Accepted Manuscript

This is an *Accepted Manuscript*, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this *Accepted Manuscript* with the edited and formatted *Advance Article* as soon as it is available.

You can find more information about *Accepted Manuscripts* in the [Information for Authors](#).

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal's standard [Terms & Conditions](#) and the [Ethical guidelines](#) still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this *Accepted Manuscript* or any consequences arising from the use of any information it contains.

6 22 Accurate measurements of neodymium isotope ratios in irradiated nuclear fuel samples are
7
8 23 fundamental for the validation of neutronic calculation codes, in particular for burn-up
9
10 24 qualification. To prevent possible spectral and non-spectral interferences, neodymium is
11
12 25 generally purified from the complex sample matrices prior to measurements by mass
13
14 26 spectrometric techniques. This work describes the on-line coupling of ion exchange
15
16 27 chromatography with a multi-collector inductively coupled plasma mass spectrometer for Nd
17
18 28 isotope ratio measurements. In the first part of the paper, the causes of the isotope ratio drifts
19
20 29 traditionally observed during transient signal acquisitions are investigated. Both mass-
21
22 30 dependent isotopic fractionation on the chromatographic column and distinct time lags
23
24 31 between amplifier responses of the Faraday cup configuration were shown to be the main
25
26 32 phenomena involved in the observed isotope ratio drifts. In the second part, we present a new
27
28 33 approach for mass bias correction called “Intra Injection Sample-Standard Bracketing
29
30 34 (IISB)” based on direct “on-line” injection of the standard via the chromatographic system
31
32 35 before and after the analyte. This new method, particularly adapted to analysis of nuclear
33
34 36 materials, was validated by on-line measurements on a simulated sample representative of
35
36 37 fission products present in an irradiated uranium material. Reproducibilities obtained by
37
38 38 IISB were found to be comparable with those found in off-line measurements and classical
39
40 39 sample-standard bracketing technique for mass bias correction on all Nd isotope ratios.

1. Introduction

In the nuclear research field, the precise knowledge of the isotopic composition of actinides and fission products and their atomic ratios with respect to uranium is mandatory to improve the nuclear fuel management and neutronic calculation code qualification. The main requirement is to obtain the best accuracy of elemental and isotope ratio determination. Mass spectrometry techniques involving multiple collector systems such as thermal ionization mass spectrometry (TIMS) and multiple collector inductively coupled plasma mass spectrometry (MC-ICPMS) have the capability of very accurately measuring isotope ratios. These mass spectrometric measurements are generally subsequent to a chromatographic elemental separation procedure¹⁻⁴ to prevent possible spectral (isobaric, polyatomic or doubly charged) and non-spectral (matrix effects) interferences on the element of interest.

Nd is one of the fission products present in nuclear fuel samples or irradiated uranium and/or plutonium materials and is a precise burn-up indicator (degree of fuel consumption)⁵⁻⁷.

Therefore, Nd isotope ratios (all Nd isotopes are of interest in the nuclear field for various purposes) are determined routinely in nuclear fuel samples or irradiated actinide materials^{8, 9}.

In our laboratory, Nd is usually isolated from the complex nuclear sample matrix using a two-step chromatographic separation procedure^{3, 10}. The first step leads to the chemical purification by gravitational chromatography of U and Pu from the sample. The second step aims at individual isolation by High Performance Liquid Chromatography (HPLC) of Nd and other analytes of interest from the complex residual Fission Products/Minor Actinides fraction (FP fraction).

On-line coupling of liquid chromatography to an inductively coupled plasma mass spectrometer (ICP-MS) is a well-established method to reduce the handling time and consequently the analyst's exposure to radiation in the case of radioactive samples. Several

1
2
3 70 applications of coupling between ion chromatography (IC) and quadrupole inductively
4
5 71 coupled plasma mass spectrometry (Q-ICPMS) for lanthanides are reported in the literature¹,
6
7 72 ¹¹⁻¹⁴. To obtain accurate measurements of Nd isotope ratios, the coupling between IC and
8
9
10 73 multiple collector inductively coupled plasma mass spectrometry (MC-ICPMS) is one of the
11
12 74 most attractive approaches for nuclear¹⁵ and geochemical applications¹⁶. However, the
13
14 75 acquisition of transient signals has been found to be challenging compared with continuous
15
16 76 ones. A drift of the isotope ratios is classically observed during transient signal acquisition as
17
18 77 well as a significant decrease of the external precision of isotope ratios ¹⁷⁻²³. The origins of
19
20 78 this drift is a matter of debate, and both instrumentation and/or separation devices (HPLC, and
21
22 79 gas chromatography (GC)) can be involved depending on the configuration. In addition,
23
24 80 internal normalization for mass bias correction cannot be applied on nuclear samples because
25
26 81 no invariant ratios are available^{15, 24}. Therefore, bracketing procedures with successive
27
28 82 injections of standard – sample – standard in HPLC/MC-ICPMS coupling are often applied
29
30 83 for this purpose^{15, 18}.

31
32
33
34
35 84 In this study, the performances of an LC-MC-ICPMS coupling were tested in the case of Nd
36
37 85 isotope ratio measurements in simulated fission product fraction from a ²³⁵U irradiated target.
38
39 86 In a first step, the possible causes of the isotope ratio drift observed during transient signal
40
41 87 acquisition at our particular instrumental settings were investigated. We then present a new
42
43 88 approach called Intra Injection Sample-Standard Bracketing (IISB) for mass bias correction
44
45 89 based on the injection of a reference standard before and after the Nd elution peak. The
46
47 90 reproducibility obtained on the Nd isotope ratio measurements using different methods of data
48
49 91 treatment^{25, 26} is discussed.

2. Materials and methods

2.1. Reference materials and reagents

Isotopic reference material. For Nd isotopic measurements, the *JNdi-1* standard solution was used²⁷. This material is qualified for its $^{143}\text{Nd}/^{144}\text{Nd}$ isotope ratio and is especially employed in geochemical applications. In irradiated materials, all Nd isotope ratios have to be measured. Reference values of isotope ratios are generally qualified by TIMS using the total evaporation method^{28, 29}. In this study, we used the *JNdi-1* values obtained by Wakaki et al.²⁹ and using the normalization ratio $^{146}\text{Nd}/^{144}\text{Nd} = 0.72333$ defined by the total evaporation method²⁸. These reference values, used for mass bias correction in the present study, are listed in Table 1.

Elemental solutions. Solutions were prepared daily by appropriate dilution of the $10^3 \mu\text{g}\cdot\text{mL}^{-1}$ individual stock standard solutions of Mo, Ru, Gd, Eu, Sm, Cs, Nd, Pr, Ce, La and Sr (from Specpure[®], Schiltigheim, France). All sample dilutions were performed with 0.5M HNO_3 obtained from 65% ultra-pure nitric acid (Suprapur from Merck, Darmstadt, Germany) and de-ionized water (Milli-Q system, Millipore, Milford, USA). The chromatographic eluent for lanthanide separation was prepared daily by dissolution of 2-hydroxy-2-methylbutyric acid HMB (Sigma–Aldrich, Saint-Quentin-Fallavier, France) in purified water. The pH of the mobile phase was adjusted with a 25% ammonia solution (Merck, Darmstadt, Germany).

2.2. Instrumentation

2.2.1. High Performance Liquid Chromatography (HPLC)

The lanthanide separation was performed with a chromatographic system composed of a binary analytical pump (ICS 5000 Dionex) combined with an analytical column, LUNA SCX

1
2
3 119 and a guard column (Phenomenex, Torrance, CA, USA). The column diameter was 4.6 mm
4
5 120 and different column lengths were used (250, 150, 50 mm). The stationary phase consisted of
6
7 121 silica bonded with benzene sulfonic acid groups from the same batch. The particle size was 5
8
9 122 μm . All tubings were in polyetheretherketone (PEEK). The samples were injected using a six-
10
11 123 way Rheodyne valve. All parameters of the chromatographic system and the separation
12
13 124 conditions are listed in Table 2.

17 125 **2.2.2. MC-ICPMS**

18
19 126 Nd isotope ratios were determined on a *NEPTUNE Plus* MC-ICPMS (Thermo Scientific,
20
21 127 Bremen, Germany), modified in order to accommodate a glove box around the ion source.
22
23 128 Operating parameters are detailed in Table 2. The analyses were conducted at low mass
24
25 129 resolution and in static mode. Faraday cups were positioned in order to simultaneously
26
27 130 measure the seven Nd isotopes and to correct for potential Ce and Sm isobaric interferences
28
29 131 by monitoring ^{140}Ce and ^{147}Sm (Table 2).

30
31
32
33
34 132 *Continuous mode.* A stable introduction system (SIS) composed of a $100 \mu\text{l}\cdot\text{min}^{-1}$
35
36 133 microconcentric PFA nebulizer (Elemental Scientific, ESI, USA) mounted onto a tandem
37
38 134 quartz spray chamber arrangement (cyclonic + Scott double pass) was used. The sensitivity
39
40 135 was optimized on a daily basis for maximum intensity and stability. In SIS mode, the
41
42 136 sensitivity was around 70V/ppm for Nd during the analytical sessions and the Nd acquisition
43
44 137 method consisted of 50 integrations (5 blocks of 10 cycles) with an integration time of 8.4s,
45
46 138 and removal of outliers using a 2σ test. Further data treatment was performed off line. The
47
48 139 instrumental mass fractionation (mass bias) was corrected by classical Sample Standard
49
50 140 Bracketing (SSB) using an exponential fractionation law³⁰. Concentrations of samples and
51
52 141 bracketing standards were matched to within 20%. The results and reproducibility obtained on
53
54 142 the *JNdi-1* standard with this approach during the analytical sessions are presented in Table 1.
55
56
57
58
59
60

1
2
3 143 *Hyphenated mode*. To adapt the flow rate between the chromatographic column and the
4
5 144 ICPMS, the column output tubing was split using a “Y” connection. Only 10% of the flow
6
7 145 was sent to the MC-ICPMS via a 100 $\mu\text{L}\cdot\text{min}^{-1}$ pneumatic glass concentric nebulizer
8
9 146 (Meinhard Glass Product, Golden, USA). (Figure 1A). For transient signals, the acquisition
10
11 147 time was set at 0.262s (discussed later).

12
13
14 148 For isotope ratio drift investigations on transient signals, some experiments were performed
15
16 149 by flow injection analysis (FIA). In this case, a six-way Rheodyne valve was directly coupled
17
18 150 to the nebulizer of the MC-ICPMS.

19
20
21 151 For the implementation of the IISSB approach for mass bias correction, a particular
22
23 152 instrumental setting called “dual inlet LC-MC-ICPMS” was developed (Fig. 1B). This system
24
25 153 rendered it possible to inject the reference standard at a 1 $\text{mL}\cdot\text{min}^{-1}$ flow rate using a second
26
27 154 chromatographic pump, at selected steps of the elution (before and after Nd elution peak). In
28
29 155 this case, a second six-way Rheodyne valve was used and the split ratio was modified in order
30
31 156 to send only 5% of the flow to the ICP. As for the continuous mode, both sample and
32
33 157 bracketing standard concentrations were matched to within 20%.

34 35 36 37 38 158 **2.2.3. Q-ICPMS**

39
40
41 159 A quadrupole inductively coupled plasma mass spectrometer X series II (Thermo Electron,
42
43 160 Winsford, UK) was used for elemental determinations. Sample introduction was performed
44
45 161 with a pneumatic quartz concentric nebulizer ($0.4 \text{ mL}\cdot\text{min}^{-1}$) connected to a quartz cyclonic
46
47 162 spray chamber and using a PC³ Peltier Chiller (Elemental Scientific, ESI, USA). The
48
49 163 instrument was optimized daily with a 1 $\text{ng}\cdot\text{g}^{-1}$ multi-element test solution in order to obtain
50
51 164 the maximum counting rates and stability on ^{115}In and ^{238}U signals. The key parameters
52
53 165 (sensitivity, stability, and oxide level) were verified daily. The employed Q-ICPMS
54
55 166 instrumental parameters are summarized in Table 2.

167

3. Results and discussion

169

3.1. Drift phenomenon investigations

171 Previous studies performed when coupling LC and MC-ICPMS have shown isotope ratio drift
172 during acquisition on transient signals (see²² and reference therein). This phenomenon largely
173 detailed in the literature is generally ascribed to a variety of sources (such as mostly variable
174 time responses between Faraday amplifiers³¹, isotope fractionation during separation³², ...)
175 without an assessment of their individual contribution.

176 First, the acquisition of Nd isotope ratios on transient signals with our coupling was studied.
177 A single elemental solution of *JNdi-1* was injected in the chromatographic column (length
178 250 mm) at a concentration of 50 $\mu\text{g}\cdot\text{g}^{-1}$ which corresponds to an injected mass of 500 ng
179 (injection volume of 10 μl). Considering the split conditions, about 50 ng of Nd was sent to
180 the ICPMS (Figure 1A). The maximum intensity collected on the ^{142}Nd isotope was 30 volts.
181 Considering that the maximum signals collected were higher than 5 volts at the peak apex for
182 all isotopes, baseline contributions were negligible, and a 10 mV signal threshold on the ^{142}Nd
183 isotope was chosen for the beginning of the data treatment (baseline of the ^{142}Nd isotope was
184 around 0.5 mV before the elution peak).

185 The integration time was set at 0.262 s corresponding to roughly 400 data points for each
186 elution peak. Different integration times (0.008 s to 1.049 s) were tested with no effect on the
187 amplitude of the drift. Figure 2 displays the $^{143}\text{Nd}/^{144}\text{Nd}$ isotope ratio and ^{144}Nd signal as a
188 function of the elution time. A significant drift phenomenon was observed for the $^{143}\text{Nd}/^{144}\text{Nd}$
189 ratio along the elution peak. The amplitude of the drift for this ratio was graphically estimated
190 to about 4.2% per amu. This drift amplitude of the isotope ratio was also evaluated for the

1
2
3 191 other Nd isotope ratios and was found to vary from 1.4‰ to 8.9‰ (Supplementary
4
5 192 information (SI), Figure S1) with no mass dependency observed. Investigations performed to
6
7 193 understand the dominant sources of these variations are described below.

10 194 3.1.1. Isotope fractionation on the chromatographic column

11
12 195
13
14 196 Previous studies have revealed that the chromatographic separation technique can be a source
15
16 197 of isotope fractionation of Nd isotopes during elution. On gravitational cationic exchange
17
18 198 resin (BioRad AG 50WX8) and when using HIBA as a complexing agent, an amplitude of
19
20 199 isotope fractionations around 0.7‰ per amu was observed²⁹. Another study³³ has
21
22 200 demonstrated a slight Nd isotope fractionation (<0.1‰ per amu) using a combination of TRU
23
24 201 and Ln Spec (Eichrom) resins with HNO₃ as the eluent. Furthermore, it is well documented
25
26 202 that band displacement chromatography is an efficient process to obtain enriched isotopes.
27
28 203 There are also reports of the separation of Ce, Nd and Gd isotopes using various cationic
29
30 204 exchange resins at several migration lengths and using different eluents³⁴⁻³⁹.

31
32
33
34
35 205 The possible extent of Nd isotope fractionation in the chromatographic system was then
36
37 206 evaluated. A drop-wise Nd fraction recovery was performed along the elution peak in order to
38
39 207 constrain only the drift phenomenon induced by the separation. Experiments were carried out
40
41 208 using different column lengths (250 mm, 150 mm and 50 mm) with the same diameter (4.6
42
43 209 mm) and the same batch of stationary phase. The flow rate was the same for the three
44
45 210 columns (1 ml.min⁻¹).

46
47
48
49 211 For these experiments, five µg of the *JNdi-1* solution were injected in the chromatographic
50
51 212 columns using the setup presented in Figure 1A. Drop-by-drop recovery was performed along
52
53 213 the Nd chromatographic peak. Depending on column lengths (250, 150 and 50 mm) 13, 14
54
55 214 and 23 drops were respectively recovered. Each drop was evaporated dry before dilution in

1
2
3 215 HNO₃ 0.5M in order to prevent from potential matrix effect due to organic acid. Each solution
4
5 216 was characterized for its Nd concentration in a semi-quantitative way (~20% uncertainty) by
6
7 217 Q-ICPMS. One µl of solution was diluted in HNO₃ 0.5M and analyzed by Q-ICPMS by
8
9
10 218 external calibration using an Nd Spex single element standard solution. Each solution was
11
12 219 also adjusted in concentration to 50 ng.g⁻¹ and Nd isotope ratios were performed by SIS-MC-
13
14 220 ICPMS on the Neptune Plus MC-ICPMS. The instrumental mass bias was corrected using
15
16 221 classical Sample-Standard Bracketing (SSB) with the *JNdi-1* reference standard solution.
17
18

19 222 The results for mass concentration and ¹⁴³Nd/¹⁴⁴Nd and ¹⁴⁸Nd/¹⁴⁴Nd isotope ratios obtained
20
21 223 for each drop on the 250-mm chromatographic column are presented in Figure 3. The
22
23 224 ¹⁴³Nd/¹⁴⁴Nd ratio variation from lower values at the early stage of elution to higher values at
24
25
26 225 the late stage corresponding to a variation of around 2.4‰ per amu indicate a preferential
27
28 226 elution of heavy isotopes. Conversely, the ¹⁴⁸Nd/¹⁴⁴Nd ratios varied from higher to lower
29
30 227 values corresponding to a similar variation of around 2.4‰ per amu suggesting a mass-
31
32 228 dependent isotopic fractionation confirmed in the three-isotope plots (Figure 4).
33
34

35
36 229 Three independent injections and drop recuperations were performed and the uncertainty on
37
38 230 the amplitude variation per amu was estimated to be 0.2 ‰. The ¹⁴³Nd/¹⁴⁴Nd isotope ratio
39
40 231 calculated by mass balance between the 13 drops corresponded to a value of 0.51161
41
42 232 (uncertainty not evaluated) in agreement with reference value²⁹, demonstrating a complete Nd
43
44 233 recovery.
45
46

47 234 Beta values for experimental, equilibrium and kinetic laws⁴⁰ were evaluated and no clear
48
49 235 conclusions could be drawn relative to the isotope fractionation mechanisms. For the shorter
50
51 236 columns (150 mm and 50 mm), the amplitude of fractionation was evaluated at 1.8‰ and
52
53 237 1.4‰ on the ¹⁴³Nd/¹⁴⁴Nd ratio, respectively. As mass dependent isotope fractionation was
54
55
56 238 confirmed in all three isotope plot diagrams, this indicated that mass fractionation was
57
58
59
60

1
2
3 239 dependent on the length of the column. The amplitudes of fractionation observed were larger
4
5 240 than those observed on gravitational ion-exchange chromatography^{29, 33}. This high amplitude
6
7 241 might be linked to the higher number of theoretical plates involved in our HPLC column
8
9 242 (about 1000 times higher than in typical gravitational chromatography).

11
12 243 These experiments clearly revealed that mass-dependent isotopic fractionation, with elution of
13
14 244 heavier isotopes earlier than the lighter, can be considered as a significant source of isotope
15
16 245 ratio drifts during transient signal acquisition in our system. However, as the final observed
17
18 246 drifts (Figure S1) were not purely mass-dependent, other potential drift sources were
19
20 247 investigated.

24 248 3.1.2. Delay lag of Faraday cup amplifiers

26
27
28 249 Among the other potential sources of isotope ratio drift is the slow and variable time response
29
30 250 of the amplifier system of the Faraday cups against changes of the input ion signal. A recent
31
32 251 study³¹ has demonstrated that during transient acquisition the slight time lags between
33
34 252 amplifiers involved in the Faraday detector array were able to generate significant isotope
35
36 253 ratio drifts. This demonstration was based on experiments performed by flow injection
37
38 254 connected to a demountable direct injection high efficiency nebulizer (d-DIHEN) on a
39
40 255 Neptune MC-ICPMS.

42
43
44 256 The Neptune MC-ICPMS offers the possibility of virtually assigning any amplifiers to any
45
46 257 Faraday cups. Therefore, some experiments were performed with the Neptune Plus instrument
47
48 258 by switching the amplifiers on the same couple of Faraday cups for different injections. The
49
50 259 results are presented in Figure 5. For these experiments, the *JNdi-1* standard was injected in
51
52 260 the chromatographic column (250 mm) and ¹⁴³Nd and ¹⁴⁴Nd signals were collected on L2 and
53
54 261 L1 Faraday cups. In Figure 5A, L2 and L1 were assigned to amplifiers OA2 and OA4
55
56 262 respectively and a drift amplitude of about 4.9‰ was observed with a positive slope. For the
57
58
59
60

1
2
3 263 next injection, OA2 and OA4 were switched between L2 and L1 and an inversed drift slope
4
5 264 (negative slope) with significantly lower amplitude was seen (Figure 5C). In Figure 5E, OA4
6
7 265 was replaced by OA3 on the L1 Faraday cup and the amplitude of the observed drift was then
8
9 266 around 2.2‰ (again with a positive slope). This indicates that the amplitude of the drift was
10
11 267 dependent on the amplifiers used. These experiments clearly confirm that individual amplifier
12
13 268 time lags have a significant impact on the observed drifts.

14
15
16
17 269 To estimate the time lags between the three amplifiers used, Nd was injected by flow injection
18
19 270 (the rheodyne injection valve was directly connected to the nebulizer of the MC-ICPMS) in
20
21 271 order to suppress the contribution of the drift due to column fractionation. The results are
22
23 272 presented in Figure 5B, D and F. Figure 5B shows the ^{143}Nd and ^{144}Nd signals respectively
24
25 273 acquired with L2 and L1 Faraday cups with OA2 and OA4 amplifiers. In this configuration,
26
27 274 the ^{144}Nd signal was acquired in advance relative to ^{143}Nd . This suggests that the OA4
28
29 275 amplifier had a faster response than the OA2 amplifier in our instrument. When switching
30
31 276 these two amplifiers between L2 and L1, reverse drift was observed (Figure 5D). Using the
32
33 277 Exponential Modified Gaussian model (EMG)⁴¹, the elution profile of each isotope was fitted
34
35 278 in order to precisely assess the elution time at their peak apex. The slight differences between
36
37 279 each elution time at the maximum of the isotope peaks were directly related to the time lags
38
39 280 between the amplifiers. For OA2 and OA4, this delay was about 5 ms. Likewise, using OA2
40
41 281 and OA3 amplifiers on L2 and L1 faraday cups (Figure 5F), the drift was reduced and the
42
43 282 time lag between OA2 and OA3 was estimated to 0.5 ms. These observations confirmed the
44
45 283 range of time lag previously observed by direct injection on another Neptune MC-ICPMS
46
47 284 instrument³¹. According to future technological developments, this phenomenon might be
48
49 285 reduced in the future.

50
51
52
53
54
55
56 286 The first part of this paper has demonstrated that both mass-dependent column fractionation
57
58 287 and time lags between amplifiers can explain in our setting the magnitude and the non-mass

1
2
3 288 dependent drifts observed during our LC-MC-ICPMS experiments (Figure S1). Investigations
4
5 289 on data treatment (peak area integration²⁵ or linear slope regression methods²⁶) to compensate
6
7 290 these drifts as well as instrumental mass bias corrections methods are presented in the next
8
9
10 291 part.

292 3.2. Results on Nd ratio measurements by LC-MC-ICPMS

11
12
13
14
15 293
16
17 294 Experiments were performed on a simulated sample representative of the fission products
18
19 295 fraction present in a ²³⁵U transmutation target irradiated in a French nuclear reactor^{42, 43}.
20
21 296 These experiments required accurate Nd isotope ratios for use of fission monitors^{44, 45}. A mass
22
23 297 spectra obtained by Q-ICPMS in the m/z= 80-160 mass range on the real FP fraction in the
24
25 298 ²³⁵U target is presented in supplementary information (Figure S2). Conventionally in the
26
27 299 laboratory, Nd isotope ratios are determined after separation (of the FP fraction) by HPLC on
30
31 300 a LUNA SCX column⁴⁶ and Nd fractions are collected and analyzed off line by TIMS or MC-
32
33 301 ICPMS. The uncertainties targeted for such analyses are around 0.2% for all isotope ratios¹⁰.
34
35 302 A simulated solution containing lanthanides and metallic elements present in the fission
36
37 303 product fraction (Sr, Mo, Ru, Cs, La, Ce, Pr, Nd, Sm, Eu and Gd) and in the same mass
38
39 304 proportion as those found in the irradiated ²³⁵U target was prepared.

40 41 42 305 3.2.1. Chromatographic conditions

43
44
45 306 The elution conditions have been adjusted, especially the gradient slope, in order to reduce the
46
47 307 analytical time while presenting a resolution of at least 2 between Nd and its neighboring
48
49 308 peaks (Sm and Ce). In FP fractions, Sm interferes with Nd at masses 148 and 150 and Ce
50
51 309 interferes with Nd at masses 142 and 144. A resolution of two means that peak overlapping
52
53 310 was lower than 0.05%. The linear gradient started at the time of the injection (t=0 min, 100%
54
55 311 of HMB 0.1M, pH=3.6) and at the end of the program (t=35 min) there was 100% of the
56
57 312 second eluent (HMB 0.2M, pH=4.5). The separation obtained under these conditions and
58
59
60

1
2
3 313 using a Q-ICPMS as the detector is presented in Figure 7. The 11 elements were separated in
4
5 314 the following elution order: Mo, Ru, Gd, Eu, Sm, Cs, Nd, Pr, Ce, La and Sr. Nd was eluted
6
7 315 after 15 minutes and was separated from its potential interferents Sm ($t_{\text{elution}}=11$ minutes) and
8
9 316 Ce ($t_{\text{elution}}=20$ minutes). As shown in Figure 6, the Nd elution peak was included in the
10
11 317 decreasing part of the Cs peak with no consequence as Nd and Cs isotopes do not interfere.

14 318 3.2.2. Mass bias correction approach

15
16
17 319 Since there is no invariant ratio usable for Nd in an irradiated sample, the internal mass bias
18
19 320 correction traditionally performed in geochemical applications⁴⁷ cannot be applied to nuclear
20
21 321 samples^{15, 18, 24}. In the nuclear field, the most conventional approach is the SSB. To
22
23 322 compensate for the matrix effect previously observed in the literature¹⁸, the reference standard
24
25 323 has to be injected via the LC system in the same conditions as the sample⁴⁸. In addition for
26
27 324 optimal performance this approach requires a short analysis time between the sample and the
28
29 325 two standards.

30
31
32
33 326 To optimize both bracketing standard injections and gradient matching, a new approach called
34
35 327 Intra Injection Sample-Standard Bracketing (IISB) was developed. For this purpose, a
36
37 328 rheodyne valve controlled by a second chromatographic pump was added in order to inject the
38
39 329 standards during the elution (Figure 1B). The chromatographic system was set to guarantee a
40
41 330 perfect matrix matching between the separation flow (branch (a), Figure 1B) and the standard
42
43 331 flow (branch (b), Figure 1B). The start of the gradient in branch (b) was delayed for a period
44
45 332 of time corresponding to the difference in void volume between branch (a) and (b). By this
46
47 333 way, at the converging point of the two flows, the matrices were rigorously similar.

48
49
50
51 334 Some experiments were performed by injecting only the standard by branch (b) and no
52
53 335 significant variations of mass bias were observed regardless of the HMB concentration during
54
55 336 the elution gradient. To define the appropriate timing for injecting the Nd bracketing
56
57
58
59
60

1
2
3 337 standards before and after Nd elution peak (of the sample), baselines on Nd isotope signals
4
5 338 were carefully controlled. For the injection of the first standard, in order to minimize the
6
7 339 baseline contribution, it was essential that the Sm signals, that could interfere with the Nd
8
9 340 isotopes (^{144}Sm , ^{148}Sm , ^{150}Sm), had returned to the baseline values $< 1\text{mV}$. Following this, the
10
11 341 first Nd standard could be injected 1 minute after the Sm peak or 4 minutes before the Nd
12
13 342 peak sample (figure 7B). For the second injection, as there was not enough time for an
14
15 343 injection between Nd and Ce (isobaric interferences at masses 142 and 144 in nuclear fuel
16
17 344 samples), the Nd standard was thus injected just after the La peak (7 minutes after the Nd
18
19 345 peak).

20
21
22
23
24 34625
26
27 347 *3.2.3. Reproducibility on Nd isotope ratios*
28

29 348

30
31 349 Different methods of data treatment can traditionally be used for the determination of raw
32
33 350 isotope ratios on transient signals. Among these, the point by point (PbP), linear regression
34
35 351 slope (LRS) and peak area integration (PAI)^{22, 25, 26, 49} techniques have been intensively
36
37 352 compared in literature²². The LRS and PAI methods are used for transient signals because
38
39 353 they correct the isotope ratio drifts^{25, 26}. In the PbP and PAI methods, the background is taken
40
41 354 into account by subtracting the baseline before the elution of the peak. In our case, the
42
43 355 baseline corrections were negligible. In this work, the PbP and PAI calculation methods were
44
45 356 applied for the different zones of the peak, similarly to the approach previously described⁴⁹.
46
47
48 357 Considering the reproducibility and accuracy obtained at different zones of the peak, an
49
50 358 integration window of 95% was chosen for the PbP and PAI approaches. As the LRS method
51
52 359 does not require the selection of a specific percentage of the peak area²⁶, 100% of the peak
53
54
55 360 zone was considered.

1
2
3 361 Table 3 presents the results obtained on six injections of a ^{235}U simulated fraction containing
4
5 362 simulated Nd Spex solution (concentration of 500 ng.g^{-1}) on the chromatographic column.
6
7 363 Mass bias was corrected with the IISBB approach for all ratios using the *JNdi-1* solution.
8
9 364 Data on the bracketing standard and simulated sample were evaluated using the same data
10
11 365 treatment technique. The last column of the table lists the $^{143}\text{Nd}/^{144}\text{Nd}$ ratio as calculated by
12
13 366 internal mass bias correction using the $^{146}\text{Nd}/^{144}\text{Nd}$ ratio in order to carry out a comparison
14
15 367 with data obtained in previous studies¹⁶.

16
17
18
19 368 The results were compared with those obtained on the Nd Spex solution analyzed at a
20
21 369 concentration of 50 ng.g^{-1} on continuous signals corrected for mass bias by a classical SSB
22
23 370 approach. The isotope composition of the Nd Spex solution was different of the *JNdi-1*
24
25 371 isotopic standard composition in agreement with a previous study²⁹. According to Table 3, all
26
27 372 of the isotope ratios obtained by on-line measurements were in agreement with isotope ratios
28
29 373 measured off-line and no bias was observed. The LRS and PAI methods gave a better external
30
31 374 reproducibility than the PbP method. These results were in agreement with a previous
32
33 375 investigation²⁵. The best reproducibilities were obtained with LRS and were comparable to
34
35 376 those acquired by the off-line procedures. The interest of the IISBB approach using LRS
36
37 377 method of data treatment was demonstrated for application in the nuclear field.

38
39
40
41
42 378 Considering the $^{143}\text{Nd}/^{144}\text{Nd}$ ratio internally corrected for mass bias, the best reproducibility
43
44 379 was found using the LRS method and this reproducibility was only slightly larger than
45
46 380 counterparts obtained in continuous mode by a factor below two, which is in agreement with
47
48 381 previous Nd isotope ratios obtained in transient mode¹⁶.

49
50
51
52 382

53 54 383 **Conclusion**

55
56
57 384
58
59
60

1
2
3 385 The present article has described the coupling between a LUNA SCX chromatographic
4
5 386 column and a MC-ICPMS Neptune Plus for lanthanide separation and on-line Nd isotope ratio
6
7 387 measurements on nuclear samples. The first part of the study was dedicated to the
8
9 388 comprehension of isotope ratio drifts observed during transient signal acquisition with our
10
11 389 particular instrumental settings. In our chromatographic system, Nd isotope ratio variation due
12
13 390 to column fractionation was evaluated by collecting the column outlet of several Nd peak
14
15 391 fractions and analyses in continuous sample introduction mode. For the 250-mm column, 2.4
16
17 392 ± 0.2 ‰ per amu of isotopic drift was explained by isotopic fractionation on the column.
18
19 393 Subsequent tests performed by virtually assigning any amplifiers to any Faraday cups
20
21 394 confirmed that another contribution of isotope ratio drift was attributed to the different time
22
23 395 lags between amplifiers. Moreover, the amplitude of the drift was dependent on the amplifiers
24
25 396 used on each Faraday cup. Both mass-dependent column fractionation and the time lag
26
27 397 between amplifiers can mostly explain in our setting the magnitude and the non-mass
28
29 398 dependent drifts observed during our LC-MC-ICPMS experiments.

30
31
32
33
34
35 399 In a second part of the study, a new method for mass bias correction called Intra Injection
36
37 400 Sample-Standard Bracketing (IISB), based on the injection of an Nd reference standard
38
39 401 before and after the Nd elution peak, was proposed. The reproducibility obtained on all Nd
40
41 402 isotope ratios on a simulated ^{235}U FP fraction, using linear regression slope (LRS) and peak
42
43 403 area integration (PAI) methods of data treatment, was lower than 0.2% and comparable to
44
45 404 isotope ratio uncertainties obtained by an off-line procedure and Sample Standard Bracketing
46
47 405 (SSB) mass bias correction.

48
49
50
51 406 The feasibility and performances on such on-line Nd isotope ratio measurements have been
52
53 407 demonstrated as an alternative to off-line methods for nuclear samples. Further studies are
54
55 408 required to strengthen the performances of this procedure for applications on real samples.
56
57 409 This method is particularly attractive for reducing the analysis time and consequently the
58
59
60

1
2
3 410 analyst's exposure to radiation. Further developments are also required to reduce the waste
4
5 411 volumes of effluent by decreasing the flow rate of the chromatographic system
6
7 412 (chromatographic column and standard injection). An automation of the system may also be
8
9 413 envisaged as an optimization.

13
14 419 instrumentation.

17
18 420 **Table 3:** Results of Nd isotope ratios on an Nd Spex solution. Off-line data were obtained on
19
20 421 an Nd Spex solution and mass bias was corrected using an SSB approach. On-line data were
21
22 422 obtained on an Nd Spex doped with other elements (Sr, Mo, Ru, Cs, La, Ce, Pr, Sm, Eu and
23
24 423 Gd) and different methods of data treatment (peak area integration, linear slope regression and
25
26 424 point by point). Mass bias was corrected with the IISSB method using a *JNdi-I* solution. *
27
28 425 $^{143}\text{Nd}/^{144}\text{Nd}$ isotope ratio internally corrected using the value $^{146}\text{Nd}/^{144}\text{Nd}=0.72333$ ²⁸. The
29
30 426 uncertainties represents the standard deviation of the n measurements expressed at k=2.

33
34 427 **Figure 1:** Schematic diagrams of (a) the LC-MC-ICPMS system and (b) the dual inlet LC-
35
36 428 MC-ICPMS system with post-column addition of standard to perform intra injection mass
37
38 429 bias correction.

40
41 430 **Figure 2:** Elution profile of the ^{144}Nd signal (*JNdi-I* standard solution) by LC-MC-ICPMS in
42
43 431 gradient mode (integration time 0.262 s) and uncorrected $^{143}\text{Nd}/^{144}\text{Nd}$ isotope ratios across the
44
45 432 transient signals. The approximate amplitude of the drift was estimated by the variation of
46
47 433 isotope ratios between the two horizontal lines.

48
49 434 **Figure 3:** Nd concentration profile and $^{143}\text{Nd}/^{144}\text{Nd}$ and $^{148}\text{Nd}/^{144}\text{Nd}$ isotope ratios in the
50
51 435 eluted drops after chromatographic separation on the LUNA SCX column (l=250 mm). The
52
53 436 error bars for mass concentration correspond to a relative standard deviation equal to 20%.
54
55 437 The error bars for isotope ratio correspond to a relative standard deviation at k=2 of three
56
57
58
59
60

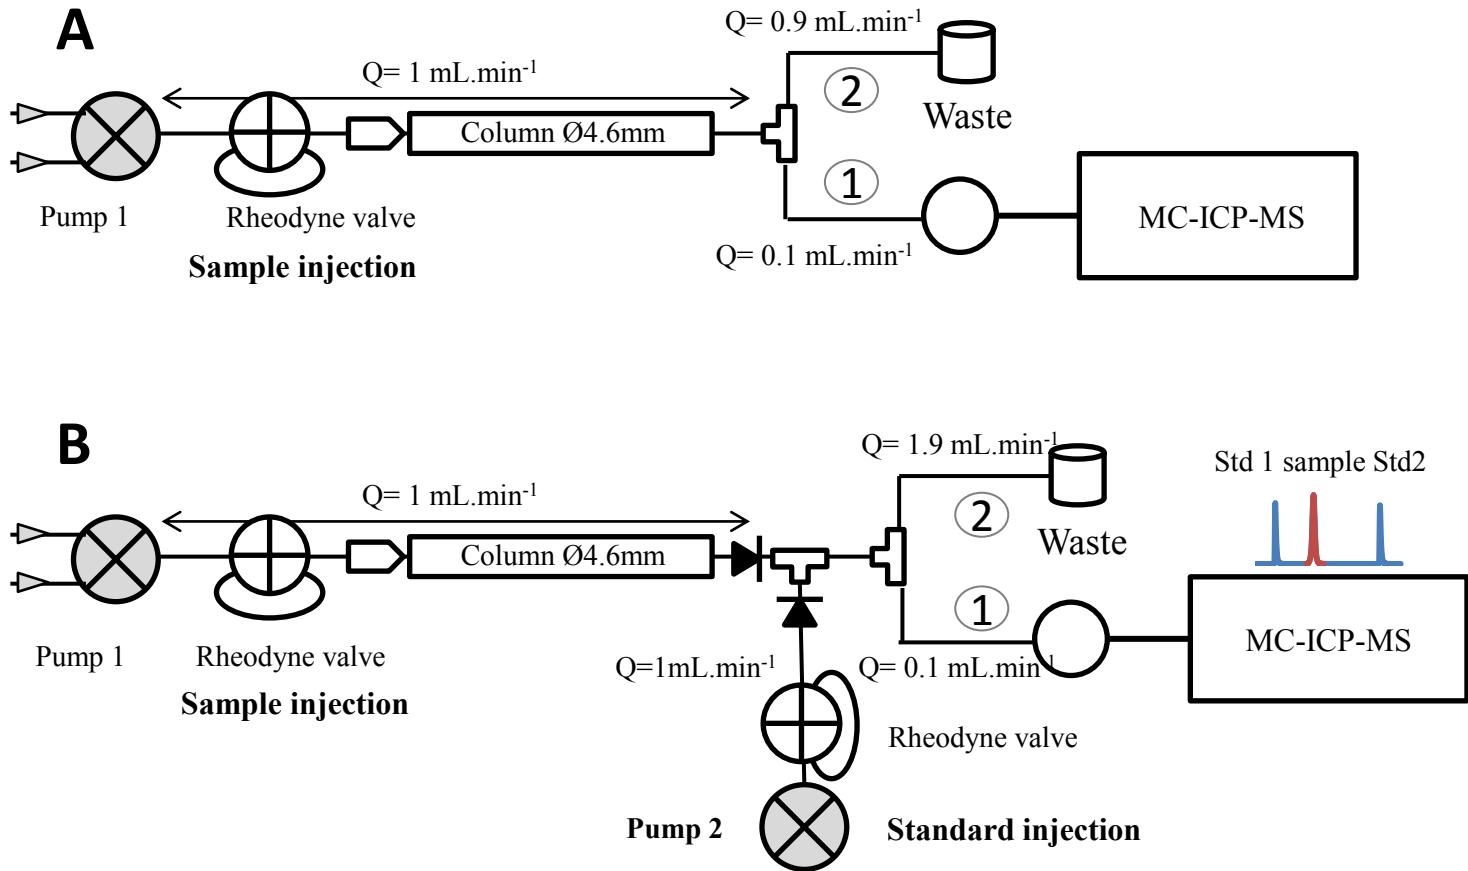

Figure 1: Schematic diagrams of (a) the LC-MC-ICPMS system and (b) the dual inlet LC-MC-ICPMS system with post-column addition of standard to perform intra injection mass bias correction.

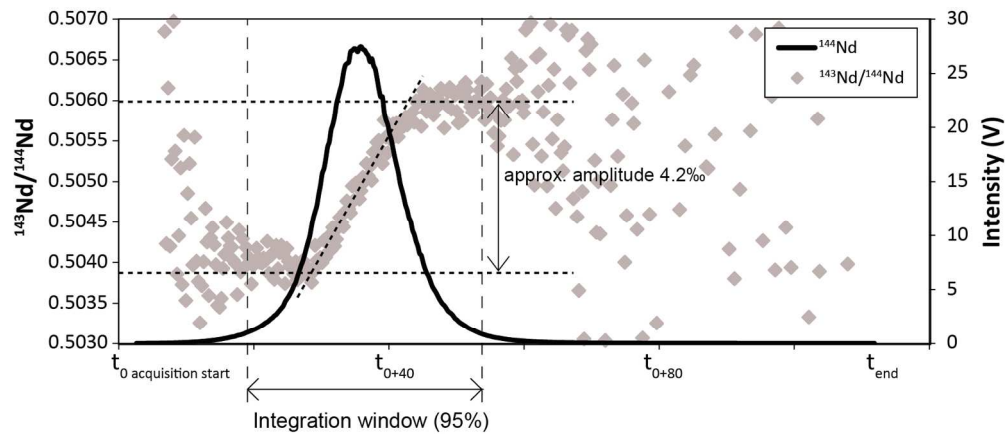

Figure 2: Elution profile of the ^{144}Nd signal (JNdi-1 standard solution) by LC-MC-ICPMS in gradient mode (integration time 0.262 s) and uncorrected $^{143}\text{Nd}/^{144}\text{Nd}$ isotope ratios across the transient signals. The approximate amplitude of the drift was estimated by the variation of isotope ratios between the two horizontal lines.

Figure 3: Nd concentration profile and $^{143}\text{Nd}/^{144}\text{Nd}$ and $^{148}\text{Nd}/^{144}\text{Nd}$ isotope ratios in the eluted drops after chromatographic separation on the LUNA SCX column ($l=250$ mm). The error bars for mass concentration correspond to a relative standard deviation equal to 20%. The error bars for isotope ratio correspond to a relative standard deviation at $k=2$ of three replicate analyses. The dotted lines represent the $^{143}\text{Nd}/^{144}\text{Nd}$ and $^{148}\text{Nd}/^{144}\text{Nd}$ reference values²⁹.

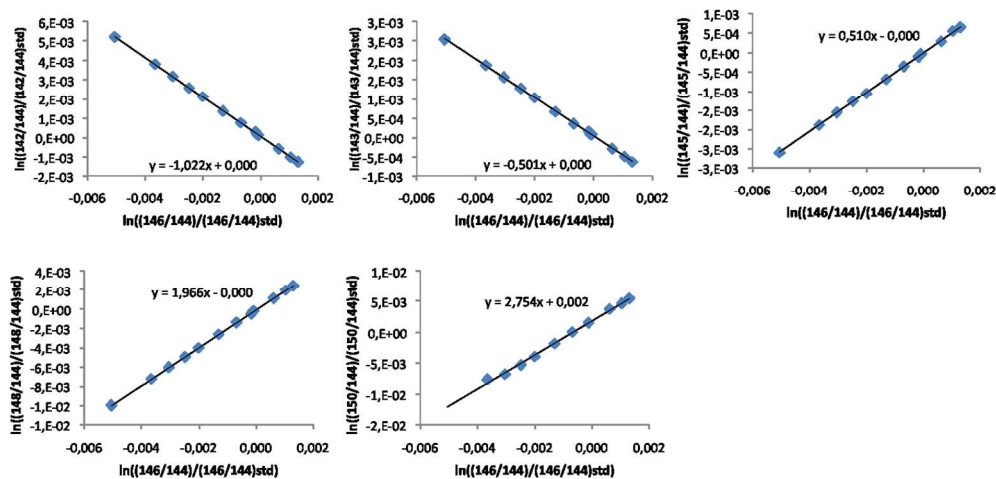

Figure 4: Three isotope plots of Nd isotope ratios using the approach developed by Young et al⁴⁰. The experimental mass-dependent fractionation of the $^{142}\text{Nd}/^{144}\text{Nd}$ and $^{146}\text{Nd}/^{144}\text{Nd}$ was a straight line. The slope of the linear regression line was equal to the fractionation exponent β . The uncertainty associated with the Nd isotope ratios was smaller than the data points.

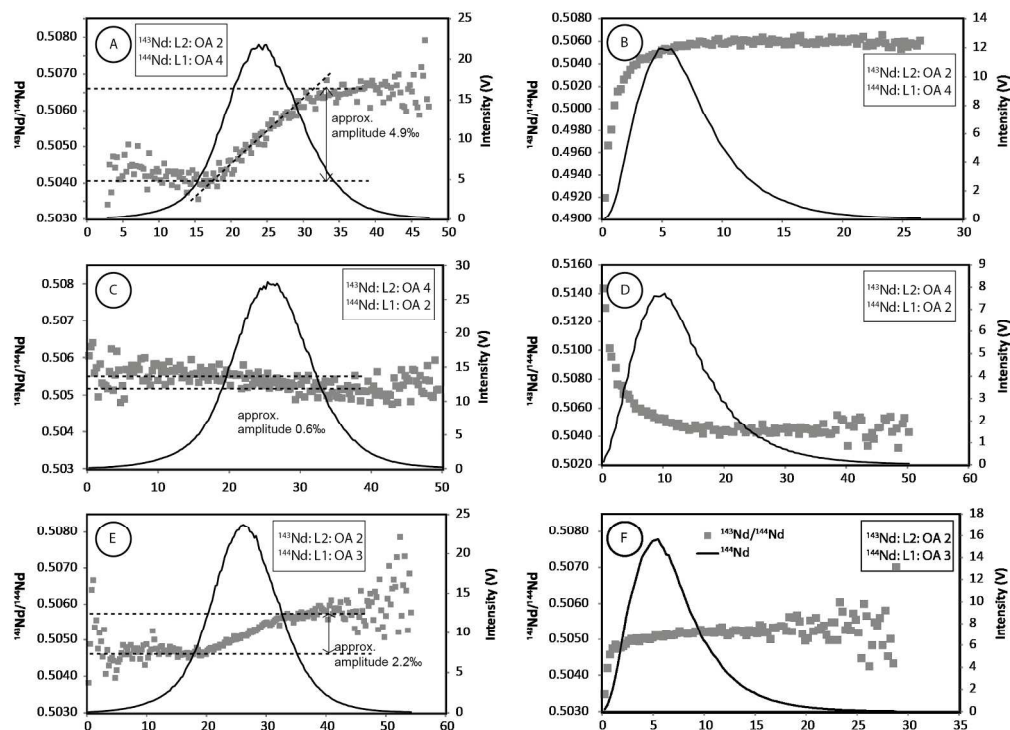

Figure 5: Uncorrected $^{143}\text{Nd}/^{144}\text{Nd}$ isotope ratio across the transient signals by LC-MC-ICPMS (A, C, E) and FIA (B, D, F). Different amplifiers were successively attributed to Faraday cups: configuration A and B: ^{143}Nd : OA2; ^{144}Nd OA 4; configuration C and D: ^{143}Nd : OA 4; ^{144}Nd OA 2; configuration E and F: ^{143}Nd : OA2; ^{144}Nd OA 3.

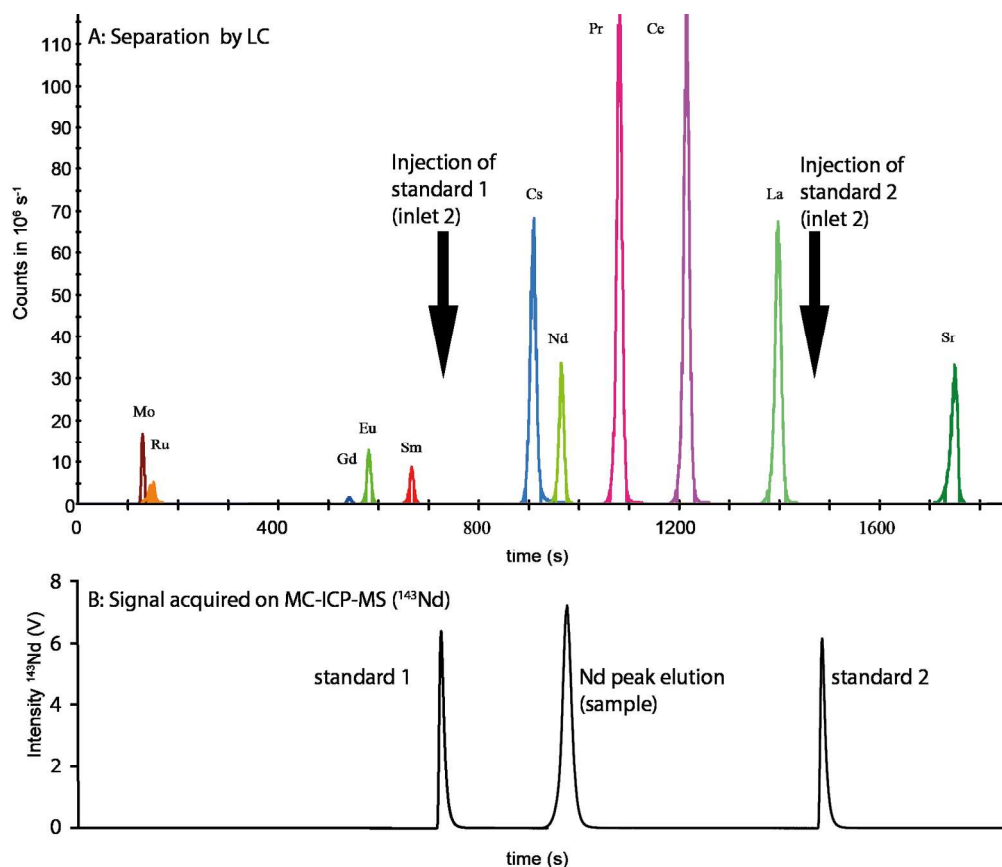

Figure 6: A: Chromatographic separation of a representative fission product fraction of a ²³⁵U-irradiated target with a LUNA SCX column (\varnothing 4.6 mm) at a flow rate of 1ml.min⁻¹ and T=20°C. The elution gradient started at t=0 min with 100% HMB at 0.1M in water, pH=3.6 and finished at t=35min with 100% HMB at 0.2M in water, pH=4.5. B: ¹⁴³Nd intensity signal recorded by MC-ICPMS during the time of elution. The Nd standard was injected between the Sm and Nd peaks (telution=720s) and after the La peak (telution=1450s).
