicating its potential to enhance photovoltaic performance. Fig. 9(b) presents a schematic model that demonstrates how the prepared co-doped sample could improve the

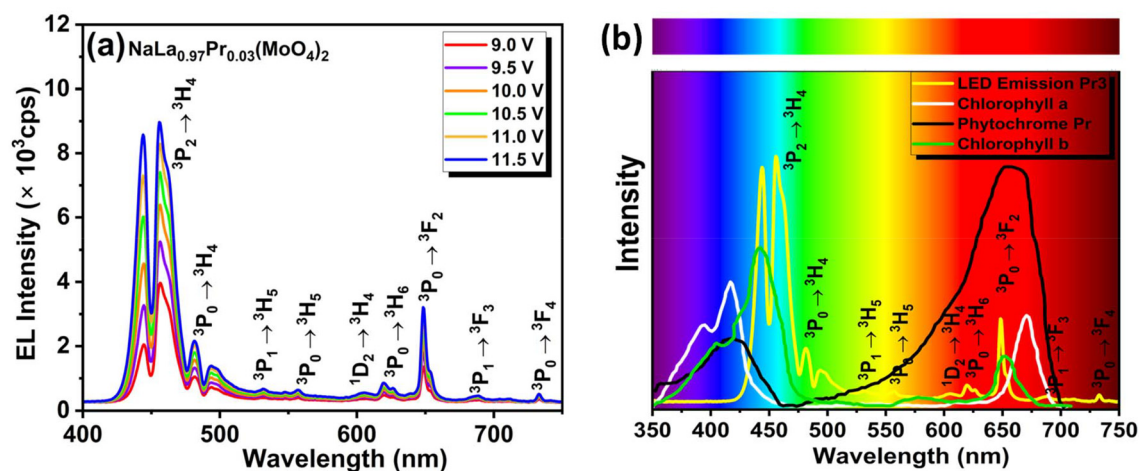

Fig. 8 (a) Emission spectra of the developed pc-LED at various applied voltages, and (b) comparison of the emission spectrum of the developed pc-LED at a fixed applied voltage with the absorption spectra of chlorophylls a and b and phytochrome of the plant.

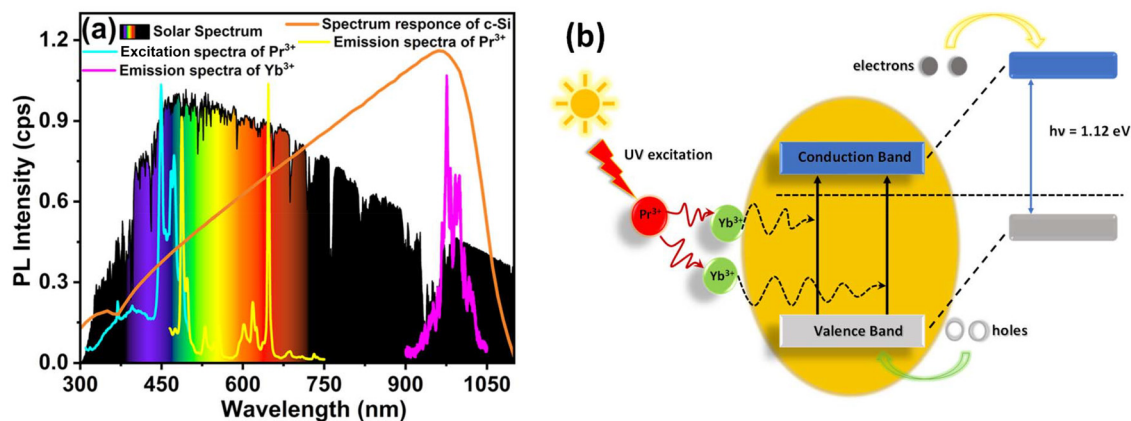

Fig. 9 (a) Comparison among the solar spectrum, the spectral response curve of c-Si solar cells, and the observed emission/spectrum of the $\text{NaLa}_{0.86}\text{Pr}_{0.03}\text{Yb}_{0.11}(\text{MoO}_4)_2$ sample, and (b) representation of the model of how the prepared co-doped sample can improve the photovoltaic performance of the c-Si solar cells.

efficiency of solar cells using the quantum cutting (QC) process. When the sample is stimulated by UV light (240–393 nm), the Pr^{3+} ions are excited to move to the higher energy level $^3\text{P}_2$, from which they undergo radiative transitions. Among the excited Pr^{3+} ions, a few of the Pr^{3+} ions participate in transferring their energy to nearby Yb^{3+} ions through a cooperative energy transfer process, in which a single Pr^{3+} ion excites two Yb^{3+} ions to emit near-infrared light at a wavelength of 980 nm, with an energy of 1.26 eV. This process generates two electrons that can surpass the band gap ($E_g = 1.12$ eV) of single-crystalline Si, potentially doubling the electric current. Thus, the prepared co-doped phosphors can potentially improve c-Si solar cell efficiency.

7. Conclusion

In summary, a series of Pr^{3+} doped and $\text{Pr}^{3+}/\text{Yb}^{3+}$ co-doped $\text{NaLa}(\text{MoO}_4)_2$ phosphor samples were synthesized using the facile solid-state reaction method. The multimodal light emission characteristics of the samples were inspected systematically. In the visible region of the emission spectra recorded under 449 and 980 nm excitation, the emission band lies in the red region and arises from the dominant $^3\text{P}_0 \rightarrow ^3\text{F}_2$ transition of Pr^{3+} . The investigation of optical concentration quenching indicates that the quadrupole–quadrupole (q–q) interaction in $\text{NaLa}_{1-x}\text{Pr}_x(\text{MoO}_4)_2$ phosphors is responsible for the concentration quenching. Additionally, the emission in the visible region is decreased in $\text{Pr}^{3+}/\text{Yb}^{3+}$ co-doped samples, which may be due to energy transfer from Pr^{3+} ions to Yb^{3+} ions, which results in the appearance of the NIR emission band. This energy transfer increases with the amount of Yb^{3+} , which is further supported by the decay kinetics measurements. In this case, the $\text{NaLa}_{0.83}\text{Pr}_{0.03}\text{Yb}_{0.14}(\text{MoO}_4)_2$ composition exhibits a maximum energy transfer and an internal quantum cutting efficiency of approximately 8.58 and 109%, respectively. For the practical applicability of the prepared

sample, it was first tested for optical thermometry using the LIR technique. The observed maximum absolute and relative sensitivities are $2.5 \times 10^{-3} \text{ K}^{-1}$ (at 448 K) and 0.41% K^{-1} (at 448 K), respectively.

Furthermore, the optimized sample was used to develop a pc-LED by coupling it with a blue LED chip, and the developed pc-LED exhibited voltage stability. The comparison of the observed emission/excitation spectrum, the absorption spectrum of chlorophyll/phytochrome, and the spectral response curve of the solar cells suggests that the prepared samples have potential for use in solar cells and plant growth applications. Thus, the prepared phosphor materials with multimodal light-emitting capabilities can be used for multifunctional applications.

Data availability

The datasets generated and analysed during the current study are not publicly available but are available from the corresponding author upon reasonable request.
