23 Abstract

24 In this paper, the effects of rice dreg protein hydrolysates (RDPHs) obtained by
25 various proteases on hydrogen peroxide-induced oxidative stress in HepG-2 cells
26 were investigated. Cell cytotoxicity was evaluated through the aspects of cell viability,
27 ROS level, antioxidant enzyme activity, and production of malondialdehyde (MDA).
28 Cell apoptosis was assessed by flow cytometry. Molecular weight distribution was
29 analyzed by gel permeation chromatography, and amino acid composition was
30 measured using an automatic amino acid analyzer. The survival of cells and the
31 activities of superoxide dismutase (SOD) and Glutathione peroxidase (GSH-Px) were
32 significantly increased through the pre-incubation of HepG-2 cells with RDPHs
33 before H₂O₂ exposure. Additionally, these pretreatments also resulted in a reduction in
34 ROS and MDA levels. As a result, apoptosis and loss of mitochondrial membrane
35 potential of the HepG-2 cells were alleviated. Furthermore, the protective effects of
36 protein hydrolysates obtained by various proteases were noticeably distinct, in which
37 RDPHs prepared by alkaline protease showed higher antioxidant activities. The
38 difference in the protective effects might be attributed to the specific peptide or amino
39 acid composition. Therefore, enzymatic hydrolysis with different enzymes studied
40 here could attenuate H₂O₂-induce cell damage, and the type of protease greatly
41 influenced the anti-oxidative activity. Particularly, optimum use of Alcalase could
42 produce peptides with higher antioxidant activity.

43 Key words: Rice dreg protein; Protease type; Antioxidant activity; Hydrogen peroxide;
44 HepG-2 cells

45 1. Introduction

46 Rice dreg protein (RDP), which contains up to 50% of protein in its dry form¹,
47 is a rice by-product produced during the starch extraction process. RDP is gaining a
48 lot of interest in food industry due to its unique nutritional value and nutraceutical
49 properties. It is also gaining interest because it is plentiful and readily available^{2,3}.
50 However, these protein residues are normally used as low-cost animal feed because of
51 their low digestibility and poor solubility at a neutral PH⁴. In order to overcome these
52 defects, protease enzymatic protein modification can be applied. The functional
53 properties of RDP can be improved through the proteases treatment⁵. Several
54 researchers have found that RDP is also a potential protein resource needed to
55 improve the biological activities of RDP, such as its anti-oxidative and
56 ACE-inhibitory properties^{6,7}. These studies indicated that RDPH might serve as an
57 inexpensive and efficient dietary source of protein for human nutrition.

58 Although the antioxidant activities of rice protein have been documented through
59 chemical tests^{8,9}, the particular effects of hydrolyzed rice protein on cells with
60 radical-initiated oxidative damage have not been studied extensively. To the best of
61 our knowledge, influence of enzyme type on the effects of hydrolysates against H₂O₂
62 induced cell damage has never been reported.

63 Generally, equilibrium between the generation and elimination of reactive
64 oxygen species (ROS) in normal cell systems is maintained by the antioxidant system.
65 However, when ROS generation grows beyond the capacity of the cellular antioxidant
66 system, or when the normal antioxidant defenses of the cell are inhibited, such

67 balance is broken, and oxidative stress occurs. Oxidative stress-induced cell damage
68 causes many human chronic diseases such as many cardiovascular diseases, aging,
69 neurodegenerative diseases, diabetes, and cancer¹⁰. Human HepG-2 cells, which are
70 well-differentiated transformed cell lines from hepatic origins, have been used for the
71 development of cell-based bioassays for food antioxidant activity analysis¹¹⁻¹³.
72 Hydrogen peroxide (H₂O₂) is thought to be a particularly important contributor to
73 oxidative stress. Therefore, treating HepG-2 with hydrogen peroxide could serve as a
74 model for evaluating the antioxidant activity of food. In addition, studies supported
75 the protective role that natural antioxidants might play in controlling and mitigating
76 oxidative stress-induced diseases¹³⁻¹⁵.

77 In this study, five commercially available and low-cost proteases were selected to
78 hydrolyze the RDP. The RDPs prepared with various enzymes were evaluated for
79 their protective effects against hydrogen peroxide-induced oxidative stress in HepG-2
80 cells by considering cytotoxicity and cell viability, intracellular ROS level, activities
81 of antioxidant enzymes, lipid peroxide level, apoptosis, and the related mechanisms.

82 **2. Materials and methods**

83 **2.1. Materials**

84 Rice dreg protein (82.9% protein, 7.9% water, 1.35% ash, 6.25% lipid, 1.60%
85 sugar) was provided by Shanyuan Biotechnology Co. LTD (Wuxi, China). Alcalase
86 (2.4 L), Neutrase (0.8 L), Flavourzyme, and Protamex (2.4 AU/g) were purchased
87 from Novozymes (Beijing, China). Trypsin was obtained from Sinopharm Chemical
88 Reagent Co. LTD. HepG-2 cells were purchased from the Institute of Biochemistry

89 and Cell Biology, SIBS, CAS (Shanghai, China). Modified Eagle's Medium (DMEM),
90 fetal bovine serum (FBS), and other cell culture materials were purchased from Gibco
91 BRL, LifeTechnologies (USA). A Cell Counting Kit-8 (CCK-8), a Reactive Oxygen
92 Species Assay Kit, Malondialdehyde (MDA), superoxide dismutase (SOD), and
93 glutathione peroxidase (GSH-Px) assay kits were all purchased from Beyotime
94 Biotechnology Co. LTD (Shanghai, China). An Annexin V-FITC Apoptosis Detection
95 Kit, and a Mitochondrial membrane potential assay kit with JC-1 were also obtained
96 from Beyotime Biotechnology Co. LTD (Shanghai, China). A Reactive Oxygen
97 Species Assay Kit was purchased from Nanjing Jiancheng Bioengineering Institute
98 (Nanjing, China). These and all other chemicals and reagents were of analytical grade
99 or higher.

100 **2.2. Preparation of RDP hydrolysate with various enzymes.**

101 Five commercially available proteases were chosen to hydrolyze the RDP. The
102 hydrolysis followed the conditions given in parenthesis: Alcalase 2.4 L (pH 8.5,
103 55 °C), Neutrase 0.8 L (pH 7, 45 °C), Protamex (PH 7, 50 °C), Flavourzyme (pH 6,
104 50 °C), Trypsin (PH 8, 50 °C).

105 The RDP was stirred into distilled water (5% [w/v]) for 30 min at the optimum
106 temperature for each enzyme. Reactions were then carried out with proteases for 2 h
107 at each enzyme's respective optimum hydrolysis conditions as described above. The
108 enzyme to substrate (E/S) ratio was 1:100 (w/w) and the pH level of the slurry was
109 kept constant with 1 M NaOH. The resulting hydrolysates were heated in a boiling
110 water bath for 10 min to inactivate the enzyme. After cooling, the hydrolysates were

111 each adjusted to a pH level of 7.0 and centrifuged at 10000 g for 20 min. The
112 solutions were then freeze-dried and stored at -20 °C before use.

113 **2.3. Analysis of cell cytotoxicity and viability**

114 Cell culture: HepG-2 cells were cultured in Dulbecco's Modified Eagle's Medium
115 (DMEM), which contains 10% fetal bovine serum (FBS), 100 units/mL penicillin, and
116 100µg/mL streptomycin under conditions of 5% CO₂ and 37 °C in an incubator.

117 Cells were inoculated into a 96-well plate (4×10⁵ cells/mL for cytotoxicity
118 analysis and 1×10⁵ cells/mL for viability analysis) and incubated at 37 °C in a CO₂
119 incubator for a specific amount of time (72 h for cytotoxicity analysis and 24 h or 48
120 h for viability analysis). After that, 10 µl of the prepared CCK-8 solution was added
121 into each well of the plate and then incubated for another 4 h. Absorbance was
122 measured at 450 nm by a microplate reader (M5, Molecular Devices, USA). The
123 percentage of cell growth inhibition and cell viability was expressed as the following
124 equation:

$$125 \quad \text{Cell Cytotoxicity} = (A_{\text{control}} - A_{\text{treated}}) / A_{\text{control}} * 100\%$$

$$126 \quad \text{Cell Viability} = A_{\text{treated}} / A_{\text{control}} * 100\%$$

127 **2.4. Measurement of intracellular reactive oxygen species (ROS)**

128 The level of ROS was determined using the Reactive Oxygen Species Assay Kit.
129 HepG-2 cells were incubated with five RDPHs (1 mg/ml) for 48 h and then 0.4 mM
130 H₂O₂ was added for 4 h. After washing the cells with PBS three times, DCFH-DA (10
131 mM) was added and the cells were incubated for 30 min at 37 °C in the dark. The
132 DCF fluorescence of the treated cells was measured by a laser scanning confocal

133 microscope (LSM 710, Carl Zeiss AG, German). Relative DCF fluorescence was
134 provided directly by the apparatus.

135 **2.5. Measurements of SOD, MDA and GSH-Px**

136 The assay for superoxide dismutase (SOD), Glutathione peroxidase (GSH-Px),
137 catalase (CAT) and m-alondialdehyde (MDA) was carried out suing commercial
138 assay kits (Beyotime Biotechnology Co. LTD, Shanghai, China). All the steps were
139 taken in strict accordance with the kit-specified method. Briefly, SOD activity was
140 assayed by detecting the concentration of formazan dye (450 nm) formed from WST-8
141 after it reacted with superoxide ions produced from the xanthine–xanthine oxidase
142 system. One unit of SOD activity was defined as the inhibition rate when the above
143 response reached 50%. GSH-Px was detected through the catalytic oxidation of
144 glutathione using t-Bu-OOH as peroxide. Then the presence of glutathione reductase
145 could catalyze the reduction of the GSSH generated above to GSH and the oxidation
146 of the NADPH to NADP⁺, which could be monitored at 340 nm. One unit of GSH-Px
147 was defined as the 1 μmol NADPH oxidized in 1 min. The assay for CAT was based
148 on its ability to scavenge H₂O₂. The content of MDA was determined by measuring
149 the absorbance of MDA-TBA reacted by MDA and TBA at 450 nm.

150 **2.6. Cell apoptosis and mitochondrial transmembrane potential ($\Delta\Psi_m$) analysis**

151 An Annexin V-FITC apoptosis detection kit was used to evaluate the apoptosis of
152 the cells. Briefly, after the HepG-2 cells were pre-incubated with RDPHs for 48 h, 0.4
153 mM H₂O₂ were added and the cells were incubation for another 4 h. The treated cells
154 were harvested by trypsinization, washed with PBS once, and centrifuged to collect

155 the cell pellet. Then they were stained with 5 μ L Annexin V-FITC, and 10 μ L
156 propidium iodide (PI) for 15 min at room temperature in the dark. The cells were
157 analyzed on a flow cytometer (FACSCalibur, BectonDickinson, USA).

158 The HepG-2 cells were harvested after the above treatment and the
159 mitochondrial transmembrane potential ($\Delta\Psi_m$) was examined using a Mitochondrial
160 Membrane Potential assay kit with JC-1. In brief, the collected cells were incubated
161 with 0.5 mL of a JC-1 working solution for 20 min at 37 $^{\circ}$ C in the dark, then washed
162 twice with a JC-1 staining buffer, and re-suspended in 0.5 mL of PBS. Flow
163 cytometry (FACSCalibur, BectonDickinson, USA) was used to analyze the cells.

164 **2.7. Determination of molecular weight distribution**

165 The molecular weight distribution of the RDPHs was measured by gel
166 permeation chromatography (1260 Infinity, Agilent Technologies, USA) on a
167 TSKgel2000 SW XL column (7.8 mm i.d. \times 300 mm; Tosoh, Tokyo, Japan) with a
168 UV detector at 220 nm. The following describes the mobile phase:
169 acetonitrile/water/trifluoroacetic acid was 45/55/0.1 (V/V), at a flow rate of 0.5
170 ml/min. The following four protein standards were taken to make a reference curve:
171 cytochrome C (12.5 kDa), bacitracin (1450 Da), tetrapeptide GGYR (451 Da), and
172 tripeptide GGG (189 Da) (Sigma St. Louis, MO, USA).

173 **2.8. Amino acid analysis**

174 200 mg of RDPHs were hydrolyzed in 8 ml of 6 M HCl and heated in a sealed
175 tube for 24 h at 110 $^{\circ}$ C. After being evaporated under nitrogen at 60 $^{\circ}$ C, the
176 hydrolysates were diluted with water to 100 mL and then filtered. Amino acid analysis

177 of the filtrate was measured using an automatic amino acid analyzer (L-8800, Hitachi,
178 Japan).

179 **2.9. Statistical analysis**

180 Data were analyzed using IMB SPSS statistics 2.0 software. The differences
181 between the mean values of samples were determined using the least significant
182 difference (LSD) test at a level of 0.05.

183 **3. Results and discussion**

184 **3.1. Cell viability of HepG-2 cells injured with H₂O₂**

185 A reliable in-vitro cellular model was required to represent what occurs in the
186 human body more accurately¹⁶. In this study, the H₂O₂-induced injury on HepG-2
187 cells was assessed. As shown in Figure 1A and Figure 1B, time-dependent and
188 dose-dependent decreases in cell viability were indicated by CCK-8 assays in cells
189 exposed to H₂O₂. Furthermore, considering the state of cell growth and sensitivity to
190 the H₂O₂, pre-culture of the cells before H₂O₂ injury for 48 h was better than 24 h.
191 After pre-culture for 48 h, the cell viability decreased to 53.95% ± 2.08 when the
192 HepG-2 cells were then treated for another 4 h with 0.4 mM H₂O₂ (Figure 1A and 1B).
193 When treatment time or H₂O₂ concentration increased, the cell viability decreased
194 slightly. From the previous studies, H₂O₂-injured cellular models were established as
195 the cell viability reduced by 50%~70%^{5, 7}. Therefore, further experiments were
196 carried out with 0.4 mmol/l of H₂O₂ for 4 h.

197 **3.2. Cytotoxic and proliferative effects of RDPHs on HepG-2 cells**

198 Firstly, the CCK-8 assay was used to examine whether or not RDPHs (1 mg/ml)

199 alone would cause cell death. Figure 1C shows that the cytotoxicity levels of RDPHs
200 obtained by five different proteases were all within 10%, suggesting that there was no
201 toxicity to cells at the concentration used in this study¹⁷. Then, HepG-2 cells were
202 pre-treated with RDPHs over various periods of time (24 h and 48 h) in the
203 concentration of 1 mg/ml before H₂O₂ incubation (0.4 mmol/l for 4 h). As shown in
204 Figure 1D, pretreatment with RDPHs prior to H₂O₂ exposure markedly increased the
205 cell viability of HepG-2 cells when compared to the cells treated with H₂O₂ alone (P <
206 0.05). The protective effects were more pronounced when cells were pre-treated with
207 various RDPHs for 48 h. Samples hydrolyzed with Alcalase and Trypsin showed the
208 strongest inhibitory effect against H₂O₂-induced cytotoxicity, while after 48 h of
209 pretreatment, the Flavourzyme hydrolysate was the least efficient, with cell viability
210 values of 86.33% ± 2.78, 85.80% ± 2.19, and 60.13% ± 1.22, respectively. This
211 indicated that the RDPHs had the potential to protect HepG-2 cells against the injury
212 induced by H₂O₂. The differences in the ability to suppress H₂O₂-induced cell death
213 might be attributed to the different proteases employed¹⁸. During hydrolysis, enzymes
214 with special action sites generated a wide variety of smaller peptides and free amino
215 acids. Moreover, peptide chain length, size, level, and composition of free amino
216 acids greatly influenced the antioxidant activities of the hydrolysates^{19, 20}.
217 Hydrolysates of Alcalase and Trypsin seemed to contain more anti-oxidative peptides
218 than the other hydrolysates.

219 3.3. RDPHs inhibited the ROS formation induced by H₂O₂

220 The intracellular content of ROS provides insights into the anti-oxidative activity

221 of RDPHs. In order to assess the levels of intracellular ROS in RDPHs-treated
222 HepG-2 cells, a DCFH-DA fluorescent probe was used. The fluorescent signal of
223 RDPHs prepared with various proteases for 2 h are shown in Figure 2A. There were
224 significant differences in the fluorescent signals of RDPHs obtained with various
225 proteases. In decreasing order they were: Alcalase > Trypsin > Neutrase > Protamex >
226 Flavourzyme. Furthermore, the signal for each of the hydrolysates-protected groups was
227 considerably lower than that of the H₂O₂-induced group ($p < 0.05$). The results show
228 that RDPHs can efficiently protect the cells from intracellular ROS damage induced
229 by H₂O₂. Additionally, RDP enzymatic hydrolysis by Alcalase showed the highest
230 scavenging activity of intracellular ROS. In contrast, the use of Flavourzyme released
231 the least scavenging groups when compared to the other proteases. Images of the
232 HepG-2 cells treated with different proteases demonstrate the same result (Figure 2B).
233 Lower fluorescent signals indicate more scavenging of free radicals. As can be seen,
234 the brightness group was the one treated with H₂O₂ alone. However, the average
235 brightness of the Alcalase-treatment group tended to be more muted than that of the
236 groups pre-treated with the other four kinds of RDPHs. These results provide
237 evidence that rice protein hydrolysates can effectively reduce oxidative damage
238 induced by H₂O₂. Generally, exogenous treatment with H₂O₂ can induce abnormal
239 accumulation of intracellular ROS and damage cellular antioxidant defenses²¹.
240 Furthermore, excess ROS results in protein and lipid oxidation, causes destruction of
241 nuclear DNA and mitochondrial integrity, and ultimately leads to cell death^{22, 23}.
242 However, pre-treatment of cells with RDPHs at the concentration of 1 mg/ml

243 dramatically abrogated these negative impacts by reducing the ROS levels in cells,
244 indicating that the anti-apoptosis properties of the RDPHs was related to ROS
245 scavenging. Moreover, when cells were pre-treated with the same amount of added
246 hydrolysates, the considerable differences among RDPHs might be due to the fact that
247 RDP was more susceptible to the enzymatic attack by Alcalase, resulting in a release
248 of anti-oxidative amino acids and a change in ROS scavenging ability, as previously
249 reported²⁴. The peptides released from RDP by various enzymes also reveal distinct
250 peptide chain lengths (Table 1), causing a discrepancy in the ability to enter cells and
251 play a protective role²⁰.

252 **3.4. Effects of RDPHs on the activities of antioxidant enzymes and lipid peroxide** 253 **levels in H₂O₂-treated HepG-2 cells**

254 As mentioned above, the levels of intracellular ROS increased sharply after the
255 H₂O₂ damage (Figure 2A). Nevertheless, the redundant ROS could be eliminated by
256 several pivotal antioxidant enzymes, including SOD and GSH-Px^{25, 26}. As shown in
257 Figure 3A, the activities of SOD and GSH-Px in HepG-2 cells that were exposed to
258 H₂O₂ at 0.4 mM for 4 h were reduced by 50.59% and 49.07%, respectively, when
259 compared to the control group. However, pretreatment with RDPHs significantly
260 attenuated the loss of enzyme activity in H₂O₂-treated cells. An H₂O₂-induced
261 decrease in SOD activity was restored by 40.93% in HepG-2 cells pretreated with
262 Alcalase hydrolyzed RDP, which was higher than the restoration obtained by other
263 RDPHs. Similar to the results seen for SOD, GSH-Px and CAT activity rose
264 significantly in HepG-2 cells that were pretreated with RDPHs when compared with

265 the control group, and the highest activity was observed for the Alcalase hydrolysates
266 (Fig.3B and C). On the other hand, Malondialdehyde (MDA), a product of lipid
267 peroxides induced by reactive oxygen species, was also detected. As can be seen in
268 Figure 3D, cells that were subject to H₂O₂ stress had a marked increase in the
269 intracellular MDA (nearly 4-fold vs the control group). However, the overproduction
270 of MDA induced by H₂O₂ was significantly inhibited when the cells were pre-treated
271 with RDPHs. Again, the Alcalase hydrolysates showed the strongest inhibitory effect,
272 with the MDA content decreased by 49.28% compared to the control group. The
273 addition of hydrolysates obtained by the other four kinds of enzymes (Trypsin,
274 Neutrase, Protamex, and Flavourzyme) reduced the content of MDA by 46.80%,
275 30.73%, 22.07%, and 10.94%, respectively, when compared to the control group.

276 In summary, excessive ROS readily results in damage of the biomolecules within
277 the cell, causes proteins to denature and aggregate along with the collapse of cell
278 membrane, and eventually leads to cell apoptosis²⁷. Pre-incubation with RDPHs
279 clearly activates the intracellular antioxidant system, facilitates the expressions of
280 antioxidant enzymes, and thus protects the cells against H₂O₂-induced damage by
281 scavenging intracellular ROS. Additionally, the decrease of MDA content indicates
282 that RDPHs protects the fragile cell membrane from oxidative damage, inhibits the
283 lipid peroxidation and, thus, prevents reactive oxygen from pouring into the cells²⁸.
284 One of the probable reasons for the inhibition of the H₂O₂-induced oxidative stress by
285 RDPHs is found in the antioxidant activities of some peptide fractions²⁹. During the
286 same hydrolysis time, RDPs were substantially fragmented into peptides by the

287 cleavage reaction of the various proteases⁵. Moreover, there were differences in the
288 exposure of polypeptide chains among the hydrolysates. Stronger inhibitory activity
289 was observed for the hydrolysates prepared by Alcalase and Trypsin, indicating that
290 both contain more essential amino acids and significantly smaller peptides, which
291 greatly enhances the antioxidant properties and thereby effectively inactivates free
292 radicals, than the other hydrolysates.

293 **3.5. Effects of RDPHs on apoptosis of H₂O₂-treated HepG-2 cells**

294 The degree of apoptosis was determined by the Annexin V-FITC/PI assay based
295 on flow cytometry. In Figure 4A, normal cells are seen in the lower left quadrant.
296 Cells in the lower right quadrant are classified as early apoptotic. The cell population
297 in the upper right quadrant has been described as advanced apoptotic or necrotic.
298 When compared to the control group, H₂O₂-injured HepG-2 cells increased the
299 apoptosis rate from 6.64% to 44.98%. However, the ratio of apoptosis was
300 significantly decreased in response to RDPH pretreatment when compared with the
301 control group, indicating clearly that pre-incubation of HepG-2 cells with RDPHs
302 protects the cells against H₂O₂-induced apoptosis. In terms of protective efficiency,
303 Alcalase and Trypsin hydrolysates were found to be the most efficient, while
304 Flavourzyme protease hydrolysates were the least efficient, with apoptosis rates of
305 18.33%, 19.52%, and 38.13%, respectively, after 48 h of incubation. On the other
306 hand, accumulation of intracellular ROS leads to a profound alteration in
307 mitochondrial function. This is closely related to a steep fall in the level of
308 mitochondrial membrane potential³⁰. To assess the change of $\Delta\psi_m$ during apoptosis

309 induced by H₂O₂ in HepG-2 cells, flow cytometric analysis was carried out using JC-1.
310 In addition, a decrease of the red/green ratio indicates dissipation of the mitochondrial
311 $\Delta\psi_m$. As shown in Figure 4B, a marked drop in the mitochondrial membrane
312 potential was observed when cells were exposed to 0.4 mM H₂O₂ for 4 h (the
313 red/green ratio decreased from 2.62 ± 0.09 to 0.68 ± 0.7). Pre-incubation with various
314 hydrolysates significantly reduced the changes in $\Delta\psi_m$ induced by H₂O₂, indicating
315 that H₂O₂-induced mitochondrial membrane depolarization was partly suppressed by
316 pretreatment with RDPHs. The inhibiting effect of RDPHs prepared with Neutrase,
317 Protamex, and Flavourzyme were relatively low, with a red/green ratio of 1.63 ± 0.12 ,
318 1.48 ± 0.11 , and 1.08 ± 0.07 , respectively. The inhibitory effect of RDPHs hydrolysed
319 with Alcalase and Trypsin were much higher than those hydrolysed with other
320 proteases, mainly due to their ability to scavenge high levels of intracellular ROS
321 (Figure 2B). Generally, H₂O₂ can diffuse freely into and out of cells and tissues,
322 destroying the intracellular environment, and ultimately leading to cell death via
323 apoptosis^{25, 30}. In fact, cell apoptosis is one of the most easily demonstrable factors for
324 oxidation-induced changes. Furthermore, mitochondrion plays a fundamental role in
325 the apoptotic process, and the level of mitochondrial membrane potential ($\Delta\psi_m$) is
326 considered to be an indicator of apoptosis^{31, 32}. Our results reveal that RDPHs can
327 efficiently attenuate H₂O₂-induced apoptosis and inhibit the decrease of the
328 mitochondrial membrane potential. These positive effects can be attributed to the
329 hydrolysates' capability to neutralize H₂O₂-induced oxidative stress to some extent
330 (Figure 2) and to ensure the membrane integrity of the mitochondria by avoiding

331 oxidation of the cell membrane (Figure 3C). Alcalase and Trypsin may be a better
332 choice for the production of peptides with anti-oxidative properties. Apart from high
333 peptide levels resulting from enzymatic hydrolysis, specific amino acid composition
334 may also be a vital factor for this choice, because both of the indicators are closely
335 correlated with oxidation resistance.

336 **3.6. Molecular weight distribution and amino acid composition of RDPHs**

337 RDPHs obtained by various proteases were found to exhibit antioxidant abilities by
338 protecting the cells against H₂O₂-induced damage, and the protective effects were
339 noticeably distinct. This phenomenon may be associated with peptide length, which is
340 closely related to biological activities³³. Smaller peptides with low molecular weights
341 resulting from enzymatic hydrolysis were more activated. Table 1 shows the
342 molecular weights of peptides hydrolysed by different proteases for 2 h. The peptides
343 released from RDP by various enzymes were mainly composed of low
344 molecular-weight peptides (< 3 kDa). Meanwhile, differences in the distribution of
345 molecular weights were observed among the hydrolysates prepared by various
346 proteases. For Alcalase, the percentages for < 3 and 1-3 kDa fractions were 95.24%
347 and 17.18%, respectively, while only half of the peptides hydrolyzed by Flavourzyme
348 had a molar mass lower than 1kDa. The neutral protease hydrolysates were mainly
349 composed of 1-3 and < 1 kDa fractions (22.17% and 70.39% for Neutrase, 20.19%
350 and 68.9% for Protamex). In addition, the use of Trypsin also produced small peptides,
351 with 93.34% of the peptides falling in the range of 120 to 3,000 Da. This result
352 indicates that Alcalase was much more efficient at producing smaller peptides than

353 were the other proteases.

354 On the other hand, amino acid composition is considered to be critical to the
355 antioxidant properties of the hydrolysates. The amino acid composition of RDPHs at
356 2 h of hydrolysis time is indicated in Table 2. The RDPHs are rich in Asp, Glu, Arg,
357 phe, pro, and Leu, most of which reportedly are related to antioxidant activities either
358 in their free forms or as residues in proteins and peptides³⁴. Moreover, after hydrolysis
359 with different enzymes, the amino acid compositions of RDPHs were noticeably
360 distinct, reflecting the differences in exposure of the terminal amino groups. As shown
361 in Table 2, the content of amino acids related to anti-oxidation (take Asp and Glu as
362 representative)²⁴ was higher for the alkaline protease hydrolysates (Alcalase 22.76
363 g/100g and Trypsin 22.48 g/100g) when compared with the neutral protease
364 hydrolysates (21.58 g/100g for Neutrase; 20.96 g/100g for Protamex). In addition, the
365 use of Flavourzyme resulted in the lowest amount of Asp and Glu (14.85 g/100g).

366 These outcomes, in combination with the data for the H₂O₂-induced cell damage
367 model, suggests that peptide chain lengths and amino acids could greatly influence the
368 antioxidant activities of the hydrolysates, and that Alcalase may be the best choice for
369 the production of peptides with anti-oxidative properties.

370 **4. Conclusion**

371 This study demonstrated that the anti-oxidative peptides prepared from five
372 commercially available and low cost proteases were highly capable of inhibiting
373 H₂O₂-induced oxidative damage in human HepG-2 cells. This protection was
374 associated with the ability to neutralize H₂O₂-induced ROS, thereby enhancing certain

375 antioxidant enzymes, protecting the fragile cell membrane from oxidative damage,
376 and alleviating cell apoptosis. In addition, the protective effects were significantly
377 influenced by the type of enzyme used for hydrolysis. Samples hydrolyzed with
378 Alcalase and Trypsin showed the strongest protective effects against H₂O₂-induced
379 cytotoxicity, while the Flavourzyme hydrolysate was the least efficient, possibly
380 because of the difference in molecular weight distribution and amino acid
381 composition. This work provided the foundation to produce peptides with high
382 antioxidant activity.

383 **5. Acknowledgments**

384 This research was supported by National Natural Science Foundation of China
385 (31471616& 31201381), a grant from National Key Technology R&D Program
386 (2012BAD34B02&2012BAD37B02) and the National High Technology Research
387 Development Program of China (863 Program) (2013AA102206).
