ABSTRACT

The objective of the study is to characterize the endogenous porphyrin fluorescence in dimethylbenz(a)anthracene (DMBA) induced mouse skin tumor model using native fluorescence emission and excitation spectroscopy. Two intensity ratio parameters I_{580}/I_{635} and I_{420}/I_{515} were selected to represent the key fluorophore of endogenous porphyrins from emission and excitation spectra recorded *in vivo* from 31 DMBA treated animals and 5 control animals. In the emission spectrum, the endogenous porphyrin was elevated at 635 nm during different transformation lesions such as hyperplasia, papilloma, dysplasia, ESCC and WDSCC. This is corroborated by the endogenous porphyrin elevation at 420, 515, 550 and 588 nm in the WDSCC lesions from the excitation spectra. The elevation of endogenous porphyrin, probably protoporphyrin IX (PpIX), is due to biochemical and metabolic alterations in epithelial cells during tissue transformation. The loss of ferrochelatase activity might be responsible for enhanced PpIX in the transformed tissues. The sensitivity and specificity were determined for different lesion pairs from the scatter plot based on the discrimination value by validation with histopathological results. The emission intensity ratio I_{580}/I_{635} at 405 nm excitation was selected to discriminate normal from hyperplasia, hyperplasia from papilloma, papilloma from dysplasia, dysplasia from early squamous cell carcinoma (ESCC), and ESCC from well differentiated squamous cell carcinoma (WDSCC) with specificities of 100%, 88%, 100%, 86%, and 100% and sensitivities of 100%, 80%, 100%, 100% and 100% respectively. Similarly, the excitation intensity ratio I_{420}/I_{515} for 635 nm emission to discriminate between WDSCC lesions from normal gives 100% specificity and 100% sensitivity.

INTRODUCTION

Over half of all human cancers originate in the stratified squamous epithelia. Examples of tissues with stratified squamous epithelia include the cervix, skin, and oral cavity. Approximately 1 million cases of non-melanoma cancers of the stratified squamous epithelia are identified each year.¹ Hence, early detection and treatment of squamous epithelial cancers is important to minimize morbidity and mortality. Native fluorescence (NF) spectroscopy for cancer detection is a promising technique proposed as "Optical Biopsy" by Alfano in 1984.² Later, NF spectroscopy has been considered as one of the powerful techniques because of its sensitivity to metabolic, structural and microenvironmental changes of the various endogenous fluorophores present in the tissues.^{3,4} Of the various fluorophores, the fluorescence of collagen, more generally protein, is related to the structural arrangement of cells and tissues. The other fluorophores, NADH, FAD, and endogenous porphyrin are related to metabolic processes.⁵ A change in the state of the tissue that occurs during physiological processes or in connection with the onset of pathological conditions, results in modifications of the amount of fluorophores, their distribution, and the biochemical properties of their environment.⁴ Among the various optical spectroscopic techniques, native fluorescence spectroscopy has been considered as one of the powerful techniques because of its sensitivity to structural and microenvironmental changes of the various endogenous fluorophores present in the tissues.⁵

A number of clinical investigations carried out on a variety of tissue sites including the cervix,⁶ skin,⁷ and oral cavity⁸ demonstrate that NF provides sensitive and specific

1
2
3 detection of squamous epithelial cancer. However, most of the clinical cases are reported
4
5 for diagnosis after the early neoplastic changes, which are considered as a major
6
7 drawback in exploring the potentiality of NF technique for the early detection of cancer.
8
9 Further, it is practically difficult to measure the spectra of a lesion in a patient, during its
10
11 progression from normal to premalignant and malignant condition. Hence, understanding
12
13 the fluorescence characteristics from a single site during onset of the neoplastic changes
14
15 during the tissue transformation sequence is important from the clinical perspective. In
16
17 this context, mouse skin carcinogenesis model has the potential to provide a better
18
19 understanding of how fluorescence spectra are changing during normal tissue progresses
20
21 through dysplasia to cancer sequence. Several *in vitro* and *in vivo* studies have been
22
23 performed in which squamous cell carcinoma initiated with 7,12 dimethyl
24
25 benz(a)anthracene (DMBA) induced hamster cheek pouch/skin carcinogenesis and then
26
27 NF characterization of the tissue transformation was measured.⁹⁻¹² However, to the best
28
29 of our knowledge, no comparison of histological categorization of various tissue
30
31 transformation conditions with respect to normal tissues in mice skin carcinogenesis
32
33 model for measuring emission spectrum at 405 nm excitation and excitation spectrum at
34
35 635 nm emission has been made till date. Therefore, the novelty of this study is that for
36
37 the first time a NF spectroscopy using a selective combination of specific emission and
38
39 excitation wavelengths, mentioned above has been made for measuring various tissue
40
41 transformation conditions in mice skin carcinogenesis *in vivo*.

20 21 **MATERIALS AND METHODS**

22 23 *Animals*

24 For the present study, 36 Swiss Albino mice, both male and female, 6-8 weeks old at the
25 start of the experiment were obtained from National Institute of Nutrition, Hyderabad, India.
26
27 At the beginning of the study, all animals weighed approximately 25-30 g each. The animals
28 were housed four per cage with a right diet but ad libitum access to food and water. The
29 animals were maintained at 27°C with 12 hours dark/light cycle. Animals care and
30 procedures were in accordance with guidelines of ethical committee, Government of India.

40 41 *Mice Skin Carcinogenesis Model*

42 At the beginning of the experiment, all hair of the animals on their dorsal side approximately
43 1 cm² were removed with a hair removing cream (Anne French, Geoffrey manners and Co.
44 Ltd., Mumbai, India). On confirmation of no scar on the skin surface, they were subjected to
45 tumor induction. Healthy animals were divided into two groups. One group of animals
46 treated for epithelial carcinogenesis (n=31) and other consisted of control animals (n=5).
47
48 The first group was treated with 0.5% of DMBA in heavy mineral oil (Sigma Aldrich Co.,
49 St. Louis, Missouri) thrice a week during the first 3 weeks. However, from the fourth week,

52
53
54
55
56
57
58
59
60

1
2
3 treatment was reduced to twice per week due to the reddening and erosion of the skin. The
4 control group was treated only with heavy mineral oil. Separate No.5 camelhair brushes
5 were used for the topical application of DMBA/mineral oil solution on the epithelial
6 carcinogenesis group and mineral oil alone on the control group. The carcinogen treatment
7 was carried out for a period of 18 weeks.
8
9

16 ***Instrumental Description***

18 *In vivo* fluorescence of emission and excitation spectral measurements was recorded using a
19 spectrofluorometer with a Y-guide fiber optic probe (Fluoromax-2, ISA, Jobin Yvon-Spex,
20 Edison, New Jersey, USA) of their schematic instrumentation is shown Fig.1. The excitation
21 source (150 W Ozone free Xenon arc lamp) coupled to the monochromator delivers light to
22 a fiber optic probe coupled to one end of the Y-wave guide fiber. The other end of the fiber
23 collecting the signal was coupled to the emission monochromator connected to a
24 photomultiplier tube (PMT; R928P, Hamamatsu, Shizuoka-Ken, Japan). The collected
25 signal is transferred to the PC through an RS232 interface, and processed by the windows-
26 based data acquisition program, DataMax (ISA, Jobin Yvon-Spex). The excitation and
27 collection end of the fiber assembly were connected to the excitation and emission
28 monochromators, respectively. The fiber optic assembly (~8 mm outer diameter) contained
29 31 delivery and 31 collection fibers of 250 μm diameter randomly mixed. A flexible spacer
30 1 cm long, disposable, black PVC sleeve was inserted at the common end of the fiber-optic
31 probe assembly maintains a fixed separation of approximately 0.5 cm between the probe tip
32 and tissue surface. The common end of the fiber tip was mounted perpendicularly on XYZ
33 micrometer translational stage for precise location and for prevention of handheld tremor
34 during measurements.

3 The emission spectral measurements of control and DMBA treated mice skin were
4 recorded between 430–700 nm for the excitation wavelength of 405 nm for which the
5 excitation and the emission wavelength band passes were 2 and 3 nm respectively with
6 integration time of 0.1 sec. For the excitation spectra recorded between 340–600 nm at an
7 emission wavelength of 635 nm, the excitation and emission band passes were set at 5
8 and 3 nm respectively with the integration time being the same as that of emission
9 spectral measurements. The excitation wavelength for 405 and 635 nm from the
10 spectrometer was low in intensity, which is about 2–5 $\mu\text{W}/\text{cm}^2$, and did not induce any
11 significant photobleaching of endogenous porphyrin. Prior to start of each measurement
12 day, a background spectrum was obtained at each excitation and emission wavelength by
13 inserting the probe into a nonfluorescent bottle filled with distilled water. The
14 background spectrum was then subtracted from the corresponding tissue fluorescence
15 spectrum.

35 *Mice Skin Fluorescence Measurements*

36
37 Two groups of live animals were monitored on a weekly basis periodically for 18 weeks for
38 any changes in their NF emission and excitation characteristics using a fiber-optic probe
39 based spectrofluorometer. In order to avoid residual fluorescence due to DMBA application,
40 the experiments were designed in such a way that, the fluorescence measurements always
41 took place at least 48 hrs after DMBA treatment.¹⁰ Before optical measurements, the tumor
42 induction site of the mice skin was swabbed with saline and cleaned dry with a piece of
43 sterilized cotton. Using translational XYZ micrometer, the probe with spacer was moved
44 into at least three different sites of the tumor induction area of each animal and subsequently
45 optical measurements were recorded. Among the three sites of each animal in the DMBA

2
3 treated group, that site showing more porphyrin fluorescence was marked for biopsy and
4
5 subsequently that animal was sacrificed that week. The biopsy site of the corresponding
6
7 emission and excitation spectral measurements of that animal was taken out for data
8
9 analysis. Likewise, at least one or two animals were selected from the DMBA treated group
10
11 and were sacrificed every week and the skin was removed surgically for histopathological
12
13 evaluation. Similarly, each one of the control group animals was periodically sacrificed. The
14
15 periods of sacrifice of the DMBA treated mice and control group were noted.
16
17
18
19

20 21 *Histological Evaluation*

22
23 At different time periods (1 to 18 weeks) during the tumor induction, animals were
24
25 euthanized by over dosage of isoflurane (5%). Following euthanasia, the tissue specimens
26
27 were excised from the tumor induction spot of the measured site, using 2 mm biopsy punch
28
29 and preserved in 10% formalin solution for hematoxylin and eosin (H&E) and submitted for
30
31 histological evaluation.
32
33
34
35

36 37 *Data Analysis*

38
39 The skin samples of 36 mice were classified into six different groups based on the
40
41 histopathology report which indicated that a biopsy site of the mice was normal, and then
42
43 the measurements on that date of mice data were assumed to be normal. The skins of the
44
45 five control mice were treated only with mineral oil, all were diagnosed as histologically
46
47 normal. Similarly, the spectroscopic data of the DMBA treated animals were classified into
48
49 five groups according to their histopathology report. For example, if histopathology
50
51 indicated that a biopsied site was hyperplasia then the measurements on that date of mice
52
53 data were assumed to be hyperplasia. Similarly, we obtained the data for papilloma,
54
55 dysplasia, ESCC and WDSCC in the different weeks of DMBA treated periods. The number
56
57
58
59
60

1
2
3 of animals as well as the number of spectra obtained from the control and different tissue
4 transformation of the DMBA treated group for the data analysis and different periods of
5 sacrifice week are shown in Table 1. Of the 31 DMBA treated mice skins were assumed to
6 be diagnosed as 8 had hyperplasia, 5 had papilloma, 7 had dysplasia, 6 had ESCC, and 5 had
7 WDSCC.
8
9

10
11 The purpose of measuring the three sites of each animal is to identify the accurately
12 transformed site by measuring the porphyrin fluorescence. The site showing the highest
13 porphyrin fluorescence was marked for biopsy and sent for histopathological evaluation. For
14 cross-verification, the other two sites which did not show porphyrin fluorescence were also
15 biopsied and sent for histopathological evaluation, but no definite histological changes were
16 observed. Hence, other two sites were not included in the spectral and classification
17 analysis. In the present study each animal was subjected to histological evaluation during the
18 tissue transformation process and the spectral profiles of each histological category were
19 grouped for the classification analysis. A few of the spectral data were discarded due to
20 artifacts because of animal movement, probe pressure and angulations during the
21 measurement, resulting in reducing the total to 36 mice of skin samples.

3 normal (N) tissues. Like that, the difference spectrum was generated as (N-H), (N-P), (N-D),
4
5 (N-E), and (N-W) for emission spectrum at 405 nm excitation and excitation spectrum at
6
7 635 nm emission were shown in Figures 2 (a-e) and 3 (a-e) respectively.
8
9

10 11 *Statistical Analysis*

12
13
14 In order to verify the diagnostic potential of these observed spectral signatures between
15
16 normal and various tissue transformation conditions, five ratio parameters I_{480}/I_{550} ,
17
18 I_{480}/I_{580} , I_{480}/I_{635} , I_{550}/I_{580} , and I_{580}/I_{635} for emission spectra at 405 nm excitation and three
19
20 ratio parameters I_{420}/I_{515} , I_{515}/I_{550} , and I_{550}/I_{585} for excitation spectra at 635 nm emission
21
22 were generated. The mean and standard deviation values of all the experimental group of
23
24 subjects were calculated and their statistical significance was verified using one-way
25
26 Analysis of Variance (ANOVA) with 95% confidence interval.
27
28
29

30
31
32 The classification analysis for the different tissue transformation groups were determined
33
34 on the basis of discrimination cut-off (threshold) values. Discrimination cut-off lines are
35
36 drawn between the normal (mean of all normal tissues) and hyperplastic (mean of all
37
38 hyperplastic tissues), hyperplastic and papilloma, papilloma and dysplasia, dysplasia and
39
40 ESCC, ESCC and WDSCC, at values that correspond to the mean ratio value of the
41
42 respective groups. The sensitivity and specificity in discriminating each of these categories
43
44 were determined on the basis of the cut-off values identified by ratio method by validation
45
46 with histopathological results of biopsy specimens taken from spectral measurements sites.
47
48 Similar ratio intensity variable methods and the sensitivity and specificity were determined
49
50 on the basis of the discrimination cut-off lines adopted by earlier researchers to discriminate
51
52 normal from different tissue categories of oral and bladder tissues.^{8,13}

RESULTS

Fluorescence Emission Spectral Characteristics at 405 nm Excitation

The normalized average fluorescence emission spectrum of normal and DMBA treated skin lesions such as hyperplasia, papilloma, dysplasia, ESCC and WDSCC with their corresponding difference spectrum at 405 nm excitation is shown in Figures 2(a-e). The normalized average fluorescence emission spectrum of normal tissue has a primary peak around 470 nm with a small shoulder observed at 550 nm and then it decreases towards longer wavelengths with a small hump at 635 nm. In the case of DMBA treated skin, the amplitude of the hump at 635 nm increases with respect to normal tissues. Further, the intensity of peak emission wavelength at 635 nm increases as the stage of skin transformation increases. The difference spectrum between normal and hyperplasia (N-H), and normal and papilloma (N-P), and normal and dysplasia (N-D) skin condition has primary negative peak around 480 nm and a secondary peak at 635 nm (Figures 2a, 2b & 2c), whereas in the case of difference spectrum between normal and ESCC (N-E), and normal and WDSCC (N-W) skin condition, it has a maximum negative peak at 635 nm and minimum broad peak around 480 nm with an isosbestic point at 580 nm (Figures 2d & 2e).

Fluorescence Excitation Spectral Characteristics for 635 nm Emission

The normalized average fluorescence excitation spectrum of normal and various skin transformation condition such as hyperplasia, papilloma, dysplasia, ESCC and WDSCC with their corresponding difference spectrum at 635 nm emission is shown in Figures 3(a-e). From these excitation spectra, it was found that there was a little amount of increased fluorescence intensity throughout the wavelength region (350–600 nm) with small hump was observed around 450 nm for hyperplasia, papilloma, dysplasia, ESCC than normal

1
2
3 tissues. The corresponding difference spectrum also shows, there was no appreciable
4 differences were found out between (N-H), (N-P), (N-D), and (N-E) groups (Figures 3a, 3b,
5 3c & 3d). However, the excitation spectra of WDSCC lesions displayed a prominent
6 primary band at 420 nm and three secondary spectral bands at 515, 550 and 588 nm
7 respectively (Figure 3e). But these bands were completely absent in the case of normal,
8 hyperplasia, papilloma, and ESCC skin lesions. The corresponding difference spectrum
9 shows an apparent difference between normal and WDSCC (N-W) skin lesions has a
10 maximum negative peak at 420 nm and three minimum peaks at 515, 548 and 585 nm.

23 ***Results of Histological Evaluation***

24
25 In order to confirm the different morphological changes that occur during the sequential
26 tissue transformation process, animals were sacrificed at different time periods for
27 histological evaluation. Histological images of the mouse skin at different periods are shown
28 in Figures 4(a-f). Five control mice skin (treated only with mineral oil) were all diagnosed as
29 histologically normal. The histological normal mouse skin shows thin epithelial layer with
30 intact collagen matrix. Further, epidermis and the dermis contain numerous hair follicles
31 (Fig. 4a). Of the 31 DMBA treated mice skin 8 had hyperplasia, 5 had papilloma, 7 had
32 dysplasia, 6 had ESCC and 5 had WDSCC. According to the histopathology report, from the
33 DMBA treated skin was separated by five transformation conditions. (1) During 4-6 weeks
34 of DMBA treatment, the skin appeared thick and reddened while the histology of the skin
35 showed hyperplastic changes (i.e) increased thickness of epithelium with the indications of
36 moderate hyperplastic and the early stage of papillary hyperplasia (Fig. 4b). (2) During 5-9
37 weeks, papillomatous outgrowths were noticed that was confirmed by the histopathology
38 showing papillomatous proliferation of the epidermis (Fig. 4c). (3) At about 10-13 weeks,

the skin lost its normal orientation between the epithelial cells leading to dysplastic stratified squamous epithelium (Fig. 4d). (4) Numerous nodular growths were seen during 14-16 weeks. Atypical squamous cells replaced the entire epithelium giving histology of early invasive squamous cell carcinoma (Fig. 4e). (5) After 17-18 weeks, the tumor grew larger in size with features of well-differentiated squamous cell carcinoma, demonstrating invasion of tumor cells into the dermis with atypical mitoses and keratin pearls were also seen (Fig. 4f).

Results of Statistical Analysis

Among five ratio parameters (I_{480}/I_{550} , I_{480}/I_{580} , I_{480}/I_{635} , I_{550}/I_{580} , and I_{580}/I_{635}), the ratio parameter I_{580}/I_{635} was identified as the most significant ($P < 0.0001$) ratio in discriminating the normal from different tissue transformation conditions for emission spectrum at 405 nm excitation. The intensity I_{580} has been chosen to represent the hemoglobin absorption and I_{635} represent the characteristic emission because of endogenous porphyrin. The mean and standard deviations of the ratio parameter (I_{580}/I_{635}) for normal and different tissue transformations are shown in Table 2. It can be seen that the mean value of the normal group is high but there is a gradual decrease in the mean values according to the progression to higher grades of malignancy. Similarly, out of three ratio parameters (I_{420}/I_{515} , I_{515}/I_{550} , and I_{550}/I_{585}), the ratio parameter I_{420}/I_{515} was identified as the most significant ($P < 0.0001$) ratio in discriminating the normal from WDSCC lesions for excitation spectra at 635 nm emission. This intensity ratio value corresponds to solet band (I_{420}) and Q-band (I_{515}). Mean standard deviation of the ratio parameter (I_{420}/I_{515}) for normal and WDSCC lesions also shown in Table 2, from which the mean value of normal is low and it increases for WDSCC lesions.

1
2
3 The ratio parameter (I_{580}/I_{635}) showed best discrimination not only between normal and
4 malignant but also between different tissue transformation conditions such as (a) normal
5 vs hyperplasia (b) hyperplasia vs papilloma (c) papilloma vs dysplasia (d) dysplasia vs
6 ESCC (e) ESCC vs WDSCC for emission spectrum at 405 nm excitation. Discrimination
7 lines were drawn between contiguous normal-hyperplasia, hyperplasia-papilloma,
8 papilloma-dysplasia, dysplasia-ESCC, and ESCC-WDSCC groups at values that
9 correspond to the mean ratio values of the respective groups. The discrimination (cut-off)
10 value in the scatter plot which is the weighted mean of the paired values was used to
11 classify different lesions. There are five cut-off lines in Fig. 5. The cut-off values for
12 normal-hyperplasia, hyperplasia-papilloma, papilloma-dysplasia, dysplasia-ESCC, and
13 ESCC-WDSCC pairs are 1.07, 0.97, 0.81, 0.63, and 0.55 respectively. Diagnostic
14 accuracies such as specificity and sensitivity for each pair were calculated by correlating
15 the position of ratio value for each lesion in the scatter plot (Fig. 5) with the
16 corresponding histopathological results given in Table 3. For example, the I_{580}/I_{635} ratio,
17 the first cut-off line discriminating the normal from the hyperplasia was drawn at 1.07
18 that corresponds to mean of normal (1.14) and that mean of hyperplastic (0.99) group
19 gives 100% specificity and 100% sensitivity was obtained for discrimination of the
20 normal from hyperplasia. The second cut-off line drawn at 0.97 that corresponds to mean
21 of hyperplasia (0.99) and that mean of papilloma (0.94) discriminates the hyperplasia
22 from papilloma with the specificity and sensitivity of 87.5% and 80% respectively. In this
23 classification analysis, only 1 of 8 hyperplastic tissues was misclassified as papilloma,
24 and 1 of 5 papilloma tissues was misdiagnosed as hyperplasia. The third cut-off line
25 drawn at 0.81 that corresponds to mean of papilloma (0.94) and that mean of dysplasia

DISCUSSION

Early detection of premalignant and malignant lesions may reduce patient morbidity and mortality because treatment at a less invasive stage is more successful, and therefore is of great clinical importance. In the present study, the NF characterization of sequential tissue transformation in a DMBA induced mouse skin carcinogenesis model was explored and the spectral data were analyzed using a statistical method for better discrimination of normal from the early stages of neoplastic conditions.

Fig. 2(a-e) shows the primary NF emission band at 470 nm and a small hump at 550 nm may be attributed to emission from fluorophores like NADH and FAD respectively, while the emission at 635 nm is from enhanced occurrence of endogenous porphyrin present in different tissue transformation lesions. An increased NADH fluorescence in hyperplasia, papilloma, dysplasia, ESCC and WDSCC due to proliferation of cells could be the result of an increased metabolic activity associated with progression of neoplastic changes. The corresponding difference spectra of the different tissue transformation lesions showed a parabolic curve of spectral profile with the negative peak observed at 480 nm. On the whole, the difference spectrum between N-H, N-P, N-D, N-E, and N-W reveals increased NADH fluorescence when compared with normal lesions. Further, it is evident that the NADH emission which increases at 470 nm during the tissue transformation could be well appreciated in the overall emission spectrum (Fig.7). These observations indicate increased level of NADH during the neoplastic progression due to (i) rapidly multiplying neoplastic cells with increased metabolic activity,¹² (ii) decreased blood flow due to the rapid cell division,¹⁴⁻¹⁶ (iii) decrease in oxygen supplied to the

1
2
3 cells.¹⁴⁻¹⁶ Further, it is noticed that the increased metabolic activity during the neoplastic
4 transformation is highlighted by an enhanced FAD emission at 550 nm, when compared
5 with normal lesions. Hence, the concentrations and distributions of coenzymes NADH
6 and FAD correlate with the metabolic and physiological states of cells and tissues.
7
8
9
10
11

12
13
14 In addition to the NADH and FAD emission, the fluorescence emission spectra of
15 different tissue transformation condition exhibit a distinct emission peak at 635 nm,
16 which is absent in the case of normal mice skin [Fig. 2(a-e)]. It is noted that, the intensity
17 of the emission peaks at 635 nm increases as the skin lesions changes from normal into
18 different stages of tissue transformation namely: hyperplasia, papilloma, dysplasia, ESCC
19 and WDSCC. The corresponding difference spectra show a prominent negative peak at
20 635 nm, and this peak is going down steeper and steeper as the stages of tissue
21 transformation increase. The additional fluorescence peak at 635 nm observed after
22 DMBA application is attributed to endogenous porphyrin.^{9,12} Earlier literature reported
23 that porphyrins have been associated mainly with ulcerating tumors, because of the
24 bacteria that grow in these tissues.^{18,19} This phenomenon has been reasonably excluded in
25 the present study since the mice skin did not display any ulceration. As there is no sign of
26 an ulceration seen in the mouse skin there is a systematic increase at 635 nm due to
27 endogenous porphyrins that accumulate and concentrate in viable tumor tissues. The
28 accumulation and retention of endogenous porphyrin in the viable tumor tissues is
29 confirmed by the earlier report on the tissue extracts from DMBA induced hamster cheek
30 pouch and mouse skin tumor exhibiting typical porphyrin fluorescence at 635 nm.^{9,20}
31
32 This systematic porphyrin emission which increases at 635 nm during the tissue
33 transformation could be well appreciated in the overall emission spectrum displayed in

3 Fig. 7. In this spectra, it is evident that the amount and rate of endogenous porphyrin
4 accumulation increases with increasing degree of malignancy. This is due to chronic
5 application of DMBA to the mouse skin; the cellular proliferative activity increases
6 during malignant transformation leading to biochemical and metabolic alterations in
7 epithelial cells affected by the changes that occur during tissue transformation.²¹ These
8 changes can modify the synthesis of endogenous porphyrin, probably protoporphyrin IX
9 (PpIX), which preferentially accumulates in tumor cells due to changes in the activity of
10 two main enzymes: porphobilinogen deaminase (PBG) and ferrochelatase (FC).²² In
11 tumor cells, while the activity of PBG increases, the activity of FC decreases resulting in
12 the building up of PpIX. But in normal cells, FC catalyses the conversion of
13 photosensitive PpIX to heme, which is not photosensitive.²²⁻²⁴

31 A small bump noticed in the emission spectra at 666 nm from normal and DMBA treated
32 mice skin may be due to the degradation products of *chlorophyll a*, namely, *pheophytin a*
33 and *pheophorbide a* present in the food pellets.^{25,26}
34
35
36
37
38
39

40 In order to confirm the origin of the red emission peak at 635 nm observed in the
41 fluorescence emission spectra of DMBA treated animals at 405 nm excitations, the
42 fluorescence excitation spectra were also measured at 635 nm emission for both normal
43 and DMBA treated animals. These are shown in Fig. 3(a-e). The normal and different
44 tissue transformation lesions shows sharp spectral peaks at 362 and 387 nm due to
45 Rayleigh scattering effect and stray light contribution from the excitation light. In the
46 case of hyperplasia, papilloma, dysplasia and ESCC lesions exhibits a small hump was
47 observed around 430–460 nm may be attributed to absorption band of FAD. However,
48

53
54
55
56
57
58
59
60

1
2
3 the WDSCC lesion revealed a prominent primary band at 420 nm and three secondary
4 spectral bands around 515, 550 and 588 nm respectively. The band around 420 nm is
5 predominant when compared with the other bands. These observed primary and
6 secondary bands correspond to Soret and Q-band absorption of endogenous porphyrins
7 respectively.^{5,19} Further, this observed spectral signature of the WDSCC lesions
8 resembles the typical absorption spectra of the porphyrin molecule, it indicates that
9 higher amount of porphyrins synthesized in WDSCC lesions than other transformation
10 conditions. This finding is consistent with the previous work by Ebenezer *et al*, who
11 found out that similar Soret and Q-bands were observed in WDSCC of buccal mucosa of
12 oral cancerous patients at 635 nm emission by fluorescence excitation spectroscopy *in*
13 *vivo*.²⁷

29
30
31 Although the NF signal shows distinct differences in the spectral signatures, an *in vivo*
32 quantitative estimation of the different fluorophores at different tissue pathological
33 conditions to discriminate different stages of tissue transformation process is complex due to
34 the tissue heterogeneity and the dependency of fluorescence signal on the tissue optical
35 properties. For instance, optical behaviour of tissue will be highly affected by thickening of
36 skin or change in tissue vascularization that occurs during tissue transformation.^{12,21,28} This
37 highly correlates with the present study of the difference spectrum of hyperplasia from
38 normal, papilloma from normal, and dysplasia from normal (Fig. 2a, 2b & 2c) shows a
39 primary negative peak around 480 nm which corresponds to NADH and a secondary peak at
40 635 nm due to porphyrin. On the other hand, the difference spectra of the ESCC from normal
41 and WDSCC from normal (Fig. 2d & 2e), show a primary negative peak at 635 nm and a
42 secondary peak around 480 nm with an isosbestic point at 580 nm. From these difference

1
2
3 spectra it is strongly inferred that the NADH level increased during initial transformations
4 such as hyperplasia, papilloma and dysplasia lesions. However, with an increase in the
5 degree of malignancy as in the case of both ESCC and WDSCC lesions, the NADH level
6 decreased in intensity compared with hyperplasia, papilloma and dysplasia lesions. The
7 variations in the relative distribution of NADH and porphyrins in the emission spectra
8 corresponding to 405 nm excitation during the tissue transformation process may be due to
9 (i) in the early weeks of DMBA initiation, the inflammatory response is triggered in the skin,
10 thereby increasing the metabolic activity of the inflamed cells, leading to increased level
11 of NADH in the early tissue transformation conditions namely hyperplasia, papilloma and
12 dysplastic lesions,²⁸ and (ii) during the degree of differentiation increases due to chronic
13 application of DMBA in the mouse skin; the NADH decreases leading to an increased level
14 of porphyrin in the malignant transformation of ESCC and WDSCC lesions.^{29,30}

33 Another possible reason for the decreased NADH intensity due to increased tissue
34 vasculature observed on ESCC and WDSCC tissues, when the animals had a nodular
35 outgrowth of the tumor volume increase in size and varying around 5-8 mm diameter during
36 14–18 weeks of DMBA treatment. As a result, a prominent spectral valley or dip in the
37 emission spectrum around 580 nm is observed as shown in Fig. 2(a-e). This valley is more
38 pronounced in ESCC and WDSCC than hyperplasia, papilloma and dysplastic tissues. In
39 addition to this, an isosbestic point in the difference spectrum was found to occur at 580 nm
40 due to higher hemoglobin absorption and strong porphyrin emission at 635 nm from ESCC
41 and WDSCC tissues (Fig. 2d & 2e). This correlates with the results reported earlier by Van
42 der Breggen *et al.* found out that an increased vascularization of the neoplastic tissues leads

3 to a higher hemoglobin concentration, and also it may contribute to an increase in the rate
4 and amount of porphyrin emission in DMBA treated animal tissues.²¹
5
6
7

8
9 Table 3 summarizes the specificity and sensitivity obtained across different histological
10 categories of experimental groups from the scatter plot (Fig. 5) using emission spectral intensity
11 ratio (I_{580}/I_{635}) at 405 nm excitation. The specificities obtained for (a) normal–hyperplasia, (b)
12 hyperplasia–papilloma, (c) papilloma–dysplasia, (d) dysplasia–ESCC, and (e) ESCC–WDSCC
13 pairs are 100%, 88%, 100%, 86% and 100% respectively and the corresponding sensitivities are
14 100%, 80%, 100%, 100%, and 100% respectively. The reduced specificity and sensitivity from
15 the classification analysis (b & d) was obtained because of some of the hyperplasia, papilloma
16 and dysplasia subjects were misclassified during the earlier weeks of tumor induction. Even one
17 sample was misclassified in the classification analysis (b & d), the specificity and sensitivity
18 was greatly reduced. If the number of sample size is to be increased in these categories, the
19 classification accuracy can be increased. Also the table 3 shows that the 100% specificity and
20 100% sensitivity was obtained from the scatter plot (Fig. 6) for single lesion pair (normal-
21 WDSCC) for intensity ratio of I_{420}/I_{515} at 635 nm emission.

41 Although, the present NF study is used to characterize the endogenous porphyrin fluorescence
42 for normal and different tissue transformation, the reflectance spectral measurements were not
43 investigated. The reflectance spectrum is used to assess the changes in the scattering and
44 absorption properties of tissues. To potentially improve the diagnostic accuracy of different
45 tissue transformation, fluorescence spectroscopy in combination with reflectance measurements
46 would be necessary in future. Such investigations with a larger number of animals for normal
47 and different tissue transformation process could be validated in a blinded manner.

CONCLUSION

The spectral signatures of the current study demonstrated that NADH, FAD, hemoglobin and porphyrin changes have good diagnostic potential which were elicited at 405 nm excitation. In particular, the significant contribution of porphyrin can be used as a tumor marker. Further, it is confirmed that the porphyrin elevated in the WDSCC tissues from excitation spectra at 635 nm emission. Finally, the intensity ratio parameters I_{580}/I_{635} and I_{420}/I_{515} represent the key fluorophore of porphyrin to diagnose the early tissue transformation process.

TABLES

Table 1. Histological Assessment Results of 36 Tissue Sites.

Histological diagnosis	Period of sacrifice week	Number of spectra / number of animals	Number of weeks DMBA treated
Normal	0–18	5	N/A
Hyperplasia	4–6	8	4.5±0.8
Papilloma	5–9	5	7.4 ±1.5
Dysplasia	10–13	7	11.5±0.9
ESCC	14–16	6	15±0.8
WDSCC	17–18	5	18 ± 0.7

Table 2. Mean values (\pm SD) of the ratio parameter from emission and excitation spectrum for normal and different tissue transformations used for statistical analysis. Their statistical significance (p) between each contiguous group was verified by unpaired student's t -test. For I_{580}/I_{635} , the p -value of normal vs hyperplasia, papilloma vs dysplasia, dysplasia vs ESCC, and ESCC vs WDSCC is 0.000. But for, hyperplasia vs papilloma is 0.091. For I_{420}/I_{515} , the p -value of normal vs WDSCC is 0.000.

Different tissue transformation	Mean \pm SD	
	Emission Spectrum	Excitation Spectrum
	I_{580}/I_{635}	I_{420}/I_{515}
Normal	1.14 \pm 0.03	2.23 \pm 0.15
Hyperplasia	0.99 \pm 0.02	
Papilloma	0.94 \pm 0.05	
Dysplasia	0.68 \pm 0.04	
ESCC	0.58 \pm 0.01	
WDSCC	0.51 \pm 0.01	5.41 \pm 0.32

Table 3. Specificity and Sensitivity Obtained for Different Lesion Pairs Consisting 36 Mice Skin Samples for Intensity Ratio of I_{580}/I_{635} at 405 nm Excitation and Single lesion Pair Consisting 10 Samples for Intensity Ratio of I_{420}/I_{515} at 635 nm Emission.

Lesion Pairs	405 nm Excitation		Lesion Pair	635 nm Emission	
	I_{580}/I_{635}			I_{420}/I_{515}	
	Specificity	Sensitivity		Specificity	Sensitivity
Normal(5) vs Hyperplasia(8)	100%	100%	Normal(5) vs WDSCC(5)	100%	100%
Hyperplasia(8) vs Papilloma(5)	88%	80%			
Papilloma(5) vs Dysplasia(7)	100%	100%			
Dysplasia(7) vs ESCC(6)	86%	100%			
ESCC(6) vs WDSCC(5)	100%	100%			

Number of samples examined is given in parenthesis

CAPTIONS

Fig. 1. Schematic of the experimental instrumentation for *in vivo* fluorescence measurements. The arrows represent the direction of excitation and emission light.

Fig. 2. Normalized average fluorescence emission spectra of normal and DMBA treated skin lesions under different stages of tissue transformation conditions such as (a) hyperplasia, (b) papilloma, (c) dysplasia, (d) ESCC, (e) WDSCC with their corresponding difference spectrum at 405 nm excitation.

Fig. 3. Normalized average fluorescence excitation spectra of normal and DMBA treated skin lesions under different stages of tissue transformation conditions such as (a) hyperplasia, (b) papilloma, (c) dysplasia, (d) ESCC, (e) WDSCC with their corresponding difference spectrum at 635 nm emission.

Fig. 4. H & E stained mouse skin before and after DMBA application. (a) Normal mouse skin without any DMBA application. The arrow marks shows normal epidermis and dermis with numerous hair follicles, (b) Hyperplasia. The bracket shows an increased thickness of epithelium which indicates moderate hyperplasia (c) Papilloma. It indicates papillomatous proliferation of the epidermis with hyperkeratinisation (d) Dysplasia. Dysplastic stratified squamous epithelium. The arrow shows hyperchromatic stained nucleus and dysplastic basal cells (e) Early invasive squamous cell carcinoma (ESCC). The arrow marks indicates dysplastic epithelial basal cells breaching the basement membrane forming epithelial island. (f) Well differentiated squamous cell carcinoma(WDSCC). It shows atypical mitotic figures and keratin pearls formation. The scale bar shown in the pictures corresponds to 50 μm .

Fig. 5. Scatter plot for intensity ratio of I_{580}/I_{635} at 405 nm excitation for Normal (\bullet), Hyperplasia (\square), Papilloma (\blacktriangle), Dysplasia (\blacklozenge), ESCC (\blacksquare) and WDSCC (\circ) correlating with histopathologic results of the 36 mice skin. The discrimination value (1.07) separates hyperplasia from normal, the discrimination value (0.97) separates papilloma from hyperplasia, the discrimination value (0.81) separates dysplasia from papilloma, discrimination value (0.63) separates ESCC from dysplasia, and the discrimination value (0.55) separates WDSCC from ESCC.

Fig. 6. Scatter plot for intensity ratio of I_{420}/I_{515} at 635 nm emission for Normal (\bullet) and WDSCC (\blacksquare) correlating with histopathologic results of the 10 mice skin. The discrimination value (3.82) separates WDSCC from normal.

Fig. 7. Normalized average overall emission spectrum of normal and different tissue transformation of mice skin at 405 nm excitation. The arrow indicates the increasing porphyrin emission as a function of different tissue transformation.

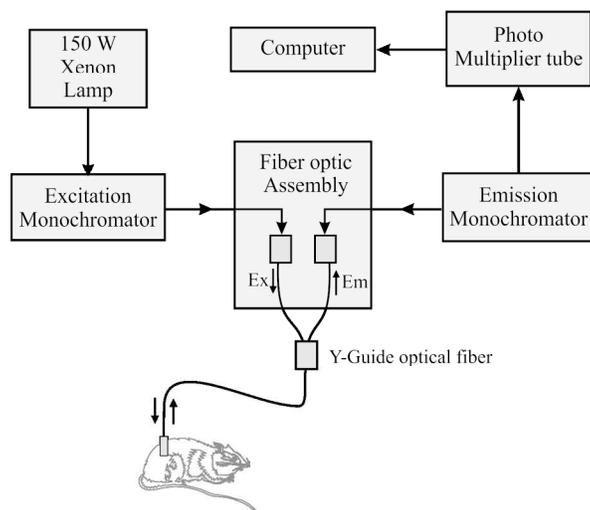

Fig. 1 Schematic of the experimental instrumentation for *in vivo* fluorescence measurements. The arrows represent the direction of excitation (Ex) and emission (Em) light.

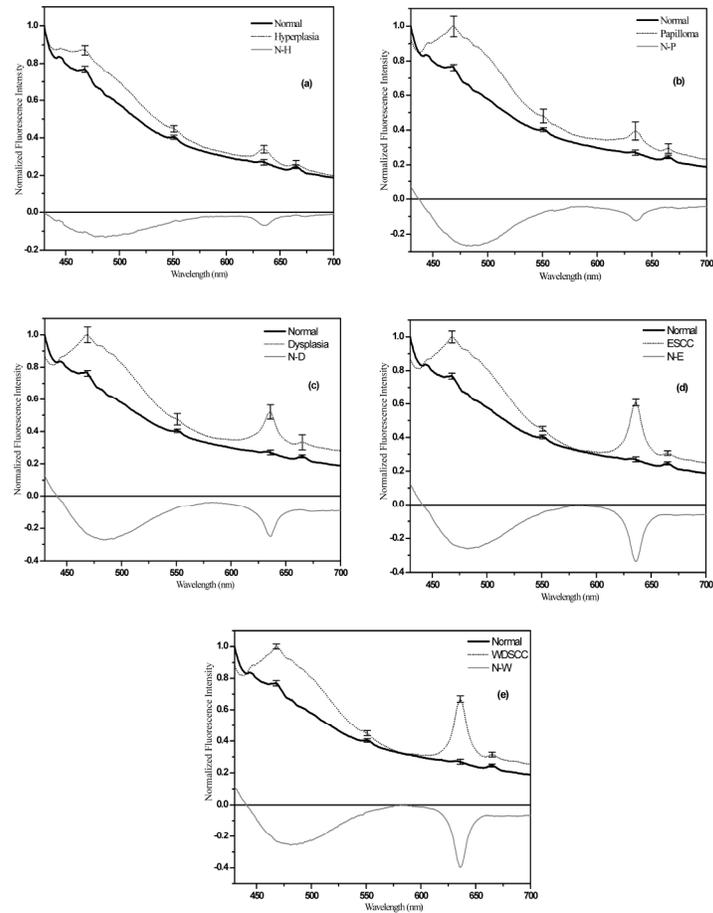

Fig. 2 Normalized average fluorescence emission spectra of normal and DMBA treated skin lesions under different stages of tissue transformation conditions such as (a) hyperplasia, (b) papilloma, (c) dysplasia, (d) ESCC, (e) WDSCC with their corresponding difference spectrum at 405 nm excitation.

196x263mm (300 x 300 DPI)

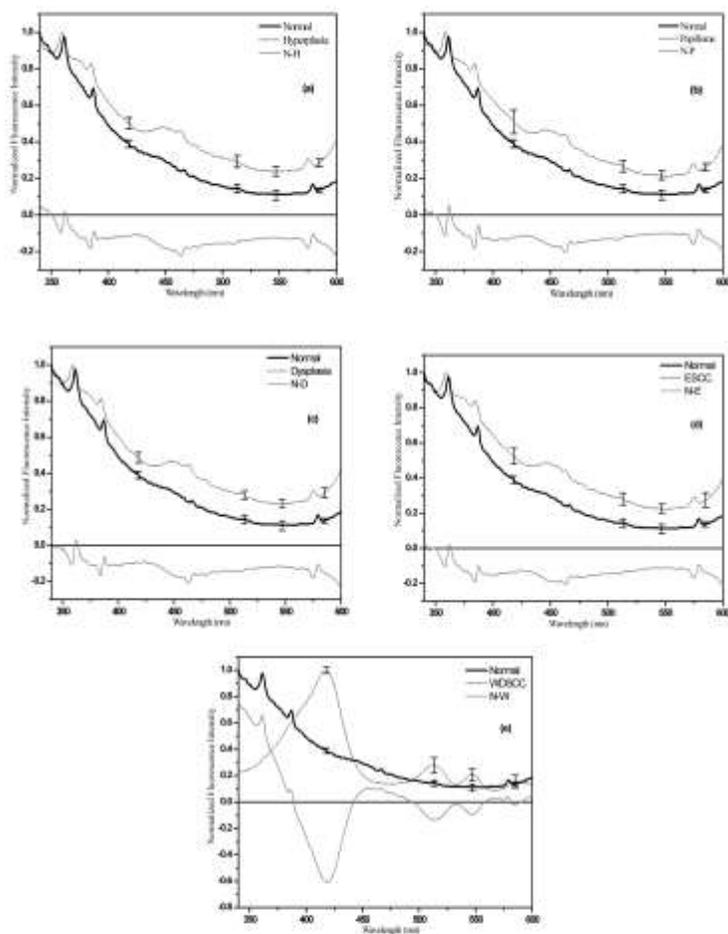

Fig. 3 Normalized average fluorescence excitation spectra of normal and DMBA treated skin lesions under different stages of tissue transformation conditions such as (a) hyperplasia, (b) papilloma, (c) dysplasia, (d) ESCC, (e) WDSCC with their corresponding difference spectrum at 635 nm emission.

184x260mm (300 x 300 DPI)

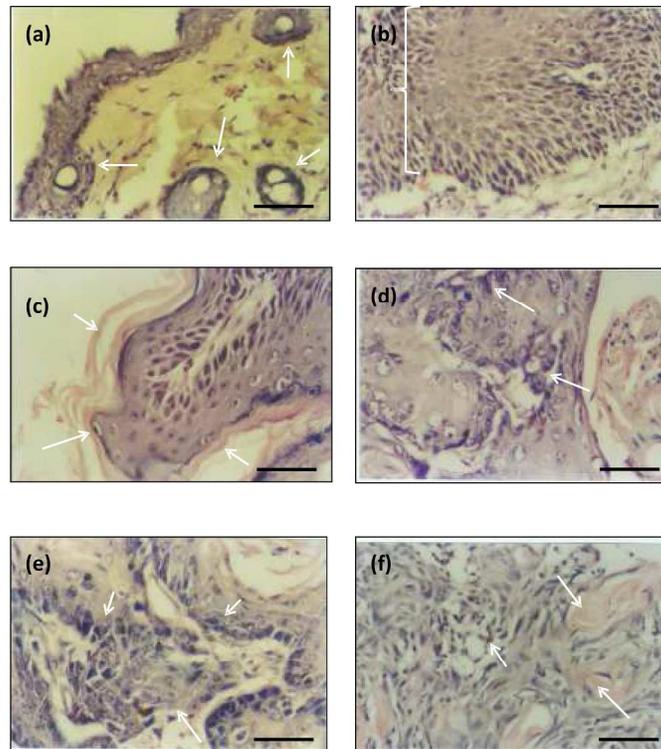

Fig. 4 H & E stained mouse skin before and after DMBA application. (a) Normal mouse skin without any DMBA application. The arrow marks shows normal epidermis and dermis with numerous hair follicles, (b) Hyperplasia. The bracket shows an increased thickness of epithelium which indicates moderate hyperplasia (c) Papilloma. It indicates papillomatous proliferation of the epidermis with hyperkeratinisation (d) Dysplasia. Dysplastic stratified squamous epithelium. The arrow shows hyperchromatic stained nucleus and dysplastic basal cells (e) Early invasive squamous cell carcinoma (ESCC). The arrow marks indicates dysplastic epithelial basal cells breaching the basement membrane forming epithelial island. (f) Well differentiated squamous cell carcinoma (WDSCC). It shows atypical mitotic figures and keratin pearls formation. The scale bar shown in the pictures corresponds to 50 μ m.

188x257mm (300 x 300 DPI)

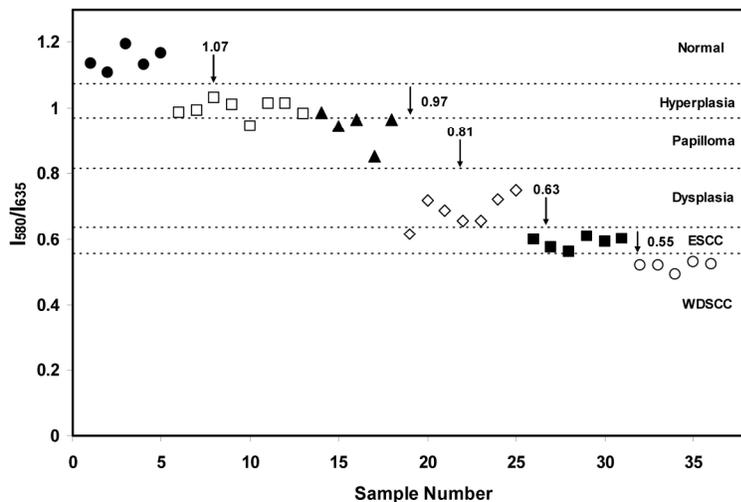

Fig. 5 Scatter plot for intensity ratio of I_{580}/I_{635} at 405 nm excitation for Normal (●), Hyperplasia (□), Papilloma (▲), Dysplasia (◇), ESCC (■) and WDSCC (○) correlating with histopathologic results of the 36 mice skin. The discrimination value (1.07) separates hyperplasia from normal, the discrimination value (0.97) separates papilloma from hyperplasia, the discrimination value (0.81) separates dysplasia from papilloma, discrimination value (0.63) separates ESCC from dysplasia, and the discrimination value (0.55) separates WDSCC from ESCC.

178x170mm (300 x 300 DPI)

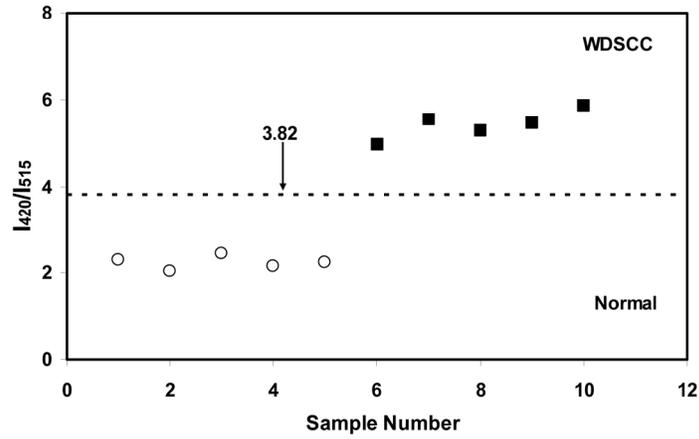

Fig. 6 Scatter plot for intensity ratio of I_{420}/I_{515} at 635 nm emission for Normal (●) and WDSCC (■) correlating with histopathologic results of the 10 mice skin. The discrimination value (3.82) separates WDSCC from normal.

174x137mm (300 x 300 DPI)

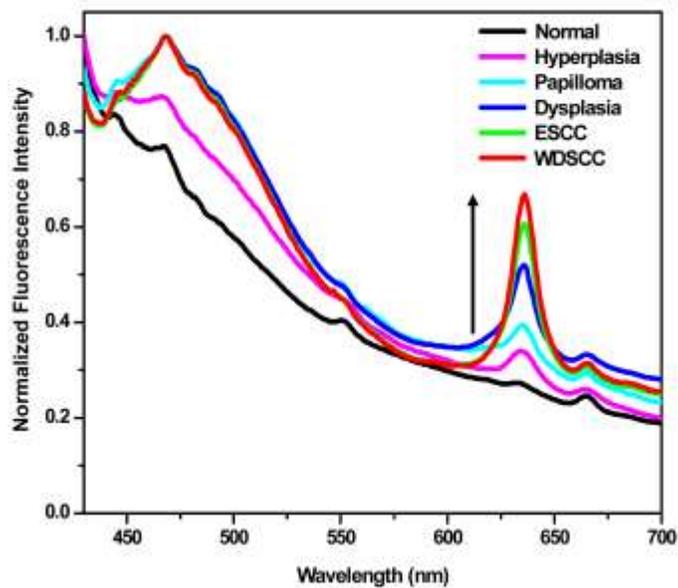

Fig. 7 Normalized average overall emission spectrum of normal and different tissue transformation of mice skin at 405 nm excitation. The arrow indicates the increasing porphyrin emission as a function of different tissue transformation.

170x166mm (300 x 300 DPI)
