Abstract: In the present work, the α -Fe₂O₃ hollow structures from nanotubes to nanorings, and α -Fe₂O₃/carbon composites composed of nanoparticles homogeneously dispersed on graphene sheets and carbon nanotubes were synthesized via a self-assemble combined with a facile hydrothermal method, respectively, and its structure, morphology and electrochemical performance were characterized by XRD, XPS, SEM, TEM, CV, charge-discharge test and EIS. The focus is put on elucidating how structural aspects, such as particle size and shape of nanoparticles as well as carbon matrix, influence the electrochemical properties of the α -Fe₂O₃ nanoparticles. The results revealed that the cycling performance of hollow structure α -Fe₂O₃ improves with the increase of aspect ratios, namely, the α -Fe₂O₃ nanotubes exhibit the best electrochemical performance in terms of reversible capacity, capacity retention and rate performance, which is comparable to that of α -Fe₂O₃

nanoparticles-carbon composites. It is expected that the synthesis of α -Fe₂O₃ nanotubes with high aspect ratios anchored on conducting graphene would be potential anode materials for high performance LIBs.

Keywords: α -Fe₂O₃; Nanotubes; Composites; Anode; Lithium-ion batteries

1 Introduction

Lithium-ion batteries (LIBs) are important power sources for portable electronic devices. In addition, LIBs are also growing in popularity for electric vehicles, military, and stationary power grid storage. So as to meet the ever-growing demand for high energy density and high power, it is essential to develop novel electrode materials with high-performance for next generation LIBs. Correspondingly, transition metal oxides have been paid a lot of attention as LIBs anodes, because they have much higher theoretical capacities than the current commercial anode material (graphitic materials). Since transition metal oxides undergo conversion reaction $2y\text{Li}^+ + 2ye^- + \text{Me}_x\text{O}_y \rightarrow x\text{Me} + y\text{Li}_2\text{O}$, involving more than one Li ion per formula unit, exceptionally high specific capacities can be attained during the redox cycle [1-6]. Among the transition metal oxides, α -Fe₂O₃ (hematite) has been suggested as a promising candidate for replacing graphite due to its high theoretical capacity (1007 mAh g⁻¹), nearly three times larger than that of graphite (372 mAh g⁻¹), which has been widely investigated as the anode material for LIBs [6-10]. However, its large volume changes and severe particle aggregation associated with the cycling of Li⁺ insertion/desertion process lead to electrode pulverization and loss of interparticle contact, thus resulting in a large irreversible capacity loss and a poor electrical conductivity. To

circumvent these obstacles, various attempts have been applied to these problems, which include (i) preparing the materials with hollow structures [11,12], (ii) embedding the materials in carbon matrix [13,14,15].

The hollow structural materials have many merits, which include (i) the large surface area endows the hollow materials with more lithium storage sites and a large electrode/electrolyte contact area for high Li^+ flux across the interface, (ii) the thin shells of permeable hollow materials could shorten the transport paths for both Li^+ ions and electrons, leading to good rate capacity, and (iii) the hollow structures with volume interior could be useful to alleviate the structural strain and accommodating the large volume variation associated with repeated Li^+ ions insertion/extraction processed, giving rise to improved cycling stability [6,7,16]. Moreover, carbon materials, which form a variety of allotropes, are commonly used matrixs, because of their good ion/electron conductivity, low volume expansion, and tolerance to mechanical stress, which not only buffers the volume changes but also refrains the aggregation of nanoparticles, therefore contributing to enhanced electrochemical performance [11,12,17,18].

In our previous studies [19-21], $\text{Fe}@\text{Fe}_2\text{O}_3$ core-shell nanoparticles attached to carbon nanotubes and $\alpha\text{-Fe}_2\text{O}_3$ nanoparticles or $\text{Fe}@\text{Fe}_2\text{O}_3$ core-shell nanoparticles anchored on graphene hybrid materials were synthesized by using a hydrothermal reaction followed by an in situ thermal reduction. Its cycling performance and rate capability are drastically improved, highlighting the importance of the embedding nanoparticles in carbon matrix for maximum use of electrochemically active Fe_2O_3 nanoparticles and carbon nanomaterials for energy storage applications.

Herein, the cubic $\alpha\text{-Fe}_2\text{O}_3$, $\alpha\text{-Fe}_2\text{O}_3$ hollow structures (from nanotubes to nanorings) and $\alpha\text{-Fe}_2\text{O}_3$ /carbon (GNS or CNTs) composites composed of $\alpha\text{-Fe}_2\text{O}_3$ nanoparticles homogeneously dispersed on GNS and CNTs were synthesized via a self-assemble combined with a facile

hydrothermal method, respectively. The size and shape control of α -Fe₂O₃ hollow structures from nanotubes to nanorings were achieved by simple adjustments of the reaction time and phosphate ions concentrations. The main purpose of this work is to investigate and discuss how structural aspects, such as particle size and shape of nanoparticles as well as carbon matrix, influence the electrochemical properties of the α -Fe₂O₃ nanoparticles in terms of reversible capacity, cycling performance and rate capability. The results showed that, the α -Fe₂O₃ nanotubes and α -Fe₂O₃/carbon composites exhibited the better electrochemical performance in terms of reversible capacity, capacity retention and rate performance than the other α -Fe₂O₃ hollow structures as well as cubic α -Fe₂O₃ particles, highlighting that the nanotubes with high aspect ratios anchored on graphene could serve as potential anode materials for lithium-ion batteries.

2 Experimental Methods

2.1 Sample synthesis

Unless specified, all chemical reagents used in this work were analytical grade and were used without further purification.

Synthesis of hollow structures α -Fe₂O₃. The hollow structures α -Fe₂O₃ was synthesized by a hydrothermal treatment of FeCl₃ solution in the presence of KH₂PO₄ and K₂SO₄ [17,28]. In a typical experimental procedure for α -Fe₂O₃ nanotubes, FeCl₃·6H₂O (3.78 g), KH₂PO₄ (0.052 g) and K₂SO₄ (0.070 g) aqueous solutions were mixed together, and then distilled water was then added to a final volume of 700 ml. After stirring for 10 minutes, the mixture was transferred into Teflon lined stainless steel autoclaves for hydrothermal treatment at 200 °C, and maintained at this temperature for 48 h. The autoclaves then cooled down to room temperature naturally, and the red precipitate was separated by centrifugation, washed with distilled water and absolute ethanol, and dried under vacuum at 80 °C. By simple adjustment of the reaction time and phosphate ions concentrations, a

series of α -Fe₂O₃ with different sizes and surface morphologies were produced.

Synthesis of α -Fe₂O₃/GNS composites. Graphene oxide (GO) used in this work was synthesized from nature graphite power by a modified Hummers method. GNS were obtained by a thermal reduction of GO. The preparation details have been described elsewhere [14]. In a typical synthesis, 0.3 g GNS and 3.125 g FeCl₃·6H₂O were dispersed in 200 ml of distilled water under ultrasonication at room temperature for 1 h. An appropriate amount of ammonia solution (NH₃·H₂O, 25 wt %) was added successively and the final pH of the resulting suspension was adjusted to about pH 6. Then the suspension was transferred into Teflon lined stainless steel autoclaves and maintained at 164 °C for 12 h. After the autoclaves cooled down to room temperature naturally, the α -Fe₂O₃/GNS composites were collected by centrifuging and washing with distilled water, followed by drying at 80 °C under vacuum overnight.

Synthesis of α -Fe₂O₃/CNTs composites. The α -Fe₂O₃/CNTs composites were prepared by a similar hydrothermal method with CNTs replace by GNS.

Cubic α -Fe₂O₃ particles. The cubic α -Fe₂O₃ particles were prepared accordingly by a similar hydrothermal method except for the absence of GNS or CNTs.

2.2 Sample characterization

The structures of the as-prepared materials were characterized by Cu K α radiation on a Bruker AXS D8 X-ray diffractometer. While, X-ray photoelectron spectroscopy (XPS) (Kratos AXIS Ultra DLD; Al (anode) X-ray source) was utilized to investigate the surface chemistries of the as-prepared materials. The composites were characterized by thermogravimetric analysis (TGA, Netzsch STA499C) under air over a temperature range of 40 °C to 800 °C with a ramp rate of 10 °C/min. Nitrogen adsorption-desorption was determined by Brunauer-Emmett-Teller (BET) tests using a Nova 1000e (Quantachrome Instruments) surface area and pore analyzer. Further, LEO-1530 Field

Emission Scanning Electron Microscopy (FE-SEM, Oxford Instrument) and Transmission electron microscopy (TEM, JEOL JEM-2010) were applied to observe the morphologies of the as-prepared materials.

2.3 Electrochemical measurement

The working electrodes were prepared by mixing 80 wt % active materials (α -Fe₂O₃ hollow structures, α -Fe₂O₃/GNS, α -Fe₂O₃/CNTs, and cubic α -Fe₂O₃), 10 wt % acetylene black, and 10 wt % polyvinylidene fluoride (Kynar FLEX 910, Elf Atochem, Issaquah, WA, USA) binder dissolved in N-methyl pyrrolidone (Fluka Inc., St. Louis, MO, USA) to form homogeneous slurries. The slurries were spread onto a Cu foil current collector. CR2032-type coin cells were assembled in an argon glove box for electrochemical characterization. Lithium foil was used as the negative electrode. The liquid electrolyte was 1 M LiPF₆ dissolved in a mixture of ethylene carbonate (EC), ethylmethyl carbonate (EMC) and dimethyl carbonate (DMC) (1:1:1 in volume %). The cells were galvanostatically charged and discharged in a battery analyzers (Neware, Shenzhen, China) for a cut-off voltage of 3.0 to 0.005 V (vs. Li/Li⁺) at room-temperature. The CV and EIS measurements were performed on an electrochemical work station (CHI660D, Chenhua Ltd Co., Shanghai, China). The CV curves were measured at 0.5 mV s⁻¹ over the range from 3.0 to 0.005 V. The amplitude of ac perturbation signal was 5 mV and the frequency range was varied from 10⁵ to 10⁻² Hz.

3 Results and Discussion

3.1 Characterization

The crystallographic structures of hollow structure α -Fe₂O₃ (48h), α -Fe₂O₃/GNS and α -Fe₂O₃/CNTs composites, and cubic α -Fe₂O₃ particles were analyzed by X-ray powder diffraction (XRD) in Figure 1. A few characteristic peaks for α -Fe₂O₃ ($2\theta=24.1, 33.2, 35.6, 64.0^\circ$), marked by their indices ((012), (104), (110), and (300)), are observed, respectively, for all of these products.

These peaks can be readily indexed to the standard hematite (PDF 33-0664). For α -Fe₂O₃/GNS composites, characteristic diffraction peak of GNS cannot be observed at 2θ of 24.5 to 27.5°, which indicates that no graphite-like layered structure is formed by re-stacking of chemically reduced graphene [22]. In case of α -Fe₂O₃/CNTs composites, a broad hump peak around 26° merged is attributed to CNTs [23,24], implying that the short-range ordered structure in the composites. These results indicate that the resultant α -Fe₂O₃ nanoparticles in the composites are pure α -Fe₂O₃ with a spinel structure.

XPS is one of the strongest techniques in characterization of materials, was employed to further reveal the valence state of elements and the chemical composition of the products. In the high-resolution Fe 2p spectrum (Figure 2(a)) for the hollow structure α -Fe₂O₃ (48 h), α -Fe₂O₃/GNS and α -Fe₂O₃/CNTs composites, two peaks at binding energies of ~711 eV for Fe 2p_{3/2} and ~724 eV for Fe 2p_{1/2} with a shake-up satellite at ~719 eV are observed, which is consistent with hematite phase [12,14]. Figure 2(b,c) show the curve fitting of C1s core levels for α -Fe₂O₃/GNS and α -Fe₂O₃/CNTs composites, respectively. The C1s XPS spectrum of both products can be fitted into three peaks, corresponding to carbon atoms in three functional groups: sp² carbon (C-C, ~284.8 eV), carbon in C-O bonds (~286.1 eV), and carboxylate carbon (O-C=O, 288.5 eV) [25]. However, the O/C ratio in the α -Fe₂O₃/GNS composites decreases remarkably compared with that of the α -Fe₂O₃/CNTs composites, indicating that most of the oxygen-containing groups in the α -Fe₂O₃/GNS composites are successfully removed. Such a low O/C ratio of GNS implies a good electronic conductivity, which is favorable for stabilizing the electronic and ionic conductivity [26]. Thus, this obvious difference should lead to the difference of their electrochemical performance as anode materials for LIBs.

The scanning electron microscopy (SEM) images provide insight into the morphology and microstructure of the hollow structure α -Fe₂O₃ (48 h), α -Fe₂O₃/GNS and α -Fe₂O₃/CNTs composites, and cubic α -Fe₂O₃ particle. Figure 3(a) shows the image of the hollow structure α -Fe₂O₃ without any dispersion treatment, from which it can be seen that the resultant sample exhibits nanotubes morphology with good uniformity. Figure 3(b) shows that the α -Fe₂O₃ nanoparticles are uniformly dispersed in the GNS matrix to prevent the restacking of the GNS and no large agglomeration can be found, which guarantees the good connection between α -Fe₂O₃ and GSN by plane-to-point networks and ensures the effective use of conductive GNS. Moreover, the random hybridization between α -Fe₂O₃ nanoparticles and GNS can form a three-dimensional (3D) porous structure, which is beneficial for achieving high rate performance [20]. From Figure 3(c), it can be seen that the CNTs intertwine with α -Fe₂O₃ nanoparticles whereas little agglomeration obtained, acting as branches to connect α -Fe₂O₃ nanoparticles, which can improve the electrical continuity by line-to-point contact. It can be seen from Figure 3(d) that the cubic α -Fe₂O₃ particles with lengths around 700 nm in size are obtained under similar experimental condition for preparing α -Fe₂O₃/GNS composites. TGA indicates that the amount of GNS and CNTs in the composites is about 13 wt% and 18 wt%, respectively (Figure 3(e)). The BET specific surface area of the nanotubes, short nanotubes, very short nanotubes, and nanorings is little difference, which is measured to be 11.9, 10.8, 10.0 and 9.3 m² g⁻¹, respectively.

To provide further insight into the nanostructure of the tubes, analytical TEM investigations were also performed. Figure 4(a) shows the TEM image of the α -Fe₂O₃ nanotubes at low magnification, where the strong contrast between the dark edge and pale center further confirm the hollow clearly, namely, tubular structure. The product consists almost entirely of nanotubes with outer diameters of 130-160 nm, inner diameters of 110-130 nm. Figure 4(b) shows typical HRTEM image of a single

α -Fe₂O₃ nanotube. A lattice spacing of 0.46 nm for the (003) planes of the α -Fe₂O₃ along the nanotubes can be readily resolved, indicating the α -Fe₂O₃ nanotubes grow along the [001] direction (also the long axes of the nanotubes). The above results illustrate that the α -Fe₂O₃ nanotubes have been successfully fabricated by a double anion-assisted hydrothermal method.

3.2 Morphology and Growth Mechanism of Hematite Hollow Structures

To have a clear understanding of the growth process of the α -Fe₂O₃ nanotubes, the products under different reaction times were collected for TEM investigation, as shown in Figure 5. It can be seen that the α -Fe₂O₃ nanotubes undergo an evolution from spindlelike precursors to nanotubes. The products obtained after 3h (Figure 5(a)) show spindlelike precursors with a diameter of 160 to 250 nm and a length of 360-600 nm, as has been extensively observed in forced hydrolysis processes [23,24,27]. Prolonging the reaction time to 12h (Figure 5(b)), the size of the products did not change so much. However, there are hollow structures in some products. A mixture of semitubular and tubular structure was formed after longer reaction time (24h, Figure 5(c)). For reaction times of 48 h (Figure 4(a)), the final structure consists predominantly of nanotubes that are completely hollow.

Based on evidence from the above time-dependent morphology evolution evidence, the formation process of the nanotubes can be proposed as taking place by “dissolution” of the spindle-like precursors from the tips toward the interior along the axis resulting in semitubular and eventually hollow nanotubes [28]. Under acidic conditions (pH=2) at a 200 °C, the sharp tips of the spindle-like precursors are highly reactive, which are easily attacked by the protons. It is clearly found that a higher proportion of the α -Fe₂O₃ nanotubes would be formed if prolonging the reaction time, and the dissolution process is not uniform resulting in partial dissolution, and the non-uniform dissolution varied from spindle to spindle and even for a single spindle.

The growth control of α -Fe₂O₃ nanocrystals by the adsorption of phosphate and sulfate ions has

been extensively studied [17,29,30]. It is proposed that the sharp tips of the spindle-like precursors may begin to dissolve in the following manner:

In the process of the hydrothermal reaction, phosphate and sulfate ions can speed up the dissolution by their coordination effect with ferric ions [17].

On the basis of the time-dependent experimental results discussed above, it is reasonable to postulate that the size and surface architecture of the nanostructures could be tuned by varying the phosphate/sulfate ratio, which controls the formation of the precursors and the subsequent dissolution process. As shown in Figure 6(a-f), it is obvious that with the decrease in the amount of phosphate ions, the aspect ratio of the products decreases, and the morphology changes from tube to ring, demonstrating that the phosphate ions are responsible for the growth of the precursors, which consequently determines the sizes and aspect ratios of the final hollow nanostructures. In addition, the XRD patterns of the hollow nanomaterials are shown in Figure 6(g), which match the XRD spectrum of the standard hematite (PDF 33-0664).

3.3 Electrochemical Performance.

Figure 7 shows the CV curves of $\alpha\text{-Fe}_2\text{O}_3$ nanotubes, $\alpha\text{-Fe}_2\text{O}_3/\text{GNS}$ and $\alpha\text{-Fe}_2\text{O}_3/\text{CNTs}$, and cubic $\alpha\text{-Fe}_2\text{O}_3$ electrodes for the first four cycles at ambient temperature at a slow scan rate of 0.5 mV s^{-1} , respectively. As shown in Figure 7(a,b), two reduction peaks are observed in the first cathodic scan for the $\alpha\text{-Fe}_2\text{O}_3$ nanotubes and $\alpha\text{-Fe}_2\text{O}_3/\text{GNS}$ electrode, respectively. The weak peak appears at about 1.5 V for the $\alpha\text{-Fe}_2\text{O}_3$ nanotubes electrode and 1.6 V for the $\alpha\text{-Fe}_2\text{O}_3/\text{GNS}$ electrode, indicating that initial lithium insertion into the $\alpha\text{-Fe}_2\text{O}_3$, which can be attributed to the reaction of $\alpha\text{-Fe}_2\text{O}_3 + x\text{Li} \rightarrow \alpha\text{-Li}_x\text{Fe}_2\text{O}_3$ [8,31,32]. However, there is no corresponding weak peak in the CV curves of $\alpha\text{-Fe}_2\text{O}_3/\text{CNTs}$ and cubic $\alpha\text{-Fe}_2\text{O}_3$ electrodes, the difference among the CV curves of the $\alpha\text{-Fe}_2\text{O}_3$

nanotubes, α -Fe₂O₃/GNS, α -Fe₂O₃/CNTs and cubic α -Fe₂O₃ electrodes is possible due to their different Li-ion insertion efficiency caused by the dimensions and structure characteristics. The second strong peak at about 0.5 V with a shoulder at about 0.75 V, which could be ascribed to the conversion reaction α -Li_xFe₂O₃ + (6-x)Li → 2Fe + 3Li₂O and the irreversible reaction related to the decomposition of the electrolyte [8,31,33]. The first anodic curves for the α -Fe₂O₃ nanotubes, α -Fe₂O₃/GNS and α -Fe₂O₃/CNTs, and cubic α -Fe₂O₃ electrodes are similar and include a broad peak at about 1.8 V, corresponding to the reversible oxidation of Fe⁰ to Fe³⁺. The CV curves of α -Fe₂O₃ nanotubes, α -Fe₂O₃/GNS and α -Fe₂O₃/CNTs electrodes are stable and show good reversibility after the first cycle. In the case of cubic α -Fe₂O₃ electrode (Figure 7(d)), the peak cathodic and anodic current is gradually decreased, indicating the in-sufficient oxidation-reduction reaction process during cycles. Furthermore, it is also worth noting that the CV curves of cubic α -Fe₂O₃ electrode are not well overlap, showing that the capacities could gradually decrease with increasing cycle number.

Figure 8 shows the charge/discharge curves of α -Fe₂O₃ nanotubes, α -Fe₂O₃/GNS and α -Fe₂O₃/CNTs, and cubic α -Fe₂O₃ electrodes at 0.1 C (1C =1007 mAh g⁻¹) in voltage window of 0.005-3.0 V, and these are typical charge/discharge curves for transition metal anode materials. In the discharge curve of the first cycle, there are potential slopes located at 1.2-0.9 V and an obvious potential plateau at 0.9 -0.8 V for α -Fe₂O₃ nanotubes, α -Fe₂O₃/GNS and α -Fe₂O₃/CNTs electrodes, in accordance to the reaction processes of the α -Fe₂O₃ and the electrolyte with lithium, respectively. Nevertheless, there is only a broad potential at 0.8-0.7 V for cubic α -Fe₂O₃ electrode. For the subsequent cycle, all the discharge curves show a higher voltage plateau at about 1.0-0.9 V, and the total discharge capacities are reduced. The initial discharge capacities are 1906, 2065, 2018, and 1603 mAh g⁻¹ for α -Fe₂O₃ nanotubes, α -Fe₂O₃/GNS and α -Fe₂O₃/CNTs, and cubic α -Fe₂O₃ electrodes, respectively. The phenomenon that overfull capacity has been widely reported for

transition metal oxides, which is usually ascribed to the formation of the solid electrolyte interphase (SEI) film and possibly lithium consumption via interfacial reactions during the first discharge process [10]. In the subsequently cycles, the discharge capacities of α -Fe₂O₃ nanotubes, α -Fe₂O₃/GNS and α -Fe₂O₃/CNTs electrodes decrease slightly, however, the discharge capacities of cubic α -Fe₂O₃ electrodes decrease markedly.

Figure 9(a) presents the cycling performances of the α -Fe₂O₃ hollow structures, α -Fe₂O₃/GNS and α -Fe₂O₃/CNTs, and cubic α -Fe₂O₃ electrodes at 0.1 C. The rapid fading of cubic α -Fe₂O₃ electrode may result from the poor kinetics of electrochemical conversion reaction. It is obvious that α -Fe₂O₃ nanotubes electrode has the best cycling performance among the hollow structures, and the cycling performance of hollow structure α -Fe₂O₃ improves with the increase of aspect ratios, which may be probably due to the nanotubes can provide more void spaces to buffer volume change and accommodate the strain associated with the volume variation, and superior electrochemical kinetics [34,35]. In addition, even nanorings show a better cycling performance than that of cubic α -Fe₂O₃ electrodes. The above results demonstrate the hollow structure especially aspect ratios is crucial to improve the cycling performance of α -Fe₂O₃ electrodes. After 60 cycles, the reversible capacities of the α -Fe₂O₃ nanotubes, α -Fe₂O₃/GNS and α -Fe₂O₃/CNTs, and cubic α -Fe₂O₃ electrodes are 1090, 1091, 929 and 576 mAh g⁻¹, respectively. The initial coulombic efficiencies of nanotubes, short nanotubes and very short nanotubes, and nanorings electrodes are 67.8%, 72.7%, 65.6% and 64.5%, respectively, which is higher than those of α -Fe₂O₃/GNS and α -Fe₂O₃/CNTs, and cubic α -Fe₂O₃ electrodes (Figure 9(b,c)). Figure 10 shows the durability of the α -Fe₂O₃ nanotubes, α -Fe₂O₃/GNS and α -Fe₂O₃/CNTs, and cubic α -Fe₂O₃ electrodes at a constant high rate of 5 C after an activation process at 1 C, respectively. The charge capacities of the α -Fe₂O₃ nanotubes, α -Fe₂O₃/GNS and α -Fe₂O₃/CNTs, and cubic α -Fe₂O₃ electrodes are 462, 471, 301, and 32 mAh g⁻¹ after 180 cycles,

respectively, indicating that the cycling performance of nanotubes electrode is comparable to that of the α -Fe₂O₃/GNS electrode and better than that of α -Fe₂O₃/CNTs electrode as well as cubic α -Fe₂O₃ electrode. Moreover, one interesting phenomenon is that the nanotubes and short nanotubes electrodes exhibit an increasing trend of the capacity after certain cycles, similar to previous reports on other transition-MO, which is possibly attributed to the gradual activation processed during charge/discharge cycles [36].

Rate capacity is another important aspect of the development of current generation batteries. To test the cell capability, the rate capacities of the α -Fe₂O₃ hollow structures, α -Fe₂O₃/GNS and α -Fe₂O₃/CNTs, and cubic α -Fe₂O₃ electrodes, were evaluated at various rates between 0.4 and 1.0 C (Figure 11). From Figure 11(a), it is obvious that the nanotubes exhibit best rate cyclability compared to the short-nanotubes, very short-nanotubes, and nanorings. The reversible capacity of nanotubes electrode is 759.5 mAh g⁻¹ at 400 mA g⁻¹, 596.3 mAh g⁻¹ at 700 mA g⁻¹, 480.3 mAh g⁻¹ at 1000 mA g⁻¹, respectively. When the current density reduces to 700 and 400 mA g⁻¹, the reversible capacity returns to 532.2 and 619.2 mAh g⁻¹, respectively. In contrast, The reversible capacity of α -Fe₂O₃/GNS electrode is 871.6 mAh g⁻¹ at 400 mA g⁻¹, 675.0 mAh g⁻¹ at 700 mA g⁻¹, 589.6 mAh g⁻¹ at 1000 mA g⁻¹ (Figure 11(b)), respectively, and when the current density reduces to 700 and 400 mA g⁻¹, the reversible capacity returns to 678.6 and 794.4 mAh g⁻¹, respectively, which is also comparable to that of nanotubes electrode and shows better rate cyclability than those of α -Fe₂O₃/CNTs, and cubic α -Fe₂O₃ electrodes. Thus, it is reasonable to deduce that the hybrid materials of α -Fe₂O₃ nanotubes with high aspect ratios anchored on conducting graphene would be potential anode materials for high performance LIBs, and synthesis and characterization of the hybrid materials is now carrying out in our research group.

Figure 12 shows the Nyquist plots of the ac impedance for the α -Fe₂O₃ nanotubes, α -Fe₂O₃/GNS

and α -Fe₂O₃/CNTs, and cubic α -Fe₂O₃ electrodes, which were measured in the open circuit voltage state using fresh cells. The plots are similar to each other in shapes, with a semicircle appearing in the high to moderate frequency region and a straight line in the low frequency region. The inclined line in the low frequency represents the Warburg impedance, which is related to the diffusion of lithium ions in the active anode material, and the depressed semicircle in the high to moderate frequency region is ascribed to the SEI film resistance (R_s) and charge transfer resistance (R_{ct}) [37-40]. It is obvious that the size of the semicircles for the α -Fe₂O₃ nanotubes and α -Fe₂O₃/CNTs electrodes are smaller than that for cubic α -Fe₂O₃ electrode, indicating a lower $R_{(s+ct)}$, suggesting that the $R_{(s+ct)}$ is some suppressed. It is worth noticing that the size of the semicircle for α -Fe₂O₃/GNS electrode is the smallest of all, showing that the $R_{(s+ct)}$ for α -Fe₂O₃/GNS electrode is the lowest one among the α -Fe₂O₃ nanotubes, α -Fe₂O₃/CNTs and cubic α -Fe₂O₃ electrodes. Therefore, these results prove that the incorporation of GNS is benefit to Li⁺ transport and the interleaved electron transfer high-way built up by GNS, thus leading to the enhanced electrode reaction kinetics and better electrochemical performance during charge/discharge process.

4 Conclusions

In summary, α -Fe₂O₃ hollow structures from nanotubes to nanorings, α -Fe₂O₃/GNS and α -Fe₂O₃/CNTs composites, and cubic α -Fe₂O₃ particles were successfully synthesized via a self-assemble combined with a facile hydrothermal method, respectively. By properly adjustments of the reaction time and phosphate ions concentrations, size and shape control of the α -Fe₂O₃ hollow structures are achieved. Electrochemical measurements show that the cycling performance of hollow structure α -Fe₂O₃ improves with the increase of aspect ratios, namely, the α -Fe₂O₃ nanotubes exhibited the best reversible lithium storage capacities, rate capability and cycling performance, which is comparable to that of α -Fe₂O₃ nanoparticles-carbon composites. The results suggest that the

flexibility and adaptability of the self-assembly route could be utilized to prepare a variety of hybrid materials of α -Fe₂O₃ nanotubes with high aspect ratios anchored on conducting graphene, and could serve as a general strategy for developing high-performance anode for lithium-ion batteries.

Figure Captions:

Figure 1. XRD pattern of α -Fe₂O₃ hollow structure (48h), α -Fe₂O₃/GNS and α -Fe₂O₃/CNTs composites, and cubic α -Fe₂O₃ particles.

Figure 2. (a) XPS survey spectrum of the α -Fe₂O₃ hollow structure (48h), α -Fe₂O₃/GNS and α -Fe₂O₃/CNTs composites, C1s high-resolution XPS spectra of (b) α -Fe₂O₃/GNS and (c) α -Fe₂O₃/CNTs composites, and their fitting results.

Figure 3. SEM images of (a) hollow structure (48h), (b) α -Fe₂O₃/GNS and (c) α -Fe₂O₃/CNTs composites, (d) cubic α -Fe₂O₃ particles, (e) TGA curves of α -Fe₂O₃/GNS and α -Fe₂O₃/CNTs composites.

Figure 4. (a, b) TEM of nanotubes under different magnifications, (c) HRTEM image.

Figure 5. TEM of the α -Fe₂O₃ hollow structures obtained after (a) 6 h, (b) 12 h, (c) 24 h.

Figure 6. SEM and TEM images of the three hollow structures: (a, b) short nanotubes, (c, d) very short nanotubes, (e, f) nanorings; (g) XRD patterns of the α -Fe₂O₃ hollow structures.

Figure 7. CV curves of (a) nanotubes, (b) α -Fe₂O₃/GNS and (c) α -Fe₂O₃/CNTs composites, (d) cubic α -Fe₂O₃ electrodes from the first to the fourth cycle at a scan rate of 0.5 mV s⁻¹ in the potential range of 0.005-3.0 V (versus Li/Li⁺).

Figure 8. The charge-discharge curves of (a) nanotubes, (b) α -Fe₂O₃/GNS and (c) α -Fe₂O₃/CNTs composites, (d) cubic α -Fe₂O₃ electrodes between 0.005 and 3.0 V at 0.1 C.

Figure 9. Cycling performance of the α -Fe₂O₃ hollow structures, α -Fe₂O₃/GNS and α -Fe₂O₃/CNTs composites, and cubic α -Fe₂O₃ electrodes at 100 mA g⁻¹, (b) coulombic efficiencies of the hollow structures electrodes, (c) coulombic efficiencies of α -Fe₂O₃/GNS and α -Fe₂O₃/CNTs composites, and cubic α -Fe₂O₃ electrodes.

Figure 10. Cycling performance of nanotubes, α -Fe₂O₃/GNS and α -Fe₂O₃/CNTs composites, and

cubic α -Fe₂O₃ electrodes at 5 C, respectively.

Figure 11. (a) Rate capability of nanotubes, short nanotubes, very short nanotubes, and nanorings , (b)

Rate capability of α -Fe₂O₃/GNS and α -Fe₂O₃/CNTs composites, and cubic α -Fe₂O₃ electrodes at various rates between 400 and 1000 mA g⁻¹.

Figure 12. Impedance plots for electrodes containing nanotubes, α -Fe₂O₃/GNS and α -Fe₂O₃/CNTs composites, and cubic α -Fe₂O₃ particles. The frequency range applied is 100 KHz-0.01 Hz.
