The release of anthropogenic toxic pollutants into the atmosphere is a worldwide threat of growing concern. In this regard, it is possible to take advantage of the high versatility of MOFs materials in order to develop new technologies for environmental remediation purposes. Consequently, one of the main scientific challenges to be achieved in the field of MOF research should be to maximize the performance of these solids towards the sensing, capture and catalytic degradation of harmful gases and vapors by means of a rational control of size and reactivity of the pore walls that are directly accessible to guest molecules.

Introduction

The release of anthropogenic toxic pollutants into the atmosphere, which include products of combustion/chemical reactions, fortuitous leaks of harmful industrial gases and vapors as well as the deliberate emission of chemical warfare agents is a worldwide risk of growing concern. Common hazardous compounds such as NO_x, SO_x, CO, H₂S, NH₃, other nitrogen (i.e. hydrogen cyanide) or sulfur-containing compounds (i.e. organo thiols), hydrocarbons, volatile organic compounds (benzene, toluene, methanol, etc.) are of major concern for environmental air pollution. The main source of these gases is anthropogenic. For example, emissions of SO₂, NO₂, CO are mainly due to the burning of fossil fuels that cover the current energy demand. SO_x and NO_x are involved in the formation of photochemical smog and acid rain, which are a major threat to environment and health. H₂S is another poisonous, corrosive and odorous gas. It is naturally occurring in both natural gas and biogas. The purification of these gases prior to their use implies the recovery of this acid contaminant. Moreover, its removal from reformat gas is of great interest for the production of ultrapure hydrogen for fuel cells as H₂S damages fuel cell catalysts. NH₃ is another contaminant widely used in pharmaceutical and chemical industries for various purposes, such as a fertilizer, cleaner, fermentant, antimicrobial agent, refrigerant, precursor of most N-containing compounds, etc.

Volatile organic compounds (VOCs) are also considered a major group of air pollutants. The European Union defines them as chemicals with a vapour pressure greater than 10 Pa at 293 K, which potentially lead to photochemical smog, carcinogenesis, teratogenesis and mutagenesis. VOCs are present in indoor/outdoor air, as a consequence of the emissions from chemical process industries, building materials, cosmetics, pesticides, detergents, etc. A particularly harmful class of VOCs are the Chemical Warfare Agents, although banned since 1997 by

the Chemical Weapons Convention, after the 65th country deposited its instrument of ratification, they are easily available to terrorist groups or unscrupulous governments and consequently are a major worldwide threat.

The properties of some of these harmful gases and vapors as well as the concentration levels that are likely to cause severe health effects are listed in Table 1.

In view of all the above, the effective sensing, capture and eventually the degradation of these harmful chemicals is of great importance both for the protection of the environment and for health issues. Noteworthy, porous materials are at the forefront of minimizing the undesired effects of human activity by means of increasing the efficiency of industrial and remediation processes.¹ In this regard, a new class of crystalline nanoporous materials known as metal-organic frameworks (MOFs) has emerged, as an alternative to zeolites, as consequence of their fascinating potential applications in adsorption, sensing and catalysis.² Consequently, one of the main scientific challenges to be achieved in the field of MOF research should be to maximize the performance of these solids towards the sensing, capture and degradation of harmful gases and vapors by means of a rational control of size and reactivity of the pore walls that are directly accessible to guest molecules. In this review, the features of classical MOFs as well as hybrid materials based on MOFs suitable for the selective sensing, capture and catalytic degradation of toxic gases and vapors will be discussed.

1. Adsorption of toxic gases and harmful volatile organic compounds.

The effective capture of harmful chemicals is of great importance both for the protection of the environment and for those who are at risk for being exposed to such substances. In this context, the use of MOFs with adequate pore size/shape is not enough for an

efficient capture of unsafe gases/vapors and other more specific interactions between the hazardous adsorbates and the host are desirable. For example, the presence of open metal sites (coordinatively unsaturated metal centres) or certain functionalizations on the pore surface may enhance the adsorption selectivity/efficiency of MOFs towards certain toxic compounds *via* coordination bonds, acid-base/electrostatic interactions, π -complex/H-bonding formation, etc.³

Table 1. Physico-chemical parameters of selected gases and vapours as well as Immediately Dangerous to Life or Health (IDLH)^a toxicity levels.

Adsorbate	BP (K) ^b	Comments	IDLH (ppm)

^c ¹²⁹I and ¹³¹I are common radioisotopes of iodine with respective half lives of ~107 years and 8 days. When iodine radioisotopes are present in high levels in the environment from radioactive fallout, they can be absorbed through contaminated food, and will accumulate in the thyroid. As it decays, it may cause damage to the thyroid with concomitant occurrence of radiogenic thyroid cancer in later life.

^d CWA= Chemical Warfare Agent

Adsorptive removal of harmful gases

The possible use of MOFs for the removal of gaseous sulphur compounds has been recently investigated. The presence of open metal sites and H-bonding donor/acceptor groups in these adsorbents have been proposed as suitable features for the efficient removal of S-compounds. In this context, two different classes of MIL systems (MIL stands for Materials of the Institute Lavoisier), the series MIL-53(Al, Cr) and MIL-47(V) [M(X)(bdc)] (bdc= 1,4-terephthalate; X = O for M = V⁴⁺, OH for M = Al³⁺, Cr³⁺) and the series MIL-100(Cr) [Cr₃F(H₂O)₂O(btc)₂] (btc= 1,3,5-tricarboxylate) and MIL-101(Cr) [Cr₃F(H₂O)₂O(bdc)₃] have been explored for the adsorption of H₂S.^{4,5} Small-pore MIL-47(V) and MIL-53(Al, Cr) exhibit reversible adsorption behaviour under H₂S pressure. Moreover, IR measurements and molecular simulations reveal that MIL-47(V) framework remains rigid upon H₂S adsorption up to a pressure of 1.8 MPa, while MIL-53(Cr) shows a flexible behaviour undertaking two structural transitions: the first one from a large pore form (LP) to its narrow pore version (NP) at very low pressure and the second one from the NP to the LP form at higher pressure. These structural transitions explain the two-step shape of the adsorption isotherm of MIL-53(Cr). Moreover, the arrangements of H₂S molecules within the pores of these MIL species have been investigated. At an initial stage, H₂S molecules form hydrogen bonds, either as hydrogen donor (in MIL-47 V) or hydrogen-acceptor (in MIL-53 Cr) with the μ_2 -O and μ_2 -OH groups, respectively, at the pore surface. In the case of MIL-47(V), the interaction of acidic H₂S is also reinforced through other basic centers of the porous matrix, such as the oxygens of the carboxylate groups and the π electrons of the benzene rings. At higher pressures (1.8 MPa), the adsorbates arrange within the channel to form dimers and the strength of the hydrogen bonds become weaker. It should be noted that the strength of H₂S-adsorbent interactions follow the sequence: MIL-53(Cr) NP > MIL-47(V) > MIL-53(Cr) LP. This means that MIL-47(V) would be the most promising candidate for purification of gases containing H₂S as a pollutant as H₂S is more easily desorbed from MIL-47(V) than from MIL-53 (Cr) NP. Preliminary simulations performed on MIL-47(V) suggest a high selectivity of H₂S towards CH₄ in the range of pressures relevant for Pressure Swing Adsorption (PSA). On the other hand, large-pore MIL-100(Cr) and MIL-101(Cr) also show a high uptake of H₂S exhibiting type-I adsorption isotherms (16.7 and 38.4 mmol⁻¹ at 2 MPa, respectively). However, the desorption appears to be irreversible, either because of a partial destruction of the framework or because of the strong interactions between the host and the H₂S molecules. Their lack of regenerability hampers the use of these mesoporous MOFs for the removal of H₂S from a practical application point of view. M-CPO-27 also known as M-MOF-74 [M₂(2,5-dhbc)(H₂O)₂], 2,5-dhbc = 2,5-dihydroxyterephthalate M= Ni²⁺, Zn²⁺) can bind H₂S relatively strongly, allowing the storage of the gas for several months.⁶ It should be noted that in spite of the rather aggressive chemical nature of H₂S, Ni-CPO-27 only shows slight loss in crystallinity after storage and release whereas Zn-CPO-27 was amorphised by prolonged storage over a year. The study of the interaction of Ni-CPO-27 with H₂S using powder X-ray diffraction and X-ray pair distribution function analysis reveals that H₂S is clearly coordinated to coordinatively unsaturated metal sites. The release of H₂S from these MOFs has also been studied for biological applications taking into account the signal properties of this molecule. It has been demonstrated that a proportion of the stored hydrogen sulfide can be released by exposing these materials to moisture as the water molecules

replace the adsorbate at the metal site. Thus, the contact of the H₂S loaded materials with a moist atmosphere gives rise to the release of around one third of the chemisorbed H₂S from Ni-CPO-27 (1.8 mmol g⁻¹) and Zn-CPO-27 (0.5 mmol g⁻¹) after 1 h. The lower adsorptive and delivery potential of Zn-CPO-27 has been attributed to difficulties in the fully activation of the sample⁷ and to the softer nature of Zn metal centres which gives rise to stronger and irreversible sulphur binding.

FMOF-2 ([Zn₂OH(2,2'-bis(4-carboxyphenyl)hexafluoropropane)_{1.5}]) is a breathing MOF, which has been tested for potential acid gas removal applications.⁸ Indeed, it remains structurally stable upon adsorption of SO₂ and H₂S reaching weight capacities of 14% and 8.3%, respectively, at 1 bar. Moreover, both gas adsorption/desorption isotherms show hysteresis confirming the breathing motion of FMOF-2 after gas adsorption-desorption.

Six iso-reticular MOFs, namely MOF-5 ([Zn₄O(bdc)₃], bdc= 1,4-terephthalate), IRMOF-3 ([Zn₄O(abdc)₃], abdc= 2-amino-1,4-benzene dicarboxylate), MOF-177 ([Zn₄O(bt₃)₃], bt₃= 1,3,5-benzenetribenzoate), IRMOF-62 ([Zn₄O(bdb)₃], bdb= butadienedibenzoate), Zn-CPO-27, and [Cu₃(btc)₂] (btc= 1,3,5-tricarboxylate) proves to be very effective in removing gas and vapor contaminants, such as sulfur dioxide, ammonia, chlorine tetrahydrothiophene, benzene, dichloromethane and ethylene oxide (Figure 1).⁹ The behaviour of each MOF has been compared to that of BPL carbon. In this section, only the behaviour related to the adsorption of toxic gases will be discussed (for the discussion of the capture of volatile organic compounds section, please see below). Noteworthy, it has been demonstrated that the presence of coordinatively unsaturated metal sites (i.e. Zn-CPO-27 and [Cu₃(btc)₂]) and amino functionality in IRMOF-3 prove to be effective in adsorbing ammonia and sulfur dioxide highly outperforming the behaviour of BPL carbon by a factor of at list 59 in the case of ammonia or performing equally well, in the case of sulfur dioxide (Figure 1).

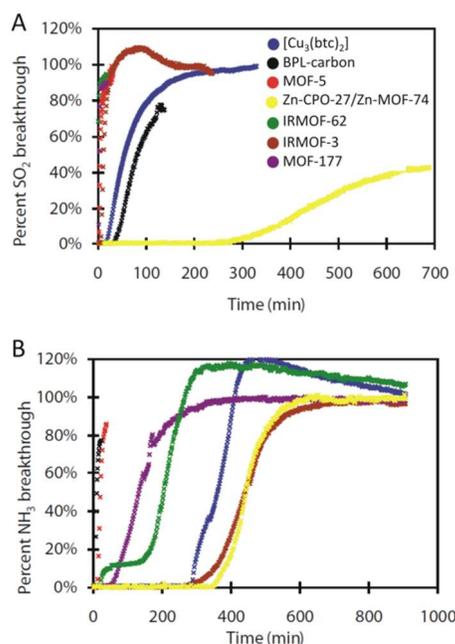

Figure 1. Kinetic breakthrough curves of SO₂ (A) and NH₃ (B) contaminants over various MOFs. Reproduced from Ref. 9.

The improvement of ammonia adsorption in Zn-CPO-27 and [Cu₃(btc)₂] is explained because of the presence of Zn²⁺ and Cu²⁺ open metal sites, which behave as Lewis acids to coordinate NH₃

Lewis bases, which is not possible in the activated carbon. Deeper studies on the interaction of NH₃ with [Cu₃(btc)₂] have postulated that [Cu₃(btc)₂] reacts with ammonia to form a presumed diammine-copper(II) complex, under dry conditions.¹⁰ Under humid conditions, initially, water enhances NH₃ adsorption on [Cu₃(btc)₂] via dissolution of NH₃ in the water film¹¹ but in a latter step Cu(OH)₂ and (NH₄)₃BTC species are formed thereby inducing an irreversible loss of structure and porosity reflected in a significant decrease in available sites and capacity over multiple dynamic adsorption cycles of breakthrough curves.¹⁰ In the case of IRMOF-3, amine groups constitute reactive electron-rich groups available for hydrogen bonding with NH₃ molecules, improving the adsorption behavior in comparison with MOF-5 and BPL carbon. MOF-5, MOF-177 and IRMOF-62 lack any reactive functionality and show worse dynamic adsorption capacity of ammonia than the previously mentioned functionalized MOFs (Figure 1). In spite of this, these MOFs show a better performance than BPL carbon towards this gas. However, they show little or no capacity for SO₂.

Regarding chlorine adsorption, open metal sites in [Cu₃(btc)₂] result to be ineffective in this case as Cl₂ does not typically act as a ligand. However, halogen molecules can give rise to oxidative addition reactions to Pt redox active metal centers as demonstrated in the spin cross-over (SCO) {Fe(py₂)[PtX_{2n}(CN)₄]} (n= 0 to 1) materials as reported by Kitagawa, Real and col.¹² Moreover, the halogen addition reaction gives rise to a precise control of the materials SCO transition temperature of the resulting {Fe(py₂)[PtX_{2n}(CN)₄]} materials. On the other hand, IRMOF-3 and IRMOF-62 have demonstrated considerable capacity for chlorine adsorption. Indeed, IRMOF-3 outperforms BPL carbon by a factor of 1.76 and the adsorption capacity of IRMOF-62 is in the same order of magnitude than the activated carbon. These results outline that despite the high capacities for thermodynamic gas adsorption, MOFs lacking reactive adsorption sites are ineffective in kinetic gas adsorption. In contrast, it should be noted that, in the case of MOFs with open metal sites (OMS) the presence of humidity may hamper the adsorption of the adsorbate of interest as a consequence of the irreversible coordination of water molecules to the open metal sites (see above). This feature is a main drawback for the application of MOFs containing OMS in competition with classical hydrophobic adsorbents like activated carbons (see also section of capture of volatile organic compounds).

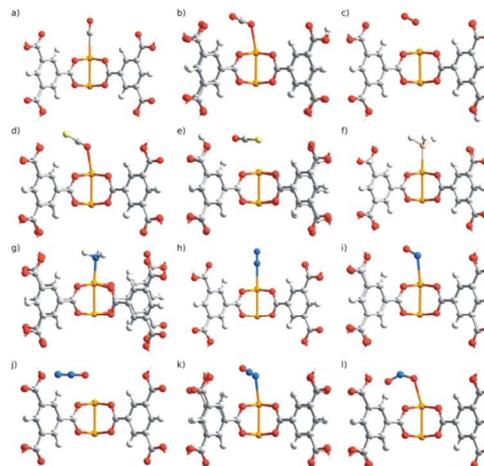

Figure 2. Optimized structures of the interaction of small gases (including highly toxic ones) with the open metal sites of [Cu₃(btc)₂]: (a) CO₂, (b) CO, (c) O₂, (d) OCS(O), (e) OCS(S), (f) PH₃, (g) NH₃, (h) N₂, (i) NO, (j) N₂O(O), (k) N₂O(N), (l) NO₂. Reproduced from Ref. 13.

Mavandronakis and col.¹³ have recently carried out a computational study of the interaction of a series of toxic gases CO, OCS, SO₂, NO, NO₂, N₂O, NH₃, PH₃ with the open metal sites of [Cu₃(btc)₂] (Figure 2). The calculated adsorption energies of the toxic gases and common adsorbate molecules follow the trend NH₃ > H₂O > PH₃ > H₂S > SO₂ > CO ~ OCS ~ CO₂ ~ N_yO_x > N₂ > O₂. Only ammonia is adsorbed more strongly on the metal sites than water, exceeding the water-framework interaction by 30 kJ mol⁻¹. Noteworthy, although hydrogen sulfide and phosphane are less strongly bound by 10 kJ mol⁻¹ compared to water, the interactions are significantly stronger than physisorption falling in the regime of chemisorption. These findings are in agreement with the experimental observations that ammonia, water and hydrogen sulfide decompose the framework.¹⁰

On the other hand, it has been demonstrated that it is possible to improve the performance of adsorption capacities of toxic gases (NH₃, H₂S and NO₂) using composites of MOFs (MOF-5, [Cu₃(btc)₂] and MIL-100(Fe)) with graphitic compounds (graphite or graphite oxide, GO) (Figure 3).¹⁴ In the case of MOF@GO composites, the results are indicative of the strong coordination of the GO oxygen groups to the MOFs' metallic centres, which in the case of MOF-5@GO and [Cu₃(btc)₂]@GO gives rise to the formation of a new pore space in the interface between the carbon layers and the MOF units. This new structural feature enhances the physical adsorption capacity of these composites towards toxic gases compared to the parent MOFs. For example, an increase of 12% (for NH₃), 50% (for H₂S) and 4% (for NO₂) is observed in the case of [Cu₃(btc)₂]@GO in comparison with the original [Cu₃(btc)₂]. However, in addition to physisorption, reactive adsorption mechanisms of NH₃, H₂S and NO₂ also takes place for these composite materials as well as for their parent MOFs (Figure 3). In the case of the [Cu₃(btc)₂] based composites, the coordination of these toxic gases to the unsaturated Cu centers takes place and the formation of diammine-copper(II) complexes, Cu₂ or Cu(NO₃)₂ is proposed, depending on the adsorbate. These processes are accompanied by the decomposition of the framework with a significant loss of porosity. However, for the MIL-100(Fe) and MOF-5 composites, which do not possess open metal sites, besides physisorption, acid-base reaction and hydrogen bonding takes place, respectively, with the frameworks retaining their original porosity. The impact of the presence of water on the adsorption of NH₃ and NO₂ was also studied for these composites. As observed for the parent MOFs, water enhances NH₃ adsorption in Cu-based composites and MOF-5@GO. However, in the latter case, this fact is counterbalanced by the collapse of the MOF structure caused by the formation of hydrogen bonds between the water molecules and the zinc oxide tetrahedra. However, competitive adsorption of water and NH₃ is observed on MIL-100(Fe)@GO. The same competitive behavior is observed for water and NO₂ in [Cu₃(btc)₂]@GO.

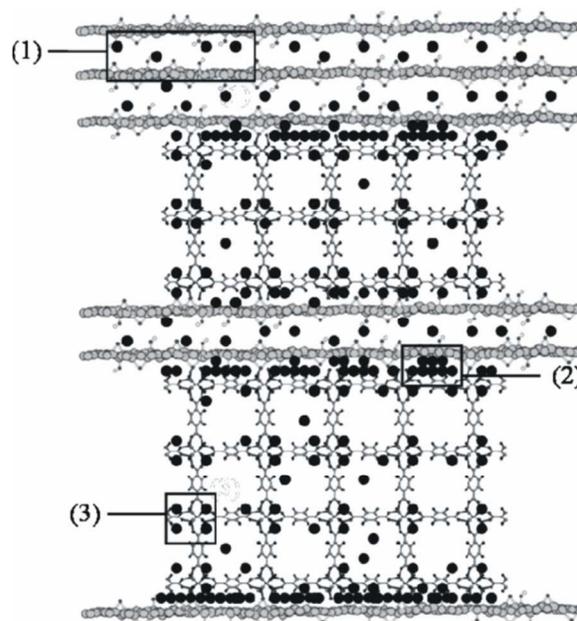

Figure 3. Scheme of the mechanisms of ammonia (black circle) adsorption in the MOF-5@GO composites including: 1) intercalation between the graphene layers, 2) adsorption at the interface between the graphene layers and the MOF-5 segments, 3) hydrogen bonding with the oxygen atoms of the zinc oxide in MOF-5. Reproduced from Ref.14.

M-CPO-27 (M-MOF-74) (M= Zn²⁺, Co²⁺, Ni²⁺, Mg²⁺) series have been tested for removing NH₃, CNCl and SO₂ from air in dry and humid conditions and dynamic breakthrough capacities were compared to 13X zeolite and BPL activated carbon.¹⁵ The results reveal that in presence of a humid atmosphere at 25°C CPO-27 analogues adsorb an appreciable amount of water accounting at least for 0.1 g of water per gram of adsorbent. In dry conditions, the dynamic loading of NH₃ on all the CPO-27 analogues are generally near to or exceed the maximum loadings of traditional materials, such as 13X zeolite, which adsorbs 2.86 mol/Kg under the same conditions, and BPL activated carbon, which has no capacity for dry ammonia. The best performing material, Mg-CPO-27 loads three times the capacity of 13X zeolite and the worst performing analog, Ni-CPO-27 loads 80% of the capacity of 13 X. It should be noted that when ammonia is loaded in dry conditions, a significant portion of the adsorbate is retained when the MOF materials are exposed to dry air during desorption. However, the 13 X zeolite did not retain any of the adsorbed ammonia under the same breakthrough conditions. As expected, the adsorptive capacity of these materials is reduced in a humid gas stream, but they maintain significant adsorption capacity for NH₃. Indeed, Mg-CPO-27, the worst performing material under humid conditions, shows 6 times the capacity of BPL activated carbon. On the other hand, CPO-27 structures adsorb dry cyanogen chloride in the same order of magnitude than classical materials, reaching the 70% of retention by Co-CPO-27 even after desorption. However, under humid conditions, none of these MOFs adsorb an appreciable quantity of CNCl resembling the behaviour of 13X zeolite in both dry and humid conditions. Regarding SO₂ removal, only Mg-CPO-27 loads this acid gas. In general, Co and Mg analogues show better adsorption of the four gases in both dry and humid conditions. Furthermore, it is clear that the presence of water diminished the adsorption capacity of these MOFs towards the studied gases as a consequence of the competition of the water molecules with the toxic gases for the adsorption at the metal centres leading to diminished breakthrough times and total capacities.

The presence of open metal sites is also highly beneficial for the capture of NO. A series of MOFs have been assayed for the capture and release of NO for biological applications. This is the case of $[\text{Cu}_3(\text{btc})_2]$ and CPO-27 structures,¹⁶ which adsorb up to 3 and 8 mmol of NO per gram of MOF, respectively, considerably more than other similar nanoporous solids, such as zeolites. However, the adsorption of NO on $[\text{Cu}_3(\text{btc})_2]$ can be considered nearly irreversible as only 1 μmol of NO per gram of material is released upon exposure to moisture while CPO-27 materials completely desorb all the stored NO under similar conditions. Other biodegradable materials, such as the Fe-based MIL-88A $[\text{Fe}_3\text{O}(\text{CH}_3\text{CO}_2)(\text{fumarate})_3]$, MIL-88B $[\text{Fe}_3\text{OX}(1,4\text{-bdc})_3]$, 1,4-bdc = 1,4-benzenedicarboxylate, X = F, Cl, OH), MIL-88B-NO₂ $[\text{Fe}_3\text{OX}(2\text{-NO}_2\text{-bdc})_3]$, 2-NO₂-bdc = 2-nitroterephthalate, X = F, Cl, OH) and MIL-88B-2OH $[\text{Fe}_3\text{OX}(2,5\text{-dhbdc})_3]$, 2,5-dhbdc = 2,5-dihydroxyterephthalate, X = F, Cl, OH) show loading capacities lying within the 1-2.5 mmol g⁻¹ range.¹⁷ In this case, the low accessibility to the pores is due to the absence of a breathing mechanism of the structure with the pores remaining closed and preventing the easy diffusion of NO to bind the accessible iron metal sites. The released amount of NO from these structures in the presence of a wet gas is even lower, few tenths of mmol g⁻¹, which is attributed to the desorption of the physisorbed NO prior to the desorption tests, but it is still enough to ensure a significant release at the biological level over prolonged periods of time. A similar behaviour is observed in BioMIL-3 $[\text{Ca}_2(\text{azbz-TC})(\text{H}_2\text{O})(\text{DMF})]$, azbz-TC = 3,3',5,5'-azobenzenetetracarboxylate), which adsorbs 0.8 mmol g⁻¹ of NO at 1 atm, a quantity which is much lower than the theoretical unsaturated Ca²⁺ metal sites.¹⁸ The absence of a plateau in the NO adsorption branch suggests a possible higher adsorption at higher pressures. However, residual coordinated DMF, steric hindrance and diffusion constraints make coordination on the unsaturated metal sites more difficult. These factors also contribute to the slow and low delivery of NO from this material (5 μmol g⁻¹ overnight). Other methodologies have been developed to store NO in MOFs. This is the case of the postsynthetic functionalization of the open metal sites in $[\text{Cu}_3(\text{btc})_2]$ with the bifunctional 4-(methylamino)-pyridine to produce secondary amines, which are able to react with NO to yield the diazenium-1,2-diolate (NONOate) derivative.¹⁹ A similar strategy consists in the functionalization of the organic linkers with amines available to interact with NO yielding NONOate compounds. CO adsorption has also been studied in MOFs with open-metal sites. It has been demonstrated that $[\text{Cu}_3(\text{btc})_2]$ preferentially adsorbs CO towards H₂ and N₂ at 298 K. This can be explained because of the electrostatic interactions between the partial charge of the Cu²⁺ sites and the CO dipole.²⁰ On the other hand, Ni-CPO-27 strongly coordinates CO at room temperature.²¹ Most of the Ni²⁺ sites are involved in the interaction (about 80%), forming 1:1 linear adducts whose interaction enthalpy is slightly above 50 kJ/mol. However, the adsorption is completely reversible at room temperature after prolonged evacuation. As well as for NO, the biocompatible series MIL-88B and MIL-88B-NH₂ $[\text{Fe}_3\text{OX}(2\text{-NO}_2\text{-bdc})_3]$, 2-NH₂-bdc = 2-aminoterephthalate, X = F, Cl, OH) have been studied for the capture and release of CO for therapeutic applications showing that CO binding occurs to unsaturated Fe^{II}/Fe^{III} coordination sites generated by the activation procedure.²²

Finally, noteworthy, the cages of ZIF-8 $[\text{Zn}(2\text{-MeIm})_2]$ (2-MeImH = 2-methylimidazole) bind iodine 4 times more strongly than activated carbon, the traditional high capacity iodine adsorbent.²³ The latter result is of relevance in order to capture radioactive iodine isotopes produced in nuclear processes.

Capture of volatile organic compounds

The characteristics of adsorbent materials for the capture of volatile organic compounds can be significantly different from the ones of gases. In this regard, the diffusion kinetics of vapor molecules might be very slow in narrow pore materials and, on the other hand, the presence of open metal sites can be sometimes disadvantageous for air/gas purification purposes in the presence of moisture.

As mentioned in the previous section, six iso-reticular MOFs, namely MOF-5, IRMOF-3, MOF-177, IRMOF-62, Zn-CPO-27, and $[\text{Cu}_3(\text{btc})_2]$ are shown as selective adsorbents of tetrahydrothiophene, benzene, dichloromethane and ethylene oxide.⁹ In the same line as the results of breakthrough experiments on gaseous contaminants, MOF-5 and MOF-177 do not perform well as kinetic adsorption media. IRMOF-62 is largely outclassed by BPL carbon except in the case of ethylene oxide adsorption, for which both materials are equally ineffective. IRMOF-3 is a poor adsorbent for the vapors chosen, because none of them behave as good Lewis acid. MOFs containing open metal sites are found to be the most effective in removing vapors from the gas stream. Zn-CPO-27 and $[\text{Cu}_3(\text{btc})_2]$ outperform BPL carbon by an order of magnitude in ethylene oxide adsorption. However, Zn-CPO-27 is not effective against the entire range of vapors, whereas $[\text{Cu}_3(\text{btc})_2]$ is effective. $[\text{Cu}_3(\text{btc})_2]$ outperforms BPL carbon in tetrahydrothiophene adsorption by a factor of 3 although there is essentially no difference in performance between the activated carbon and $[\text{Cu}_3(\text{btc})_2]$ in dichloromethane and benzene adsorption. It should be noted, however, that the presence of moisture can significantly diminish the performance of $[\text{Cu}_3(\text{btc})_2]$ as a consequence of the blockage of the open metal sites by water molecules (see below).

MIL-101 $[(\text{Cr}_3\text{F}(\text{H}_2\text{O})_2\text{O}(\text{bdc}))]$ has proved to be effective in the adsorption of a wide range of VOCs with various functional groups and polarities, i.e. acetone, benzene, toluene, ethylbenzene, xilenes, n-hexane, methanol, butanone, dichloromethane and n-butylamine. Yan et al. demonstrated that MIL-101 has higher affinity for VOCs containing heteroatoms or aromatic rings, especially the amines.²⁴ In addition, MIL-101 shows higher adsorption capacities for acetone, toluene, ethylbenzene and xilenes than other commonly used adsorbents, such as zeolites, resins, activated carbon together with their derivatives.²⁵ For example, MIL-101 adsorbs 16.7 mmol g⁻¹ of benzene at 288 K and 56 mbar, which is almost twice the values for zeolites (silicalite-1 and SBA-15) and 3-5 times larger than that of activated carbons (Ajax and ACF). In this case, the profile of the thermally programmed desorption curve shows two separated peaks corresponding to two major sites for benzene adsorption. The strong interactions would occur between the Cr³⁺ metal centers and the adsorbate molecules and the slightly weaker interactions take place between the space of the pores and the adsorbate. Consecutive cycles of adsorption-desorption show that a fast desorption kinetics, high desorption efficiency and stable

adsorption capacity over five cycles are available. The efficiency of benzene desorption can reach 97% exhibiting a high reversibility of benzene adsorption-desorption.²⁶

On the other hand, the modulation of the porous network of the anionic MOF $\text{NH}_4[\text{Cu}_3(\text{OH})(\text{capz})]$ (capz = 4-carboxypyrazolato) by means of ion-exchange processes of the extra-framework NH_4^+ cations lead to profound changes in the textural properties of its porous surface and in the adsorption selectivity towards benzene/cyclohexane mixtures.²⁷ Indeed, exposure of the $\text{A}[\text{Cu}_3(\text{OH})(\text{capz})]$ materials ($\text{A} = \text{NH}_4^+, \text{Li}^+, \text{Na}^+, \text{K}^+, \text{Me}_3\text{NH}^+, \text{Et}_3\text{NH}^+$) to benzene/cyclohexane 1:1 vapour mixtures shows significant enrichment of the adsorbate phase in the benzene component. This behaviour is explained taking into account that although the increasing bulk of the exchanged cations still permits access of molecules to the porous structure, a concomitant increase in size-exclusion selectivity takes place.

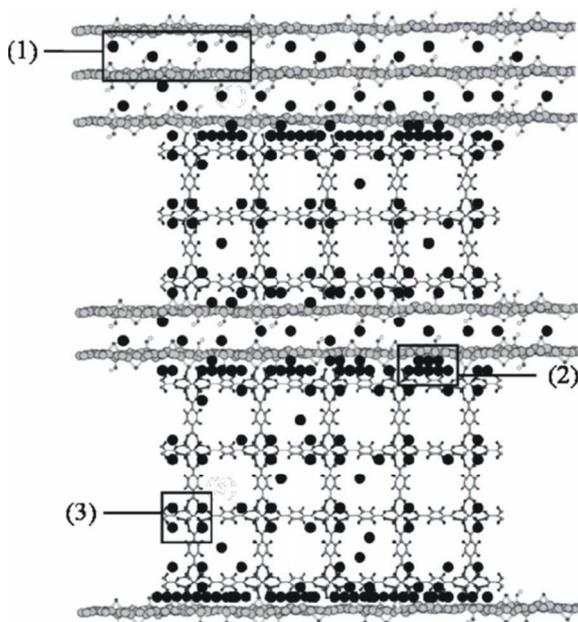

Figure 4. A) Adsorption (solid symbols) and desorption (open symbols) isotherms *o*-xylene (*oX*) and *p*-xylene (*pX*) measured at 110 °C on MIL-53 (Al). B) *p*-xylene at 110 °C in the pores of MIL-53(Al); C) X-ray diffractograms of MIL-53 (Al) with different *oX* loadings. Adapted from Ref. 28 and 29.

The flexible MIL-53(Al) framework adsorbs xylene isomers and ethylbenzene.²⁸ Adsorption isotherms at 110 °C show two well-defined steps and hysteresis, corresponding to the opening or breathing of the framework, as induced by the presence of adsorbing molecules. At low pressures, adsorption leads to framework contraction. In the limited space of the closed form of the MIL-53(Al) framework, only a single-file arrangement of molecules can be accommodated, adsorbed along the length of the pores. At much higher pressures, the pores are reopened. In the open form, there is space enough for the xylene isomers to be adsorbed in pairs along the length of the pores, leading to a doubling of the amount adsorbed (Figure 4). Due to differences in the efficiencies with which the different isomers can be packed inside the pores, the adsorption capacity is highly affected. This phenomenon is known as commensurate adsorption and occurs when molecular size and shape of the adsorbate lead to an orientation and adsorbed amount that is compatible and self-

consistent with the crystal symmetry and pore structure of the adsorbent.²⁹

A modified MOF, CuCl_2 -loaded MIL-47(V) shows remarkable adsorption capacity of benzothiophene.³⁰ MIL-47(V) shows an unexpected reduction ability to form Cu^{I} ions from loaded Cu^{II} ions probably because of the presence of V^{III} in the MOF. The obtained Cu^{I} ions show a beneficial effect on the adsorption of benzothiophene probably through π -complexation. It has been demonstrated that the adsorption capacity increases with increasing CuCl_2 loading up to a specific content ($\text{Cu}/\text{V} = 0.05$ mol/mol) and decreases with further increase in the CuCl_2 content, showing that there is an optimum CuCl_2 concentration. This is due to the contribution of both the porosity/acidity of MIL-47(V) and a Cu^{I} site derived from CuCl_2 .

On the other hand, the development of sensor materials is also a very active field of research. In this regard, $[\text{Zn}_2(\text{bdc})_2(\text{dpNDI})]_n$ (H_2bdc = benzene-1,4, dicarboxylic acid; dpNDI = *N,N'*-di(4-pyridyl)-1,4,5,8-naphthalenediimide) gives rise to strong stacking interactions with VOCs molecules with a concomitant strong change in the emission color sensitive to the ionization potential of each molecule (Figure 5).³¹

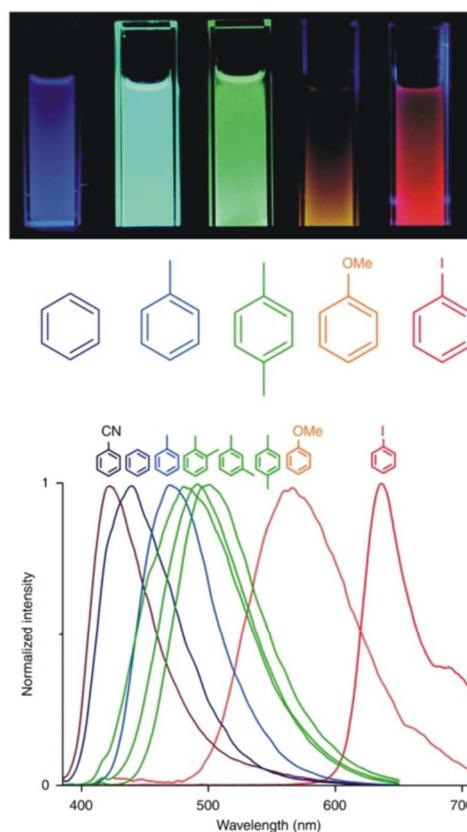

Figure 5. (Top) Luminescence of the powdered $[\text{Zn}_2(\text{bdc})_2(\text{dpNDI})]_n$ material suspended in the liquid exposed to different VOC molecules after excitation at 365 nm using a commercial ultraviolet lamp. (Bottom) Collected normalized spectra of the $[\text{Zn}_2(\text{bdc})_2(\text{dpNDI})]_n@$ VOC compounds excited at 370 nm. Adapted from Ref. 31.

In this context, the $\{\text{Fe}(\text{pyz})[\text{Pt}(\text{CN})_4]\}$ system can incorporate a variety of vapor guest molecules, namely benzene, CS_2 which modify the pore size and optical and magnetic properties of the materials and might be useful for sensing purposes.³²

As mentioned before, MOF with coordinatively unsaturated metal sites, such as $[\text{Cu}_3(\text{btc})_2]$, are ineffective for the capture of VOCs in the presence of ambient moisture. With the aim of overcoming this problem, we have reported a novel flexible MOF, namely $[\text{Ni}(\text{bpb})]^{33}$ ($\text{H}_2\text{bpb} = 1,4$ -(4-bispyrazolyl)benzene), which is efficient for the adsorption of benzene and cyclohexane. In addition, this material captures tetrahydrothiophene (up to 0.34 g of tetrahydrothiophene per gram of material) from CH_4/CO_2 mixtures in dynamic conditions even in the presence of humidity (60%), thus overcoming the problems raised by prototypic MOF-5 and $[\text{Cu}_3(\text{btc})_2]$ MOFs materials in practical applications.

As previously mentioned in the introduction, a special family of VOCs is the warfare agents. The search for efficient adsorbents of these harmful molecules in practical applications is of great interest. It should be noted that in real conditions, humidity will always be present and water molecules will constitute an important competitor in the adsorption process of these toxic molecules. In this context, we have demonstrated that the use of highly hydrophobic MOFs for the capture of warfare agents is an adequate strategy for the selective adsorption of these molecules even in extreme humid conditions. The basis of this strategy remains in the high affinity of the porous matrix towards the non polar warfare agents in contrast with its low affinity for polar water molecules. For example, the MOF-5 analog $[\text{Zn}_4\text{O}(\text{dmcapz})_3]$ ($\text{dmcapz} = 3,5$ -dimethyl-4-carboxypyrazolato) is suitable in the capture of diisopropylfluorophosphate (DIFP, model of sarin nerve gas) and diethylsulfide (DES, model of vesicant mustard gas).³⁴ This compound shows remarkable chemical, mechanical and thermal stability granted by the nature of the M-N,O(carboxypyrazolato) coordinative bonds. In addition, it is highly hydrophobic, which results in large VOC/ H_2O partition coefficients. Under ambient conditions, $[\text{Zn}_4\text{O}(\text{dmcapz})_3]$ clearly outperforms the behavior of $[\text{Cu}_3(\text{btc})_2]$ that, when hydrated, does not retain either DES or DIFP.

However, the performance of $[\text{Zn}_4\text{O}(\text{dmcapz})_3]$ approaches that of molecular sieve activated carbon Carboxen suggesting a similar adsorption processes dominated by the small size and apolar nature of the pores in both materials. Then, it has been clearly demonstrated the necessity of stabilizing MOFs against ambient humidity to turn these porous materials more suitable for specialized and industrial applications. In this context, pre or postsynthetic modification approaches have been explored in order to enhance the hydrophobicity of MOFs. One of the most successful approaches is the introduction of alkane or fluoroalkane residues in the organic linkers. In this context, Omary and col.³⁶ reported the synthesis of totally fluorinated MOFs, coined as FMOF-1 and FMOF-2, from the combination of Ag^+ with 3,5-bis(trifluoromethyl)-1,2,4-triazolate. The hydrophobic character of FMOF-1 is the main responsible for the observed efficient selective adsorption ability of aliphatic and aromatic oil components (benzene, toluene, p-xylene, cyclohexane and n-hexane), while preventing the entrance of water molecules in their pores. Likewise, the isorecticular series $[\text{Ni}_8(\text{OH})_4(\text{H}_2\text{O})_2(\text{L})_6]$ ($\text{H}_2\text{L1} = 1\text{H}$ -pyrazole-4-carboxylic acid; $\text{H}_2\text{L2} = 4$ -(1H-pyrazol-4-yl)benzoic acid, $\text{H}_2\text{L3} = 4,4'$ -benzene-1,4-diylbis(1H-pyrazole), $\text{H}_2\text{L4} = 4,4'$ -buta-1,3-diyne-1,4-diylbis(1H-pyrazole), $\text{H}_2\text{L5} = 4,4'$ -(benzene-1,4-diylthiethyne-2,1-diyl)bis(1H-pyrazole), $\text{H}_2\text{L5-R}$ (R = methyl, trifluoromethyl))

proves that the use of metal-azolate coordinative bonds gives rise to materials with enhanced stability towards hydrolysis.³⁵ Moreover, the length and functionalization of the linkers impact on the pore size as well as on the surface polarity (Figure 6). The most significant results regarding the capture of warfare agents were achieved under strongly competitive moist atmosphere (up to 80% RH) and have been compared with the hydrophobic active carbon Blücher-101408, which is the active phase of Saratoga filtering systems. Indeed, ^1H NMR analysis of the adsorbate phase after the adsorption process of DES in 80% RH moist streams reveals that only $[\text{Ni}_8(\text{OH})_4(\text{H}_2\text{O})_2(\text{L5-CF}_3)_6]$ and Blücher-101408 efficiently capture DES under these conditions, witnessing that the adsorption of DES in this MOF is not affected by the presence of humidity. This isorecticular series might be considered as the first step towards the rational design of MOFs for the capture of harmful VOCs under highly demanding environmental conditions.

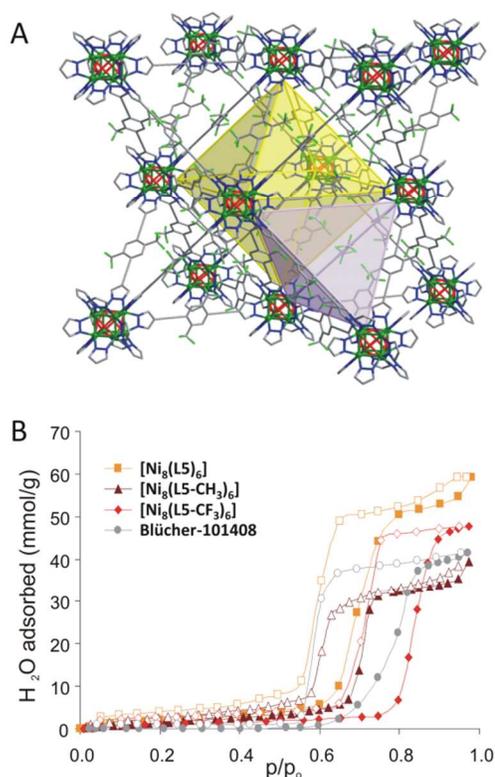

Figure 6. (A) Crystal structure of highly hydrophobic $[\text{Ni}_8(\text{OH})_4(\text{H}_2\text{O})_2(\text{L5})_6]$ ($\text{H}_2\text{L5} = 4,4'$ -(benzene-2,5-trifluoromethyl-1,4-diylthiethyne-2,1-diyl)bis(1H-pyrazole)). (B) Impact of benzene functionalization with hydrophobic residues on the water adsorption isotherms at 298 K. Reproduced from Ref. 35.

2. Catalytic degradation of harmful gases and volatile organic compounds

The catalytic degradation of harmful gases and vapors into non-toxic substances should be regarded as the ideal case for gas/air purification processes since it overcomes the problems related to adsorbent saturation or its behavior as secondary emitters.

Noteworthy, the development of tailored heterogeneous catalysts is one of the areas of major current interest in research of MOFs, since these materials are amenable for finely tuning their catalytic properties.³⁷ However, there are still few reports in which the catalytic activity of MOF materials has been applied for the removal of harmful substances from gas/air streams.

Catalytic decomposition of trace gases and vapors

CO oxidation to CO₂ can be achieved by gold nanoparticles (NPs) deposited on zeolite-type metal–organic framework ZIF-8 [Zn(2-MeIm)₂] by a simple solid grinding method. The catalytic activity of the resulting Au@ZIF-8 material for CO oxidation is improved along with increasing Au loadings with the highest catalytic activity being obtained for 5.0 wt % Au@ZIF-8, which presents half conversion of CO at ~170 °C. Gold NPs are close to being monodispersed and do not give rise to aggregation during catalytic reactions over multiple cycles.³⁸ This reaction might be useful for hydrogen purification purposes for fuel cell applications. 3D [Yb(OH)(2,6-AQDS)(H₂O)] (AQDS: anthraquinone-2,6-disulfonate)³⁹ polymeric framework act as good catalysts in hydrodesulfurization reactions of thiophene under mild conditions (7 bar of H₂ and 70 °C) as a consequence of low coordination for the Yb atom and/or lability of coordinated ligands. The enhancement of SO₂ trapping has also been achieved by impregnating [Cu₃(btc)₂] with Ba²⁺ salts (BaCl₂, Ba(NO₃)₂, Ba(CH₃COO)₂). Indeed, the BaCl₂/[Cu₃(btc)₂] composite is able to capture SO₂ in an oxidative atmosphere in the form of sulphates outperforming the reference material BaCO₃/Al₂O₃/Pt⁴⁰, which is the first generation storage reduction catalyst known to store SO₂. The formation of small microcrystals of Ba(CH₃COO)₂ and Ba(NO₃)₂ in the pores of [Cu₃(btc)₂] is observed, while the MOF structure is maintained. However, after impregnation with BaCl₂, the parent MOF loses crystallinity and the BaCl₂ appears highly dispersed in the material. The SO₂ uptake of all Ba/[Cu₃(btc)₂] samples exceeded the stoichiometric uptake capacity based on the Ba²⁺ concentration, which is indicative that a fraction of SO_x is bound to Cu cations. At low temperatures, when the MOF still maintains its structural integrity, the SO_x storage is due to the concomitant adsorption of SO₂ on Cu²⁺ and the formation of Ba-sulfates. However, at high temperatures [Cu₃(btc)₂] decomposes leading to isolated Cu species that react with SO_x to form Cu-sulfates. This process is of interest in the elimination of traces of sulphur compounds in fuels prior to NO_x storage-reduction (NO_x-SR) concept. However, irreversible SO_x adsorption is the main drawback of the above described materials. [M₃OF(bdc)₂] MIL-101 (M= Cr, Fe) have also been recently found to be active for solvent-free selective oxidation of cyclohexane with molecular oxygen and/or tert-butyl hydroperoxide under mild conditions.⁴¹ Similarly, the zeomimetic NH₄[Cu₃(OH)(capz)] system is also able to catalyse the oxidation

of cyclohexane and cyclohexene with tert-butyl hydroperoxide under mild conditions.²⁷

Polyoxometallates (POM) are regarded as active acid and oxidation catalysts in the homogeneous phase. Noteworthy, POMs can be incorporated in the structure of MOFs either as building blocks or encapsulated in the pore structure of MOFs thereby enhancing their stability and giving rise to advanced heterogeneous catalysts.⁴² In this regard, Hill and coworkers have shown that redox active POM [CuPW₁₁O₃₉]⁵⁻ encapsulated in [Cu₃(btc)₂] might be useful for the catalytic air based oxidative degradation of SH₂ and mercaptane molecules (Figure 7).⁴³ Indeed, the [Cu₃(btc)₂]@[CuPW₁₁O₃₉] hybrid material catalyzes the rapid chemo- and shape-selective oxidation of thiols into disulfides and, more significantly, the rapid and sustained removal of toxic H₂S via H₂S + 1/2 O₂ → 1/8 S₈ + H₂O (4000 turnovers in <20 h) while the POM or the MOF alone is catalytically slow or inactive. Similarly, the redox active POM [CoPW₁₁O₃₉]⁵⁻ incorporated inside [Cr₃OF(bdc)₂] MIL-101(Cr) voids behaves as an active heterogeneous catalyst for the molecular oxygen allylic oxidation of α-pinene, which can be used as flavoring substances and drug precursors.⁴⁴

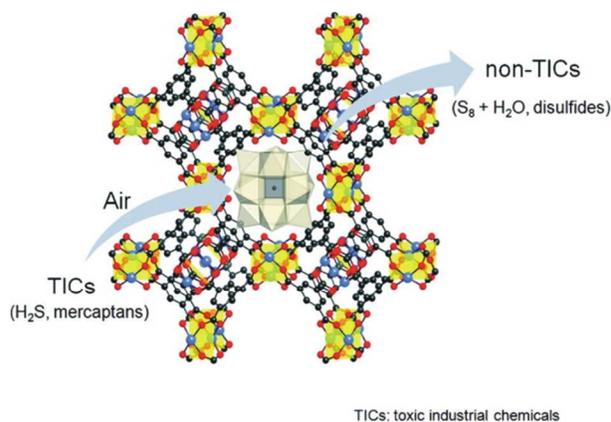

Figure 7. Schematic representation of the selective air oxidation of thiols to disulfides and the oxidation of toxic H₂S to S₈ by [Cu₃(btc)₂]@[CuPW₁₁O₃₉]. Reproduced from Ref. 43.

Lin and coworkers⁴⁵ have recently shown that it is possible to obtain oxidation and photoactive catalysts by doping of [Zr₆O₄(OH)₄(bpdc)₆] (UiO-67), bpdc = para-biphenyldicarboxylic acid) with Ir^{III} or Ru^{II} metal fragments attached to 2,2'-bipyridine-5,5'-dicarboxylato spacers (Figure 8). The resulting modified MOF-6 containing the phosphorescent Ru^{II}(bpy)₂(dcbpy)]Cl₂ (H₂L₆) (bpy = 2,2'-bipyridine) behaves as an efficient aerobic oxidation catalyst of thioanisole (Figure 8).

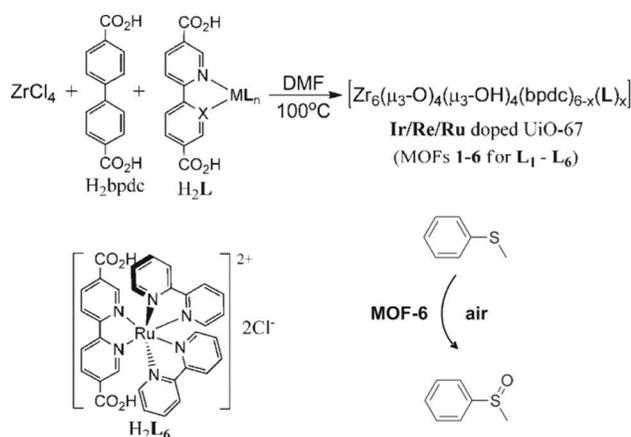

Figure 8. Synthesis of Ir^{III} and Ru^{II} doped [Zr₆O₄(OH)₄(bpdc)₆] (UiO-67) systems and the resulting aerobic catalytic oxidation of thioanisole. Adapted from Ref. 45.

The use of MOF materials with intrinsic photochemical properties is also an advantageous feature for the possible degradation of harmful substances. In this regard, [Ti₈O₈(OH)₄(bdc)₆] (MIL-125)⁴⁶ under UV-irradiation is able to oxidize adsorbed alcohols giving rise to a photochromic behaviour associated with the formation of stable mixed valence titanium-oxo compounds (Figure 9). The titanium oxo cluster are back oxidized in the presence of oxygen closing the catalytic cycle. The photogenerated electrons are trapped as Ti^{III} centers, while a concomitant oxidation of the adsorbed alcohol molecules occurs. Noteworthy, the photocatalytic properties of [Ti₈O₈(OH)₄(bdc)₆] (MIL-125) can be tuned by replacing bdc by 2-aminoterephthalate. The NH₂-MIL-125 system behaves as an active photocatalist under visible light irradiation in the reduction of carbon dioxide to the formate anion with TEOA=triethanolamine acting as an electron donor and a base.⁴⁷

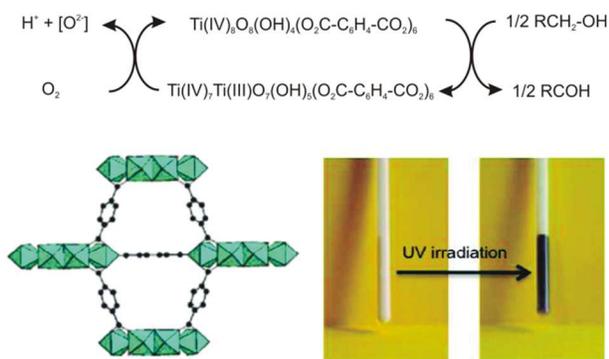

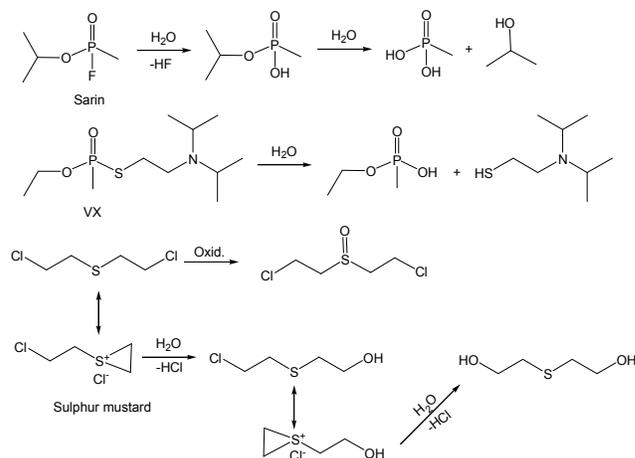

Figure 9. (Top) Proposed mechanism for the photochemical oxidation of alcohols by [Ti₈O₈(OH)₄(bdc)₆] (MIL-125) under UV radiation. (Down). Photochromic behavior of MIL-125 before and after UV irradiation in the presence of adsorbed benzyl alcohol. Adapted from Ref. 46.

Catalytic degradation of chemical warfare agents

The catalytic degradation of the highly toxic chemical warfare

agents is of high interest, since it avoids the problems related to the manipulation of the contaminated materials after exposition to such substances. In this regard, the usual degradation pathways of such substances involve oxidation as well as hydrolysis routes (Scheme 1). This fact has led to the use of redox and/or acid-base active MOFs as catalysts for the remediation systems after exposure to these extremely harmful molecules.

Scheme 1. Common oxidative and hydrolysis degradation pathways of selected chemical warfare agents.

In this regard, the presence of Cu open metal sites with Lewis acidic nature in [Cu₃(btc)₂] favors the hydrolysis, although slow, of both sulphur mustard and organophosphate nerve agents.⁴⁸ The catalytic activity in hydrolysis reactions of the [Cu₃(btc)₂] type systems can be improved by the incorporation of acid polyoxometalates in their pore structure. Thus, Su, Liu and col. have taken advantage of the improved hydrolytic activity of the sodalite type H₃[(Cu₄Cl)₃(btc)₈]₂[PW₁₂O₄₀]₃(C₄H₁₂N)₆ (NENU-11) system for the capture and posterior hydrolytic degradation of the model nerve agent dimethylmethylphosphonate (DMMP).⁴⁹ Hatton and col.⁵⁰ have reported the incorporation of highly nucleophilic 4-methylaminopyridine residues by means of covalent coupling of the amino residues of aluminum aminoterephthalate MOF systems to give rise to [Al₃OF(4-MAP-NH-bdc)₂] (NH₂-MIL-101(Al)) and [AlOH(4-MAP-NH-bdc)] (4-MAP-NH-MIL-53(Al)) active materials (Figure 10). Noteworthy, this MOF can be incorporated onto protective rubber glove surfaces prior to curing giving rise to self-detoxifying surfaces exhibiting a high catalytic activity in the hydrolytic degradation of chemical warfare simulant diisopropylfluorophosphate (DIFP) as proven by ³¹P-MAS NMR studies.

Conclusions

The use of MOFs with adequate pore size/shape is not enough for an efficient capture of hazardous gases/vapors and other more specific interactions between the harmful adsorbates and the host are desirable. For example, the presence of open metal sites (coordinatively unsaturated metal centres) or certain functionalizations on the pore surface may enhance the adsorption selectivity/efficiency of MOFs towards certain toxic compounds *via* coordination bonds, acid-base/electrostatic interactions, π -complex/H-bonding formation, etc. Thus, an effective strategy for the synthesis of materials that strongly retain one gas in preference to another is to target a particular surface chemistry instead of optimizing the surface area alone. Adsorption selectivity can, however, become a drawback for protective applications (i.e. fire rescuers or army applications). In this regard, the fabrication of multicomponent composite materials (i.e. core shell adsorbents, hybrid textiles and thin film coatings of MOFs on various substrates) is becoming a common practice, which provides a way to enhance the performance of the materials towards the generation of multitarget adsorbents. Moreover, the design of chemically, thermally and mechanically robust MOF materials able to stand the typical working conditions of practical applications (i.e. moisture, strong oxidizing/reducing agents, acidic/basic environments, high temperature/pressure ...) needs to be addressed by means of the

right choice of metal/ligand combination, synthetic and postsynthetic conditions, formation of composite materials, etc. Noteworthy, the amenable properties of MOFs offers a way towards the development of advanced catalysts suitable for the degradation of harmful gases and vapors into non-toxic substances. This strategy should be regarded as the ideal case for gas/air purification processes since it overcomes the problems related to adsorbent saturation or its behavior as secondary emitters. Finally, the integration of these catalysts into composite materials may lead to advanced filters, textiles and surfaces with self-cleaning properties.

TOC

The adsorptive and catalytic properties of metal-organic frameworks are advantageous for the capture, sensing and degradation of harmful gases and vapors.

75 publications and the quality of his research has been distinguished by the Excellence Research Award of the University of Granada (2002, 2009) and the RSEQ-Sigma-45 Aldrich Young Researcher Award (2006). He is also a member of the editorial board of ICA Journal.

10 BIOGRAPHICAL SKETCH

15 **Elisa Barea** (left) obtained her PhD in 2004 at the University of Granada. After a postdoctoral stage in the University of Milan (2006-2008), she got a research contract (Ramon y Cajal Grant) to join the University of Granada. Since April 2011, she is an Associate Professor in the Department of Inorganic Chemistry.
20 Her current research focuses on the study of porous coordination polymers with potential applications in air purification and drug-delivery. The quality of her research has been recognized by the Excellence Research Award of the University of Granada (2011) and the Young Researcher Award of the Spanish Royal Society
25 of Chemistry (2012).

Carmen Montoro (middle) born in 1983 graduated in Chemical Engineering in 2008, and received her PhD in Chemistry at the
30 University of Granada in 2013 under the supervision of Prof. Jorge A. R. Navarro and Dr. Elisa Barea. Her research focuses on novel porous materials for gas separation and storage and air purification.

35 **Jorge A. R. Navarro** (right) born in 1969 is Full Professor of Inorganic Chemistry at the University of Granada since 2010. His research is focused on the synthesis and applications of discrete and extended polygonal coordination assemblies with molecular
40 recognition properties suitable for applications on the fields of environmental and biomedical chemistry. He is the author of ca.

1773 - Toxic gas removal - Metal organic frameworks for the capture and degradation of toxic gases and vapours

Key learning points

The reader will learn:

About the major antropogenic toxic gases and vapor emitted to the atmosphere together with their toxicity levels.

About the performance of metal organic frameworks in environmental remediation processes.

About the key features of the porous structure and functionality of MOFs that determine the capture of major atmospheric pollutants.

About the relevance of catalytically active MOFs in the degradation of toxic gases and vapors into harmless substances.

About the importance of creating hybrid composites containing MOFs in order to further improve the performance of MOF materials for the capture and degradation of toxic gases and vapors.
