DOI: 10.1039/b000000x [DO NOT ALTER/DELETE THIS TEXT]

One-dimensional (1D) $\text{Bi}_2\text{O}_2\text{CO}_3\text{-Bi}(\text{OHC}_2\text{O}_4)\cdot 2\text{H}_2\text{O}$ heterostructure was synthesized by low temperature solution method using $\text{Bi}(\text{OHC}_2\text{O}_4)\cdot 2\text{H}_2\text{O}$ nanorods as template. $\text{Bi}_2\text{O}_2\text{CO}_3$ nanosheets vertically grew onto the $\text{Bi}(\text{OHC}_2\text{O}_4)\cdot 2\text{H}_2\text{O}$ rods along the long axial direction. Its adsorption capacity for organic pollutants was evaluated using methyl orange (MO) as model. The results showed that $\text{Bi}_2\text{O}_2\text{CO}_3\text{-Bi}(\text{OHC}_2\text{O}_4)\cdot 2\text{H}_2\text{O}$ heterostructure had excellent adsorption capacity of 95.78 mg/g and repeatability for MO. $\text{Bi}_2\text{O}_2\text{CO}_3\text{-Bi}(\text{OHC}_2\text{O}_4)\cdot 2\text{H}_2\text{O}$ heterostructure also possessed excellent photocatalytic activity to degrade dyes (MO, RhB and MB) under solar/UV light irradiation. 20 mg/L of RhB, 30 mg/L of MB and 75 mg/L of MO could be completely degraded by $\text{Bi}_2\text{O}_2\text{CO}_3\text{-Bi}(\text{OHC}_2\text{O}_4)\cdot 2\text{H}_2\text{O}$ photocatalyst in 15, 25 and 120 min, respectively. This superior adsorptive and photocatalytic performance is ascribed to the synergistic effect of big BET surface area and the formation of numbers of junctions in $\text{Bi}_2\text{O}_2\text{CO}_3\text{-Bi}(\text{OHC}_2\text{O}_4)\cdot 2\text{H}_2\text{O}$ heterostructure. The trapping experiment of active species during the photocatalytic degradation was carried out, and the result indicates that $\text{O}_2^{\cdot -}$ radical and $\text{h}^+\square$ play a major role in the photocatalytic degradation process. This study provides a general and effective method to fabricate unique 1D $\text{Bi}_2\text{O}_2\text{CO}_3\text{-Bi}(\text{OHC}_2\text{O}_4)\cdot 2\text{H}_2\text{O}$ heterostructure with both photocatalytic and adsorptive performance on a large scale.

Introduction

While incredible strides in science and technology have indeed raised the quality and standard of the human life and health, it has nevertheless brought about a multitude of problems as well. Nowadays, organic dyes are used for coloring in a wide range of industries, such as textiles, dying, leather, paper and other industries due to the rapid development of the industrialized global economy.¹ Unfortunately, the

synthetic origin and complex aromatic molecular structures of the pollutants in color wastewater make these dyes more stable and resistant to biodegradation, and the presence of dyes highly influences water quality because most of them are considered to be toxic or even carcinogenic, posing a serious hazard to living organisms.^{2,3} So, water pollution and contamination is one of the biggest and the most alarming problems which demands formidable and effective solutions. The situation is worrisome particularly in developing countries and the nonavailability of economical water treatment techniques further aggravates the situation.^{4,5}

Many technologies such as chemical oxidation, photochemical degradation, ultrasonic degradation, reverse osmosis, otation and adsorption procedures, and the like have been proposed for dye removal.⁶⁻¹² Nevertheless, adsorption is recognized as one of effective and economic method because of its high efficiency, low costs and easy operation.¹³⁻¹⁷ Among various available adsorbents, semiconductors have potential applications in water treatment in recent years owing to their high surface area and low production and regeneration costs.¹⁸⁻²⁰ Semiconductor photocatalysis has drawn ever-increasing worldwide interest because it is considered as cost-effective, sustainable and the most promising green chemical technology for dye removal. However, the rapid recombination of photogenerated charge carriers for single semiconductor has seriously inhibited photocatalytic performance. Interestingly, coupling two or more kinds of photocatalysts to form heterojunction can obviously enhance photocatalytic activity due to the effective charge separation.²¹⁻²⁸

In general, a semiconductor with good photocatalytic activity may not have good adsorptive performance, and vice versa. Recently, in order to combine with the advantages of photocatalysis and adsorption technology, some researchers synthesized micro/nanomaterials possessing photocatalytic and adsorptive performance as well.²⁹⁻³² Upadhyay et al.³² reviewed the role of graphene/metal oxide composites as photocatalysts, adsorbents and disinfectants in water treatment. However, the reported semiconductors couldn't simultaneously exhibit good adsorptive and photocatalytic performance.

As an important semiconductor, $\text{Bi}_2\text{O}_2\text{CO}_3$ belongs to the layered Aurivillius-related oxide family, comprising alternate $(\text{Bi}_2\text{O}_2)^{2+}$ and CO_3^{2-} layers. It has attracted great attentions due to their anisotropic crystal structure and internal static electric field effect, which favors the photo-induced charge separation and transfer. Coupling $\text{Bi}_2\text{O}_2\text{CO}_3$ with other semiconductors including Bi_2MoO_6 ,²⁵ ZnO ,²⁶ C_3N_4 ,²⁷ TiO_2 ,²⁸ and $\text{Bi}_4\text{O}_5\text{I}_2$ ²⁴ has been clearly demonstrated to improve their photocatalytic

activities due to the formation of heterojunctions which can significantly reduce the recombination and speed up the separation rate of photogenerated charge carriers. However, Bi₂O₂CO₃ heterojunctions not only with high adsorptive capability, but also with high photocatalytic activity have not been reported at present.

In this paper, we successfully synthesized one-dimensional Bi₂O₂CO₃-Bi(OHC₂O₄)•2H₂O heterostructure with both high adsorptive capability and excellent photocatalytic performance. It could adsorb 95.78 mg/g of MO dye, and degrade high concentration organic dyes in short time under the solar/UV light irradiation. This outstanding adsorptive and photocatalytic performance is due to two reasons: 1) large BET surface area; 2) the formation of a large number of junctions in Bi₂O₂CO₃-Bi(OHC₂O₄)•2H₂O heterostructure. The trapping experiment of active species during the photocatalytic degradation proved that O₂^{-•} radical and h⁺ were the main active species. The possible photocatalytic mechanism of Bi₂O₂CO₃-Bi(OHC₂O₄)•2H₂O heterostructure was discussed in detail.

Experimental Section

Sample Preparation

All reagents were analytical grade and used without any further purification in our experiment.

The Bi(OHC₂O₄)•2H₂O nanorods were prepared through a hydrothermal process according to our previous report.²² 6 mmol of Bi(NO₃)₃•5H₂O and 9 mmol of Na₂C₂O₄ were added separately in distilled water (20 mL) to obtain solution A and B. Subsequently, the solution B was added dropwise into A. The mixtures were stirred for 30 min at room temperature in air, then added into a Teflon-liner stainless steel autoclave and maintained at 120 °C for 40 h. The samples were washed several times with anhydrous ethanol and distilled water, and then dried in air at 60 °C for 6 h.

Then, Bi₂O₂CO₃-Bi(OHC₂O₄)•2H₂O samples were prepared through a stirring process. In a typical experiment, Bi(OHC₂O₄)•2H₂O nanorods (0.5 mmol), CTAB (0.5 g) and different amounts of Na₂CO₃ were dispersed into distilled water (40 mL) under magnetic stirring for 30 min, and then different amounts of Bi(NO₃)₃•5H₂O was added with constant stirring for 2 h to obtained samples. The products were washed with distilled water and anhydrous ethanol, and then dried in air at 60 °C for 4 h. The as-obtained products with the molar ratio of Bi(OHC₂O₄)•2H₂O:Bi(NO₃)₃•5H₂O 20:1, 20:2, 20:3 and 20:5, were noted as S1, S2, S3 and S4, respectively.

Test of Photocatalytic Activity

Photocatalytic performance of the obtained samples was evaluated by the degradation of dyes under solar light irradiation. The optical system used for the photocatalytic reaction consisted of a 500 W Xe lamp (PLS-SXE300/300UV, Trusttech Co., Ltd. Beijing) and a 400 nm cutoff filter. In each experiment, 100 mg of sample was dispersed in 100 mL of dye under vigorous stirring for 30 min in the dark to reach an adsorption-desorption equilibrium between the photocatalyst and dye before light irradiation. Then, the suspension was illuminated by the Xe lamp under magnetic stirring. At irradiation time intervals, 4 mL of suspension was collected, and centrifuged to remove the photocatalyst. The solution was analyzed by UV-Vis absorption spectra. Additionally, the recycle experiments were performed for ten consecutive cycles

to test the durability. After each cycle, the catalyst was centrifuged and used directly for the next test.

Adsorption experiments

To determine the adsorption capacities of different samples, the obtained samples were as adsorbents for MO removal. The 100 mg of samples were added to 100 mL MO solutions with initial concentrations from 50 mg/L to 105 mg/L (5 mg/L intervals) until the equilibrium time was reached. The two phases were separated by centrifugation. The final MO concentrations remaining in the solution were measured by a UV-Vis spectrophotometer at 465 nm.

Adsorption kinetic experiments were conducted by adding 100 mg of adsorbents into a 100 mL solution at room temperature in air. The suspension was stirred in the dark for different time and above 4 mL of suspension was withdrawn, and centrifuged to remove the precipitate with UV-Vis absorption spectra.

The amount of adsorbed MO at equilibrium was calculated according to the following equations

$$q_e = (C_0 - C_t) V/M$$

where V is the volume of the aqueous solution (L), and M is the weight of the adsorbent (g), C_0 and C_t are the initial and final concentrations of MO in solutions, respectively.

Characterization

Field emission scanning electron microscopy (FE-SEM) images were recorded on a Hitachi S-4800 microscope. Transmission electron microscopic (TEM) images, high-resolution transmission electron microscopic (HRTEM) images and the selected area electron diffraction (SAED) patterns were performed on a JEOL-2010 microscope with an accelerating voltage of 200 kV. X-Ray powder diffraction (XRD) was carried out on a Rigaku (Japan) D/max γ A X-ray diffractometer with Cu-K α radiation ($\lambda = 0.154178$ nm). UV-vis diffuse-reflectance spectrum was recorded with a UV-2450 spectrophotometer in the wavelength range of 200-800 nm at room temperature. BaSO₄ was used as the reflectance standard material. The X-Ray photoelectron spectroscopy (XPS) was performed on a Perkin-Elmer RBD upgraded PHI-5000C ESCA system. Nitrogen adsorption/desorption measurements were performed at 77 K using a Micromeritics Tristar II 3020 M analyzer after the samples were degassed at 180 °C for 6 h. The Brunauer-Emmett-Teller (BET) surface area was estimated by using adsorption data in a relative pressure range from 0.05 to 0.3.

Results and discussion

X-ray powder diffraction (XRD) was used to identify the structure and phase composition. Fig. 1 shows the XRD patterns of the obtained Bi₂O₂CO₃-Bi(OHC₂O₄)•2H₂O heterojunctions with different loaded-Bi₂O₂CO₃ contents and pure Bi(OHC₂O₄)•2H₂O nanorods. It can be seen that all the diffraction peaks of bismuth oxalate (Bi(OHC₂O₄)•2H₂O) is the same with previous report.²² With the increase of the loaded-Bi₂O₂CO₃ content, the new diffraction peaks appear and their intensities increase gradually (S1 \rightarrow S3 samples), which are ascribed to the orthorhombic phase of Bi₂O₂CO₃ (JCPDS No.

41-1488). When the loaded-Bi₂O₂CO₃ content is very high (S4 sample), only the peaks of Bi₂O₂CO₃ can be found and those of Bi(OHC₂O₄)•2H₂O nanorods disappear completely. So, it is concluded that S4 sample is pure Bi₂O₂CO₃.

The SEM image of the Bi(OHC₂O₄)•2H₂O precursor was shown in Fig.S1. It can be seen that Bi(OHC₂O₄)•2H₂O precursor is rod-like structure, with the average diameter of 450 nm and length of 5.5 μm, respectively. Fig. 2 displayed the SEM images of the obtained Bi₂O₂CO₃-Bi(OHC₂O₄)•2H₂O heterojunctions and pure Bi₂O₂CO₃. The Bi₂O₂CO₃-Bi(OHC₂O₄)•2H₂O junctions are also rod-like structures, and ultrathin Bi₂O₂CO₃ nanosheets grow vertically onto the surface of Bi(OHC₂O₄)•2H₂O nanorod (Fig. 2a). Meanwhile, the more of the loaded-Bi₂O₂CO₃ content, the more ultrathin Bi₂O₂CO₃ nanosheets grow orderly onto the Bi(OHC₂O₄)•2H₂O rods along the long axial direction (Fig. 2b, c). The gap between Bi₂O₂CO₃ nanosheets becomes narrower and narrower, and the Bi(OHC₂O₄)•2H₂O rod becomes thinner and thinner. Finally Bi(OHC₂O₄)•2H₂O rod completely disappear, and pure Bi₂O₂CO₃ is formed due to the Kirkendall effect (Fig.2d).³³ However, the one-dimensional Bi₂O₂CO₃ structure collapses due to the disappearance of the Bi(OHC₂O₄)•2H₂O skeleton, and forms short rods constituted of many nanosheets (Fig. 1d). This result implies that the BET surface area of Bi₂O₂CO₃ will be larger than that of Bi₂O₂CO₃-Bi(OHC₂O₄)•2H₂O heterojunctions, which can be proved by the following result of BET surface area (Table 1).

To further obtain information about the structure of the sample, the S2 heterojunction was characterized by transmission electron microscopy (TEM). As shown in Fig. 3a, it can be clearly seen that the Bi₂O₂CO₃ nanosheets vertically grow onto the surface of the Bi(OHC₂O₄)•2H₂O rod, which is consistent with the result of the SEM measurements. Fig. 3b shows the high-resolution transmission electron microscopic (HRTEM) image taken from the tip (red square highlighted in Fig. 3a) of the Bi₂O₂CO₃ nanosheet. It is found that the lattice fringe (the edge of nanosheet) with interplanar spacing of 0.684 nm corresponds well to (002), while the fringe spacing of 0.273 nm corresponds to (110) crystallographic planes of tetragonal Bi₂O₂CO₃.

XPS measurement was also performed to further confirm the formation of Bi₂O₂CO₃-Bi(OHC₂O₄)•2H₂O heterostructures and investigate the chemical state of elements in this heterostructure. Fig. 4a shows the full XPS spectra of the as-prepared S2, Bi₂O₂CO₃ and Bi(OHC₂O₄)•2H₂O samples, demonstrating that all the products were mainly composed of Bi, C and O elements. In the high resolution Bi 4f XPS spectrum of Bi₂O₂CO₃ (Fig. 3b), The peaks located at 164.1 and 158.8 eV are attributed to Bi 4f_{5/2} and Bi 4f_{7/2}, respectively, which proves Bi ions in Bi₂O₂CO₃ sample are in form of Bi³⁺.²¹ More importantly, in the high-resolution Bi 4f XPS spectrum of S2, the peaks of Bi 4f shift to higher binding energies due to the strong interaction between Bi₂O₂CO₃ and Bi(OHC₂O₄)•2H₂O phases. A similar phenomenon was also observed in the C 1s spectra of Bi₂O₂CO₃-Bi(OHC₂O₄)•2H₂O sample (Fig.4c). In addition, the location and relative intensity

of the Bi–O (530.2 eV) and Bi–O (531.0 eV) peaks in S2 display obvious differences from those of Bi(OHC₂O₄)•2H₂O and Bi₂O₂CO₃ (Fig. 4d), indicating that the formation of a heterojunction significantly influenced the environment of a chemical bond in the crystal.

Fig. S2a displays the nitrogen adsorption–desorption isotherms of the obtained samples. The shape of the isotherm is a type IV isotherm with a type H3 hysteresis loop at high relative pressures according to the IUPAC classification, which indicates that these samples are mesoporous structures in the pore diameter range of 2–50 nm.³⁵ This result can be further confirmed by the corresponding pore size distribution, as shown in Fig. S2b. Table 1 gives the BET surface area of different samples. It can be found that the pure Bi₂O₂CO₃ nanosheet has the largest BET specific surface areas (26.478 m²•g⁻¹) which is consistent with the result of SEM image (Fig. 2 d), and Bi(OHC₂O₄)•2H₂O nanorod has the smallest BET surface area (3.844 m²•g⁻¹). The BET surface area of Bi₂O₂CO₃-Bi(OHC₂O₄)•2H₂O heterojunctions increase gradually from S1(8.782 m²•g⁻¹) to S3 (14.227 m²•g⁻¹).

The optical absorption property of the semiconductor is one of the important factors determining its photocatalytic performance. Fig. 5 (a) displays the diffuse reflectance spectroscopy (DRS) of the obtained samples at room temperature. The absorption edge of all samples is <400 nm, which shows they only absorb UV light. The optical band gap of Bi(OHC₂O₄)•2H₂O and Bi₂O₂CO₃ can be determined by the following equation:³⁶

$$\alpha h\nu = A(h\nu - E_g)^{2/n}$$

in which α , h , ν , A and E_g are the absorption coefficient, Planck constant, light frequency, a constant and band gap, respectively. And n equals to 4 for indirect band gap and 1 for direct band gap. here $n = 1$ for Bi(OHC₂O₄)•2H₂O and $n = 4$ for Bi₂O₂CO₃. In Fig. 5b, the extrapolation of the $(\alpha h\nu)^{n/2}$ against $h\nu$ plot on the x intercepts gives the optical band gap of 3.92 eV for Bi(OHC₂O₄)•2H₂O and 3.32 eV for Bi₂O₂CO₃.

The photocatalytic activity of S1, S2, S3, Bi₂O₂CO₃ and Bi(OHC₂O₄)•2H₂O samples were evaluated by degradation of RhB (20 mg/L) dye in aqueous solution under solar light (containing 4% UV light) irradiation. As shown in Fig. 6a, S2 sample displays the highest photocatalytic activity among all the photocatalysts, and RhB molecules can be completely decolorized in 30 min under solar light irradiation. The UV-vis absorbance spectra of RhB using different samples as photocatalysts are shown in Fig. S3. Fig. 6(b) displays the linear relationship between $-\ln(C/C_0)$ and irradiation time, suggesting that the photocatalytic degradation reaction of RhB over the as-prepared catalysts should belong to the first-order kinetic relation. The calculated reaction rates have been shown in Table 1. The reaction rate constant of 0.148 min⁻¹ for S2 sample is as 200, which is twice as ones for Bi(OHC₂O₄)•2H₂O and Bi₂O₂CO₃. Compared with Bi₂O₃-Bi₂WO₆,²² BiOI/Bi₄O₅I₂/Bi₂O₂CO₃ heterojunction,²⁴ and BiPO₄/Bi₂O₂CO₃ heterostructure,³⁷ Bi₂O₂CO₃-Bi(OHC₂O₄)•2H₂O heterojunction exhibits outstanding photocatalytic performance, which is ascribed to the formation of enough junctions in the S2 sample. According to the SEM images (Fig. 2) of Bi₂O₂CO₃-Bi(OHC₂O₄)•2H₂O heterojunctions, for low Bi₂O₂CO₃ content in S1 sample, sparse Bi₂O₂CO₃ nanosheets grown on

Bi(OHC₂O₄)•2H₂O rods are observed, so only a small number of junctions are generated, leading to a low photocatalytic activity. When the Bi₂O₂CO₃ content is increased in the S2 sample, a large number of junctions are formed, thus resulting in the highest photocatalytic activity for the optimal S2 sample. With the Bi₂O₂CO₃ content further increasing, dense Bi₂O₂CO₃ nanosheets almost cover the Bi(OHC₂O₄)•2H₂O rods, as observed in S3 sample (Fig. 2c), which decreases the light irradiation on Bi(OHC₂O₄)•2H₂O rods and the junction interfaces. This shielding effect of dense Bi₂O₂CO₃ nanosheets coating on the Bi(OHC₂O₄)•2H₂O rods makes the photocatalytic activity of S3 sample decrease.

Under UV light irradiation, S2 heterojunction shows better photocatalytic activity to degrade high concentrations of MB, RhB and MO. 20 mg/L of RhB molecules, 30 mg/L of MB and 75 mg/L of MO can be completely decolorized in 15, 25 and 120 min, respectively (Fig.6c), which can be proved by the photographs of S2 after UV light irradiation (Fig. 6d).

From Fig. 6a, we also find that the mixture sample (the mole ratio of Bi(OHC₂O₄)•2H₂O and Bi₂O₂CO₃ in the mixture is equal to that in the S2 heterostructure) shows low photocatalytic activity to degrade RhB under solar light irradiation. It is proved that the formation of junctions is very important to enhance photocatalytic performance of material. Moreover, even though Bi₂O₂CO₃ nanosheets have larger BET surface area than S2 sample, its reaction rate constant *k* is obviously smaller than S2's, which further proves that junctions is a more important factor than BET surface area to improve photocatalytic activity of the sample under solar light irradiation.

To investigate the stability of photocatalytic performance in solar light region, the S2 sample was used to degrade RhB (20 mg/L) dye in ten repeated cycles, and the results were shown in Fig. S4. It is noteworthy that S2 photocatalyst exhibits good photostability under solar light irradiation (Fig. S4a), and its photocatalytic efficiency reduces 2% after ten repeated cycles. From the XRD pattern (Fig. S4b), it can be found that the crystal phase of S2 sample is still Bi₂O₂CO₃-Bi(OHC₂O₄)•2H₂O heterojunctions, demonstrating its high stability in the process of photocatalysis.

In order to explore the photocatalytic mechanism of Bi₂O₂CO₃-Bi(OHC₂O₄)•2H₂O heterojunctions in detail, the trapping experiments of active species during this photocatalytic process were carried out. Benzoquinone (BQ), tertbutyl alcohol (TBA), and ammonium oxalate (AO) were used as scavengers of superoxide radical (•O₂⁻), hydroxyl radical (•OH) and hole (h⁺), respectively.^{38,21} Fig. 7 shows the effect of different scavengers on the photodegradation rate over the S2 sample. It can be found that the addition of TBA does not cause significant deactivation of S2 photocatalyst. However, the photocatalytic performance of S2 significantly decreases by the addition of BQ or AO. These results suggest that •O₂⁻ and h⁺ are the main active species in the photocatalytic process under solar light irradiation.

To determine the relative positions of conduction band (CB) and VB edges, the total densities of states of VB for Bi(OHC₂O₄)•2H₂O and Bi₂O₂CO₃ were measured, as shown in Fig. 8. The VB edges of Bi(OHC₂O₄)•2H₂O and Bi₂O₂CO₃ are 2.55 and 1.66 eV, respectively. According to the VB edges, combining with band gap of Bi(OHC₂O₄)•2H₂O (3.92 eV) and

Bi₂O₂CO₃ (3.32 eV), the CB edge potential of Bi(OHC₂O₄)•2H₂O and Bi₂O₂CO₃ is -1.37 and -1.66 eV, respectively, calculated from the equation of E_{CB} = E_{VB} - Eg.

Based on the above results and analysis, the degradation mechanism of Bi₂O₂CO₃-Bi(OHC₂O₄)•2H₂O heterostructures under solar light irradiation was illustrated in Fig. 9. When Bi₂O₂CO₃ and Bi(OHC₂O₄)•2H₂O semiconductors are in contact to form Bi₂O₂CO₃-Bi(OHC₂O₄)•2H₂O heterojunction, the excited electrons in the conduction band (CB) of Bi₂O₂CO₃ can transfer to CB of Bi(OHC₂O₄)•2H₂O due to their different conduct band position, while the holes remain in the valence band (VB) of Bi₂O₂CO₃. Meanwhile, the photogenerated holes on the VB of Bi(OHC₂O₄)•2H₂O transfer to that of Bi₂O₂CO₃ due to different VB position, but the excited electrons stay in the CB of Bi(OHC₂O₄)•2H₂O. Thus, the photogenerated electron-hole pairs in Bi(OHC₂O₄)•2H₂O-Bi₂O₂CO₃ heterostructure can be effectively separated and then the photocatalytic activity is significantly enhanced due to the formation of Bi₂O₂CO₃-Bi(OHC₂O₄)•2H₂O heterojunctions.

According to Fig. 9, it can be seen that the CB potential (-1.37 eV) of Bi(OHC₂O₄)•2H₂O is enough negative to E⁰(O₂/•O₂⁻) (-0.046 eV vs NHE), the electrons in the CB of Bi(OHC₂O₄)•2H₂O can reduce O₂ adsorbed on the surface of Bi(OHC₂O₄)•2H₂O nanorods to •O₂⁻ through one electron reducing reaction. The oxidation potential of Bi₂O₂CO₃ is 1.66 eV, which indicates that the photogenerated holes cannot directly oxidize hydroxyl groups or water molecules adsorbed on the surface of Bi₂O₂CO₃ to generate •OH radicals (2.7 V vs NHE). Hence, the h⁺ and •O₂⁻ radicals rather than •OH are the main active species and react directly with RhB in the solution for efficient degradation.

As we know, the LUMO RhB (+0.95 V vs NHE) is excited to RhB* (-1.42 V vs NHE)³⁹ when irradiated by visible light, then RhB* injects electrons into the CB of semiconductor, and subsequently the photocatalytic process occurs on the surface of semiconductor. Apparently, the CB potential of Bi₂O₂CO₃ is much more positive than the LUMO potential of the RhB molecule (see Fig. 8). As a result, the electron injection from the excited RhB molecules into the CB of Bi₂O₂CO₃ could not be favoured. This can explain why the RhB dye only can be adsorbed, but not be degraded by pure Bi₂O₂CO₃ sample in the visible light irradiation (Fig. S5). However, when Bi₂O₂CO₃-Bi(OHC₂O₄)•2H₂O heterostructure was used as photocatalyst, the photogenerated electrons of RhB molecules can effectively inject into the CB of Bi(OHC₂O₄)•2H₂O because their LUMO potentials (-1.42V vs NHE) is more negative than the CB potential of Bi(OHC₂O₄)•2H₂O (-1.37eV). Simultaneously, RhB is efficiently degraded.

The obtained heterojunctions and pure Bi₂O₂CO₃ not only show superior photocatalytic activity, but also display excellent absorptive ability. Fig. S6 displays their absorptive activity to RhB (20 mg/L), MB (20 mg/L) and MO (20 mg/L) dyes. It can be found that all the Bi₂O₂CO₃-Bi(OHC₂O₄)•2H₂O heterostructures and Bi₂O₂CO₃ display high adsorptive capability and selectivity to MO dye. Further adsorption experiments were carried out. As shown in Fig. 10, MO (75 mg/L) dye in aqueous solution was used to evaluate the absorptive ability of S1, S2, S3 and Bi₂O₂CO₃ samples. It can be seen that S3 sample displays the highest adsorptive capability among four samples. It is noteworthy that all samples can quickly reach an adsorption/desorption equilibrium within 5 min. As we know, BET surface area plays

an important role in material's adsorptive capability. Generally, the larger BET surface area is, the stronger the adsorptive ability is. According to Table 1, BET surface area of heterostructures gradually increases from S1 to S3 and their adsorptive abilities also enhance in order. However, Bi₂O₂CO₃ owns the largest BET area in all the obtained samples, but its adsorptive ability is obviously weaker than that of S3 and S2. The above result implies that there exists other reason to affect the adsorptive ability of materials except BET surface area. Compare with their differences in detail, we can find that S3 and S2 are heterojunctions and Bi₂O₂CO₃ is single material. So, the enhanced adsorptive ability of S3 and S2 is attributed to the synergistic effect of the formation of numbers of junctions and large BET surface area.

The adsorption of MO on S3 follows the langmuir isotherm (Fig. S7) because of the high correlation coefficients ($R^2 = 0.998$). The maximum adsorption capacity (q_m) of the adsorbent S3 can be obtained from the intercept of the line of Ce/qe against Ce , and the q_m is 95.78 mg/g.

Previously some researchers investigated several adsorbents for the removal of MO from aqueous solutions.⁴⁰⁻⁵³ A comparison of the contact time and the adsorption capacities of MO onto various adsorbents is shown in Table 2, which clearly suggests that although the Bi₂O₂CO₃-Bi(OHC₂O₄)•2H₂O heterojunctions have a relatively suitable adsorption, they hold much greater potential for water treatment due to the short contact time.

A good adsorbent should not only be quick in adsorption of pollutants but also should exhibit speedy and complete desorption of pollutants during regeneration in order to be reused. For organic pollutants, such as dyes and pesticides, regeneration can be carried out by simply washing composite with a solvent to dissolve away the pollutants. The S3 heterojunction not only shows remarkable adsorptive ability for MO, but also displays good repeatability. When S3 sample adsorbed MO dye was dispersed into ethanol solution, MO dye molecules can desorb completely from S3 (Fig. S8), and S3 can be reused many times. Fig. 11 shows the adsorption capacities of the regenerated S3 adsorbent. It can be found S3 sample displays good adsorptive ability for MO (80 mg/L), and its adsorptive efficiency only reduces 2% after eight repeated cycles, which also can be proved by the photograph of MO solution after eighth adsorption (inset in Fig.11).

Conclusions

In summary, the novel one-dimensional Bi(OHC₂O₄)•2H₂O-Bi₂O₂CO₃ heterostructures with both excellent adsorptive and photocatalytic performance have been prepared for the first time. Bi₂O₂CO₃ nanosheets uniformly grew on the surface of the Bi(OHC₂O₄)•2H₂O nanorods along axial orientation. The obtained Bi₂O₂CO₃-Bi(OHC₂O₄)•2H₂O heterojunctions exhibit excellent photocatalytic activity to degrade organic dyes under solar/UV light irradiation. High concentration RhB (20 mg/L), MB (30 mg/L) and MO (75 mg/L) dyes can be completely degraded in 15, 25 and 120 min, respectively, under UV light irradiation using S2 sample as photocatalyst. The reaction rate

constant of 0.148 min⁻¹ for S2 is as 200 and 2 times as ones for Bi(OHC₂O₄)•2H₂O and Bi₂O₂CO₃ under solar light irradiation. Bi₂O₂CO₃-Bi(OHC₂O₄)•2H₂O heterostructure also shows excellent adsorption performance. Its adsorptive capacity reaches 95.78 mg/g for MO, with contact time of only 5 min. According to the investigation, these outstanding adsorptive and photocatalytic performance are ascribed to the synergistic effect of big BET surface area and the formed junctions in Bi₂O₂CO₃-Bi(OHC₂O₄)•2H₂O heterostructure. Generally, this study provides a general and effective method to fabricate unique 1D Bi₂O₂CO₃-Bi(OHC₂O₄)•2H₂O heterostructure with both photocatalytic and adsorptive performance on a large scale.

A novel one-dimensional (1D) $\text{Bi}(\text{OHC}_2\text{O}_4)\cdot 2\text{H}_2\text{O}-\text{Bi}_2\text{O}_2\text{CO}_3$ heterostructures were synthesized by simple low temperature solution-phase method. The $\text{Bi}_2\text{O}_2\text{CO}_3-\text{Bi}(\text{OHC}_2\text{O}_4)\cdot 2\text{H}_2\text{O}$ heterostructure exhibits outstanding photocatalytic activity for degrading high concentration RhB, MB and MO dyes, and excellent adsorptive capability to MO dye.
