4

11 Chlorinated solvents are some of the most pervasive pollutants found in groundwater and drinking water sources in the
12 United States (U.S.). In the early 2000s, bioremediation emerged as a novel and effective technology, but was limited by
13 challenges to delivery and transport of nutrients and microbes. Electrokinetic bioremediation (EK-Bio) has since emerged as
14 a promising alternative to solve these limitations, delivering successful results at the lab and pilot scale. EK-Bio can be
15 applied at sites where traditional bioaugmentation, the transformation of pollutants via an added microbial culture, is
16 transport limited. The application of direct current *in situ* in electrokinetic (EK) remediation facilitates transport of the
17 microbial culture and substrate in the subsurface. Despite this recent surge in interest surrounding EK-Bio, it is not clear
18 how this technology would perform at a site with elevated levels of alternative electron acceptors, another common barrier
19 to successful bioremediation. Our objectives were to use bench scale reactors to 1) determine which reactions and
20 processes would dominate when using EK-BIO to treat TCE contamination at a site with high levels of the alternative electron
21 acceptor sulfate, 2) compare EK-Bio to a traditional bioremediation application without electrokinetics, and 3) understand
22 the effect of EK-Bio on the microbial community under these conditions. Our results showed complete transformation of
23 TCE to ethene and acetylene by EK-Bio, while only 15% of TCE was transformed to cis-DCE and VC via traditional
24 bioaugmentation. Instead, the majority of the TCE was converted to acetylene, likely due to its electrochemical reduction
25 at the cathode. EK-Bio out performed traditional methods as it facilitated TCE biotic and abiotic transformation. Next
26 generation sequencing analysis showed the microbial community in the EK-Bio reactor was highly enriched by the
27 bioaugmentation culture, and community structure and diversity were minimally affected by the electrokinetic application.
28 These results demonstrate that EK-Bio is an effective and promising remedy for treating chlorinated solvent contamination
29 at transport limited sites with high concentrations of competing electron acceptors. This combined treatment strategy can
30 be used to extend traditional bioaugmentation to a greater number of polluted sites, restoring more contaminated water
31 systems for beneficial use.

32 Water Impact Statement

33
34 Trichloroethene (TCE) is one of the most widespread
35 contaminants in groundwater affecting an estimated 4.5-18%
36 of drinking water sources in the United States. Combined
37 remediation technologies are required to address the
38 increasingly complex sites which remain polluted. Here, we
39 present a combined bioelectrochemical approach which
40 improves treatment outcomes and extends applications of
41 traditional technologies.

42 1. Introduction

43
44 Chlorinated solvents like perchloroethylene (PCE) and
45 trichloroethylene (TCE) are common groundwater
46 contaminants throughout the United States (U.S.) which cause
47 concern due to their toxic properties and widespread
48 occurrence^{1,2}. Previously used as dry cleaning and degreasing
49 agents, these chemicals entered the watershed due to
50 accidental spills and improper disposal^{3,4}. PCE has been
51 detected in 4% of aquifers tested by the U.S. Geological Survey
52 (USGS), and TCE has been measured in 4.5-18% of the country's
53 drinking water supply sources^{5,6}. Health issues associated with
54 PCE and TCE range from damage to the nervous system, liver,
55 kidney, and reproductive systems, to developmental issues,
56 and possibly cancer^{5,6}. PCE and TCE daughter product vinyl

57 chloride (VC) is a known carcinogen⁷. Given the health effects
58 associated with these compounds and their daughter products,
59 complete removal or transformation to non-toxic ethene is
60 required to protect human health⁸.

61 One commonly used method for treating chlorinated
62 solvent contamination is bioaugmentation, the *in situ* addition
63 of a bacterial culture capable of dechlorinating PCE and TCE to
64 ethene^{9,10}. The key bacteria, *Dehalococcoides*, removes one
65 chlorine atom at time and replaces them with hydrogen in a
66 process known as microbial reductive dechlorination,
67 transforming PCE to TCE, TCE to cis-dichloroethene (cis-DCE), cis-
68 DCE to VC, and VC to ethene¹¹. *Dehalococcoides*, are strict
69 anaerobes that use H₂ as an electron donor and acetate as a
70 carbon source⁹. They require moderate temperatures (25-
71 40°C) and neutral pH conditions¹¹. In the subsurface, H₂ and
72 acetate can be delivered to *Dehalococcoides* through anaerobic
73 fermentation of substrates like lactate¹². Bioaugmentation
74 using cultures with *Dehalococcoides* was developed as a
75 treatment strategy in the 1990's, and hundreds of sites have
76 since been successfully treated with this remedy¹³. Despite this
77 success, there remain challenges to bioaugmentation efficacy.
78 Two of the most substantial challenges to anaerobic
79 bioremediation of chlorinated solvents are microbial
80 competition from native soil bacteria and transport of
81 bioaugmentation cultures and substrates *in situ*¹⁴.

82 One of these challenges, transport limitations, can be
83 addressed by pairing traditional bioaugmentation with
84 technologies that improve delivery of nutrients and microbes,
85 like electrokinetics (EK)¹⁵. EK is the application of direct
86 current to the subsurface to induce transport *in situ*. Soluble
87 molecules may be transported via movement of fluid through
88 pore spaces (electroosmosis) and ions or other charged
89 molecules may move to the oppositely charged electrode
90 (electromigration and electrophoresis)¹⁵. When EK is

91 combined with bioaugmentation (EK-Bio), the bioaugmentation
 92 culture and electron donor are added to the subsurface via
 93 traditional injection wells and transported via electrokinetic
 94 mechanisms in addition to the natural advective gradient¹⁵. It
 95 is important to note that the application of current causes
 96 electrochemical reactions at each electrode, namely production
 97 of oxygen gas at the anode and hydrogen gas, H₂, at the
 98 cathode according to the reactions below¹⁶.

102 Further, these reactions generate a pH gradient with acidic
 103 conditions at the anode and basic conditions at the cathode¹⁶.
 104 Both the extreme pH fronts and the oxygen produced by the
 105 anode must be carefully managed at sites where microbial
 106 reductive dechlorination is employed to maintain the specific
 107 conditions required by *Dehalococcoides*.

108 Microbial competition for H₂ in the subsurface
 109 between *Dehalococcoides* and native soil bacteria is caused by
 110 high concentrations of alternative electron acceptors, like
 111 sulfate. High levels of sulfate are often found in PCE and TCE
 112 plumes due to natural sources, like atmospheric deposition,
 113 sulfate mineral dissolution, and sulfide mineral oxidation, or
 114 anthropogenic sources, like coal mines, power plants, and
 115 refineries^{17,18}. Like microbial reductive dechlorination,
 116 microbial sulfate reduction is carried out with H₂ as an electron
 117 donor, leading to competition between sulfate reducing
 118 bacteria (SRB) and dechlorinating bacteria for the limited H₂
 119 available *in situ*¹⁷. Further, sulfide inhibition of dechlorination
 120 also occurs at high concentrations (greater than 5mM) due to
 121 the toxicity of the sulfide species (H₂S and HS⁻) produced from
 122 sulfate reduction¹⁷. These inhibitory effects are further
 123 exacerbated in the field when sites are flooded with electron
 124 donor as toxic sulfide species accumulate¹⁷. It is not clear how
 125 EK-Bio would perform at a site with elevated levels of
 126 alternative electron acceptors. Electrokinetic bioaugmentation
 127 of chlorinated solvents at sites with high concentrations of
 128 sulfate has not been extensively studied. It is possible that EK
 129 transport of substrate could favor SRB who can out-compete
 130 *Dehalococcoides* for H₂¹⁹. This scenario could cause a stall of
 131 microbial reductive dechlorination or generation of a reactive
 132 metal sulfide species capable of abiotic dechlorination²⁰⁻²². A
 133 mixture of biotic and abiotic reactions could occur, including
 134 some electrochemical transformations of TCE which have been
 135 reported in closed recirculation systems with Pt, Pd, iron, and
 136 graphite electrodes²³⁻²⁵. Our objectives were to 1) determine
 137 which reactions and processes would dominate at a TCE
 138 contaminated site with high levels of the alternative electron
 139 acceptor sulfate, 2) compare EK-Bio to a traditional
 140 bioremediation application without electrokinetics, and 3)
 141 understand the effect of EK-Bio on the microbial community
 142 under these conditions.

143 2. Materials and methods

144 **2.1 Reactor Design and Set-up** This experiment featured a
 145 combined electrokinetic bioaugmentation (EK-Bio) reactor and
 146 a traditional bioaugmentation reactor (Bio). The Bio reactor
 147 was operated with traditional bioaugmentation methods where

148 diffusion is the main processes for mass transfer. No current
 149 was applied to the Bio reactor. The EK-Bio reactor was
 150 operated with a combined electrokinetic and bioaugmentation
 151 approach. Direct current was delivered to the EK-Bio reactor
 152 via power supply (Rigol DP832). Each of the two reactors was
 153 constructed from acrylic, consisting of a central soil
 154 compartment (40 cm long, 8 cm wide, 20 cm high; 6.4 L)
 155 between two electrode chambers (10 cm long, 8 cm wide, 20
 156 cm high; 1.6 L). The soil and electrode compartments were
 157 divided with a plastic porous separator (Midland Scientific Inc,
 158 HDPE, 1.6mm, medium grade porosity). A grid of nylon
 159 Swagelok sampling ports fitted with rubber septa covered the
 160 top and front face of each soil chamber. Porous metal tubes
 161 made of rolled screening (nickel 200, wire mesh 70 x 70) were
 162 inserted into all the ports to allow collection of porewater for
 163 sampling. Graphite electrodes (Fine extruded rod, 1.27 cm OD,
 164 Graphite Store) were used for both the anode and cathode.
 165 Once the electrodes were in place, the electrode chambers
 166 were filled with glass beads (11mm OD) to decrease the
 167 electrode compartment volumes to approximately 280 mL. A
 168 gas bag (5L, PVF Tedlar bag, Cole Parmer) was fitted on top of
 169 the electrode chambers of each reactor to allow release of
 170 gases created during electrolysis and microbial reactions. In
 171 the EK-Bio reactor, a peristaltic pump (Masterflex L/S) was used
 172 to recirculate electrolyte between the anode and cathode
 173 compartment at 1mL min⁻¹ to manage the pH gradient formed
 174 from electrokinetic reactions, an approach commonly used in
 175 the field²⁶.

176 The soil used for this experiment was a mixture of local
 177 Arizona clay topsoil and F85 sand. Soil was added to the
 178 central chamber in several layers and compacted with a 0.100
 179 kg hammer with rubber tips. Approximately 6.9 kg of soil were
 180 added in total.

181 The electrolyte was synthetic groundwater at a pH of 8.5
 182 made according to the recipe outlined in previous work
 183 modified to include 10 mM sodium bicarbonate, 11.45 mM
 184 sulfate, and 2 mM TCE²⁷. This synthetic groundwater, free of
 185 TCE and sulfate, was periodically added to the EK-Bio reactor
 186 through the experiment as electrolyte levels decreased due to
 187 electrolysis reactions occurring at the electrodes.

188 **2.2 Reactor Operation** After the addition of soil into each
 189 reactor, an injection well was created by coring out a 12 mm
 190 OD (outer diameter) cylinder with metal tubing and inserting a
 191 piece of 6mm OD Teflon tubing with 1mm sized pores. The
 192 electron donor, lactate (sodium DL-lactate, 60% syrup, Sigma-
 193 Aldrich), was added to each via the injection well to a final
 194 groundwater concentration of 10 mM. An incubation stage of
 195 21 days followed this addition to allow anaerobic conditions to
 196 be reached. In the case of the EK-Bio reactor, a potential of 30
 197 V was applied to distribute the lactate during this time leading
 198 to a current that stabilized around 10 mA. With the electrodes
 199 40 cm apart and just under 20 cm in length, this results in a
 200 current density of 0.0125 mA cm⁻². This current density is in
 201 line with work conducted in the field with a current density of
 202 approximately 0.0184 mA cm⁻² (26). According to Cox et al.
 203 (2008), this 150 m² field site was treated successfully over 14
 204 months with power requirements equivalent to that of two
 205 100-watt light bulbs. This value is relatively low, especially
 206 when compared to other remedial technologies, like thermal
 207 treatments (26).
 208

209 Once anaerobic conditions were reached, as
210 quantified by measurements of oxidation reduction potential
211 (ORP), a bioaugmentation culture known as ZARA-10 was
212 injected into the reactors. The culture was enriched as outlined
213 in Delgado et al.²⁸. In the EK-Bio reactor, the current was
214 paused during the addition of the culture to allow the culture
215 to acclimate and was resumed after 14 days. A second dose of
216 lactate was added after this time. Both reactors were operated
217 for a total of 11 weeks. Samples were taken approximately
218 weekly to monitor pH, ORP, and concentrations of chlorinated
219 solvents, sulfate, sulfide, lactate, and fermentation products.
220

221 **2.3 Chemical Analysis** After pore-water samples were extracted
222 with a glass syringe, the oxidation reduction potential (ORP)
223 and pH of the samples were measured with probes (Sartorius
224 pHCore). High performance liquid chromatography (HPLC) and
225 ion chromatography (IC) were used to measure lactate and
226 volatile fatty acid (VFA) concentrations and sulfate
227 concentrations after filtration through a 0.2µm PVDF filter. The
228 instruments used were a Shimadzu HPLC (LC 20-AT) with an
229 Aminex HPX-87H (Bio-Rad) column and photodiode-array
230 detector (210nm) and a Metrohm 930 Ion Chromatograph with
231 a Metrosep A Supp 5-150/4.0 column and A Supp 5 100x
232 carbonate based eluent. Total soluble sulfides were measured
233 with the HACH kit TNT861, and hydrogen sulfide gas was
234 measured with Draeger tubes (MSI-Mid State Instruments LLC).
235 A gas chromatograph (GC) (Shimadzu) equipped with a flame
236 ionization detector (FID) with a packed column (Restek Rtx-624)
237 was used to measure TCE and daughter products. Liquid
238 samples of 1 mL were withdrawn from each port and placed in
239 a 2mL capped vial. After 24 hours of shaking, headspace
240 samples were withdrawn from the vials with a 500 µl gas-tight
241 syringe, and 200µl of gas was injected into the GC for analysis.
242 Scanning electron microscopy energy dispersive X-ray
243 spectroscopy (SEM-EDX) (Nova 200 NanoLab) at the Arizona
244 State University (ASU) Eyring Materials Center was used to
245 detect insoluble mineral compounds present in the soil at the
246 end of the experiment.
247

248 **2.4 Microbial Community Analysis** At the end of the
249 experiment, vertical soil cores were taken along each sampling
250 port. DNA was extracted from the soil samples using the
251 MoBio Powersoil® DNA isolation kit. The Qiagen DNeasy
252 PowerClean Pro Cleanup kit was then used to further improve
253 the quality of the DNA.
254

255 The barcoded primer set 515/806R was used to
256 perform sample sequencing on the V4 region of the 16S rRNA
257 gene^{29,30}. Library preparation was conducted using a protocol
258 from the Earth Microbiome Project at the Microbiome Analysis
259 Laboratory in the Biodesign Swette Center for Environmental
260 Biotechnology, Arizona State University³¹. A MiSeq Illumina
261 sequencer (Illumina Inc., Dan Diego, CA) was used for the
262 sequencing via the chemistry version 2 (2 x 150 pair-end).
263 Demultiplexed paired-end fastq files produced by CASAVA
264 (Illumina) were used as inputs to QIIME2 version 2020.2 for
265 evaluation^{32,33}. Fastq files were quality filtered, trimmed,
266 denoised, and merged with the DADA2 software package
267 wrapped in QIIME2³⁴. Sequences were truncated at 250
268 basepairs due to a decline in quality of reverse reads that point.
269 The QIIME2 feature-classifier plugin and the Naïve Bayes
270 classifier trained on the Greengenes 13.8 99% OTU full-length
sequences were used to assign taxonomy. Alpha and beta-

271 diversity analysis was completed with the QIIME2 q2-diversity
272 plugin at a sampling depth of 8,750. A pairwise PERMANOVA
273 test of beta diversity significance using weighted unifrac
274 distance was run in Qiime2 using the beta-group-significance
275 command, and the Kruskal-Wallis test of alpha diversity
276 significance was run in Qiime2 using the alpha-group-
277 significance command. Raw sequences for this project are
278 available in the NCBI SRA under the BioProject ID
279 PRJNA631539.

280 3. Results and discussion

281 3.1 EK-Bio Treatment Outperformed Traditional Bio Method

282 Figure 2 shows the transformation of TCE to daughter products
283 across the Bio and EK-Bio reactors over the 11-week
284 experiment. In the Bio reactor, products of microbial reductive
285 dechlorination, cis-DCE and VC, appeared by week 4. Trace
286 amounts of non-toxic ethene, 2.1-4.6 µM, appeared by week 8,
287 but the largest concentration of daughter products remained
288 cis-DCE and VC with average concentrations across the reactor
289 of 86.5 µM (58.4% deviation) and 17.5 µM (52.0% deviation)
290 respectively. Hindrance of microbial reductive dechlorination
291 leading to cis-DCE accumulation has been reported in cultures
292 where *Dehalococcoides* is out competed by other microbes for
293 H₂²⁸.

294 In the EK-Bio reactor, microbial reductive
295 dechlorination products appeared at week 4, similar to the Bio
296 reactor. There was also an initial spike in TCE at week 2, likely
297 due desorption caused by electroosmosis³⁵. Minimal amounts
298 of the reductive dechlorination daughter product cis-DCE were
299 observed in the EK-Bio reactor, but spikes of VC, 17.7 µM, were
300 detected by week 11. Near the end of the experiment at week
301 9.5, ethene concentrations in the EK-Bio reactor (28.3 µM)
302 were higher than the Bio reactor (4.6 µM). Acetylene, a TCE
303 daughter product formed through reaction with mineral
304 compounds or cathodic reduction, appeared in the cathode
305 chamber of the EK-Bio reactor early on in the experiment at a
306 concentration of 1.2 mM and reached 1.4 mM and 1.9 mM at
307 ports 1 and 2 by week 11. By the end of the experiment
308 acetylene concentration across the reactor averaged 824.0 µM
309 (45.5% deviation). These results suggest both biological and
310 chemical transformation of TCE occurred in the EK-Bio reactor
311 as acetylene is the signature product of abiotic reaction while
312 VC is a signature daughter product of microbial reductive
313 dechlorination found infrequently in abiotic reactions²⁰.
314

315 3.2 Conditions for Microbial Reductive Dechlorination

316 **Eventually Achieved in Both Reactors** Differing dechlorination
317 results can be attributed to variations in substrate transport
318 rates and operating conditions in each reactor. In the Bio
319 reactor, conditions for microbial reductive dechlorination were
320 reached at a slower pace than in the EK-Bio reactor. A negative
321 ORP reflective of anaerobic conditions was achieved in the
322 cathode side of the Bio reactor near the injection port by week
323 3, prior to injection of bioaugmentation culture, but reducing
324 conditions were reached in the anode side only by week 9.
325 Acetate, the fermentation product of lactate and an indication
326 of anaerobic conditions, was not measurable in the Bio reactor
327 until week 6. Concentrations of acetate remained low, < 13
328 mM, until week 10 when increased concentrations were
329 measured in the anode and cathode chambers, 43.9 and

330 38.5mM respectively. While more time was required to reach
331 reducing conditions and transport substrate, pH remained near
332 neutral in the Bio reactor for the duration of the experiment.

333 Contrastingly, in the EK-Bio reactor conditions for
334 microbial reductive dechlorination were reached quickly,
335 though with greater challenges for pH control. A negative ORP
336 was achieved by week 2, immediately following injection of
337 lactate in week 1. Detection of lactate was delayed until week
338 8, but once measurable, was present at high concentrations,
339 approximately 1-2mM, and evenly distributed throughout the
340 contaminated soil. Concentrations of acetate peaked at week
341 10, around 60 mM. This increase in acetate, seen in both
342 reactors at week 10, may have been due to uneven flow paths
343 leading to areas of high concentration or to acetate produced
344 via inorganic carbon and hydrogen via acetogenesis (Figure 4).
345 Particularly in the EK-Bio reactor, the high relative abundance
346 of these genera at port 4 corresponds to acetate peaks at week
347 10 near the anode chamber port 4. A large pH gradient
348 developed in the EK-Bio reactor by week 2 (Figure 5) but was
349 neutralized by slightly increasing the rate of recycle between
350 the anode and cathode. This gradient reappeared by week 10
351 suggesting an even greater recycling rate or added buffer might
352 be needed. While pH management was more difficult in the
353 EK-Bio reactor, reducing conditions were achieved earlier due
354 to better distribution of lactate, creating conditions that were
355 more amenable to microbial reactions than in the Bio reactor.
356

357 3.3 Sulfate Transport and Abiotic Reactions Effect Treatment

358 **Performance** Despite eventually reaching reducing conditions
359 and diffusion of electron donor throughout the reactor,
360 microbial reductive dechlorination stalled in the Bio reactor at
361 cis-DCE and VC between weeks 9 and 10. This stall can be
362 attributed to competition between Dehalococcoides and SRB
363 due to sulfate transport limitations. As seen in Figure 6, in the
364 Bio reactor, sulfate remained distributed throughout the soil
365 for the duration of the experiment. By the end of the
366 experiment, concentrations of sulfate remained over 3 mM at
367 some locations possibly leading to competition for H₂ by SRB.
368 The competition facing *Dehalococcoides* was further
369 confounded by with increasingly inhibitory concentrations of
370 sulfide, already at soluble concentrations of up to 0.2mM¹⁷.
371 Contrastingly, by week 3 in the EK-Bio reactor sulfate nearly
372 disappeared except in the anode and cathode chambers. With
373 an expected rate of electromigration of 1.2 x 10⁻⁶ m s⁻¹, sulfate
374 would be transported the length of the reactor in 4.5 days
375 (calculations in SI). The accumulation of sulfate in the anode
376 and cathode chambers by week 3 is reflective of this quick
377 migration rate. Competition for H₂ between SRB and
378 *Dehalococcoides* was quickly eliminated, allowing microbial
379 reductive dechlorination to ethene to proceed uninhibited.

380 The reduction of sulfate in the EK-Bio reactor may have
381 also contributed to formation of TCE daughter product
382 acetylene. Hydrogen sulfide generated from microbial sulfate
383 reduction (equation 3) can react with iron oxide/hydroxide
384 species to form elemental sulfur and iron (II) sulfide (equation
385 4). The iron (II) sulfide subsequently reacts with TCE to form
386 acetylene (equation 5), as outlined in the reactions below³⁶.
387 Sulfate removal of up to 75%, along with low soluble sulfide
388 concentrations measured (Figure 6), suggest precipitation of
389 metal sulfides. Transformations of chlorinated ethenes via this
390 biogeochemical pathway have been reported in lab studies and
391 in the field through monitored natural attenuation schemes or

392 engineered systems³⁶⁻³⁸. Measurements of insoluble iron
393 species by the SEM-EDX averaged 3.8% by weight, indicating a
394 high enough concentration to transform available TCE to
395 acetylene.

400 Generally, the rate of microbial reductive dechlorination has
401 been reported to be much faster than abiotic reaction with iron
402 minerals²⁰. However, the rate of abiotic reaction can be
403 significantly increased at sites with favorable environmental
404 conditions which increase reactant loading, as occurred in the
405 EK-Bio reactor²⁰. In addition to high concentrations of organic
406 carbon, iron, or sulfate, the abiotic reaction rate can be
407 accelerated with increases in pH³⁹. Weerasooriya and
408 Dharmasena³⁹ demonstrated a monotonic increase in reaction
409 rate between iron (II) sulfide and TCE from 0.03 h⁻¹ at pH 8 to
410 over 0.05 h⁻¹ at pH 10. While the pH spikes in the EK-Bio
411 reactor were detrimental to microbial reductive dechlorination,
412 they may have aided reaction rates of biogeochemical
413 transformation. While both the EK-Bio and Bio reactors had
414 high levels of sulfate and iron needed to generate the reactive
415 chemical species, but quicker attainment of reducing conditions
416 and more uniform organic carbon substrate distribution in the
417 EK-Bio reactor may have better facilitated biogeochemical
418 reduction of TCE.

419 Alternatively, acetylene can be generated through
420 direct cathodic reduction of TCE. Cathodic reduction of
421 chlorinated solvents has been investigated previously with Pt,
422 Pd, iron, and graphite electrodes in closed recirculation
423 systems²³⁻²⁵. TCE can follow several abiotic dechlorination
424 pathways with multiple daughter products, but the appearance
425 of acetylene indicates β-elimination was likely the mechanism.
426 The use of a graphite electrode has been reported to lead to
427 the by-product chloromethane, a known carcinogen, through
428 the combination of chloride and methyl radicals created
429 through the Kolbe reaction of acetate²⁵. No chloromethane
430 was detected in this experiment, likely as acetate was
431 consumed by SRB or dechlorinating bacteria.

432 Under similar conditions in a soil free reactor with a
433 granular graphite electrode and the application of 15 V, Al-
434 Abed and Fang (2007) measured transformation of 76% of TCE
435 to ethene and ethane in 25 hours. In this EK-Bio experiment,
436 acetylene may have been the primary reaction product rather
437 than ethene or ethane as it volatilized out of solution into the
438 gas bag, preventing further reaction with the cathode or iron
439 species in the soil. The early appearance of acetylene in the
440 cathode chamber of the EK-Bio reactor and the complete
441 absence of acetylene in the Bio reactor suggest cathodic
442 reduction was the primary, or at least initial, abiotic
443 transformation mechanism of TCE in this experiment²⁵. The
444 rate of electroosmosis, the primary transport mechanism for
445 acetylene, is 2.9 x 10⁻⁷ m s⁻¹ (calculations in SI). At this rate,
446 which is similar to those previously reported, acetylene
447 generated in the cathode chamber by cathodic reduction could
448 travel to the anode chamber in approximately 16 days⁴⁰. The

449 appearance of acetylene in the anode chamber at week 6 could
450 be due to cathodic reduction in earlier weeks and subsequent
451 electroosmotic transport throughout the experiment. Thus,
452 the presence of acetylene throughout the reactor does not

458 **3.4 Microbial Community Analysis Reveals Large Shift in EK-
459 Bio Reactor** Analysis of the final resulting microbial community
460 structures shows differences between the native microbial
461 community, the Bio reactor samples, and the EK-Bio reactor
462 samples. The initial soil samples are very similar to those in the
463 Bio reactor. The samples from the EK-Bio reactor are very
464 different from the initial soil samples ($P = 0.020$) or the
465 samples from the Bio reactor ($P = 0.001$), especially near port 4.
466 These data and the matrix distances can be seen in the
467 weighted unifracs beta (between sample) diversity plot in in
468 Figure 7A. In weighted unifracs analysis, the most abundant
469 taxa drive differences between the distance matrices. The
470 differences between samples from the EK-Bio reactor and
471 others is likely due to the larger increase in fermentative and
472 sulfate reducing bacteria, this is illustrated in more detail by
473 our taxonomic analysis in Figure 8. Further, the microbial
474 community appeared to be most different at port 4 of the EK-
475 Bio reactor, which is consistent with the taxonomy data
476 showing an increase in phylotype similar to Bacilli at this
477 location (Figure 8).

478 Alpha (within sample) diversity in the Bio reactor was
479 largely unchanged from that of the initial soil microbial
480 community ($P = 0.79$; Kruskal-Wallis test), but significantly
481 decreased in the EK-Bio reactor ($P = 0.038$; Kruskal-Wallis test),
482 especially near ports 1 and 4 (Figure 7B). Average operational
483 taxonomic units (OTUs) in the initial soil sample were 803
484 versus 842 in the Bio reactor and 449 in the EK-Bio reactor.
485 This type of decrease in alpha diversity has been previously
486 reported in the literature and attributed to secondary effects of
487 EK like changes in pH, which is consistent with chemical data
488 reported here in week 10 (Figure 5)⁴¹⁻⁴³. This drop can also be
489 linked to the enrichment and increased abundance of one
490 microbe, in this case, phylotypes most similar to the class
491 Clostridia.

492 Assessment of the microbial community members
493 shows many similarities between the Bio and EK-Bio reactors²⁸.
494 Both reactors displayed comparable levels of the phylotype
495 most similar to dechlorinating bacteria, though phylotypes
496 most similar those found in the overall enrichment culture
497 were slightly more elevated in the EK-Bio reactor. The
498 microbial community of the enrichment culture was previously
499 described in Delgado et al. 2014 and includes, among others,
500 Clostridia, Bacteroidia, Anaerolineae, and Dehalococcoidetes²⁸.
501 Clostridia, Bacteroidia, and Anaerolineae are known to contain
502 fermentative bacteria and are frequently found in the
503 environment⁴⁴⁻⁴⁶. The class Clostridia is also known to contain
504 species of SRB⁴⁷. Phylotypes similar to the classes Clostridia,
505 Bacteroidia, and Anaerolineae, constituted on average, 27% of
506 the community in the Bio reactor and 43% of the community in
507 the EK-Bio reactor (Figure 8). Phylotypes similar to the class
508 Dehalococcoidetes, which contains the TCE dechlorinating
509 *Dehalococcoides*, made up 0.1% or less of each community in
510 both reactors, but were slightly more abundant in the Bio
511 reactor. Both reactors also displayed similar levels of the
512 phylotype most similar to the class Deltaproteobacteria, which
513 is known to also contain SRB and iron reducing bacteria⁴⁷.
514 Unlike the Bio reactor, there was also a significant enrichment

453 necessarily imply a production through FeS minerals. In fact,
454 the early appearance of acetylene within the cathode chamber
455 suggests that cathodic reduction was likely the primary, if not
456 sole, abiotic transformation mechanism.

515 of phylotypes most similar to the class Bacilli near port 4 of the
516 EK-Bio reactor. Analysis on a genus level (not shown) indicates
517 this was most similar to the phylotype *Ammoniphilus*, an
518 aerobic haloalkalitolerant organism⁴⁸. Enrichment of this
519 organism near port 4 may have been due oxygen production
520 near the anode. The relative abundance of phylotypes most
521 similar to genera known to have homoacetogenic metabolisms
522 can be seen in Figure 4. Overall, these microbial community
523 results support the chemical data which indicate microbial
524 reductive dechlorination facilitated by a bioaugmentation
525 culture occurred in both reactors.

527 4. Conclusion

528 Electrokinetic and traditional bioremediation approaches both
529 resulted in transformation of TCE in a clay soil matrix with high
530 sulfate concentrations. Microbial reductive dechlorination was
531 the primary mechanism in the Bio reactor with a traditional
532 bioremediation approached. These microbial reactions stalled
533 at the end of the experiment, likely due to competition for H₂
534 caused by SRB or inhibitory effects of the sulfate reduction
535 product sulfide¹⁷. Greater transformation of TCE occurred in
536 the EK-Bio reactor, where acetylene was the primary daughter
537 product, indicating the dominance of an abiotic mechanism,
538 either biogeochemical reaction or direct cathodic reduction.
539 The production of acetylene near the cathode during the first
540 few weeks of experiment in the EK-Bio reactor strongly suggest
541 that electrochemical reduction was the major mechanism of
542 TCE reduction. The appearance of VC and ethene in the EK-Bio
543 reactor indicates microbial reductive dechlorination occurred
544 as well, though as a secondary transformation mechanism.
545 Taxonomic analysis showed enrichment of phylotypes similar to
546 those reported in the dechlorinating inoculum in each reactor,
547 supporting the conclusion that microbial reduction
548 dechlorination occurred in both reactors, though to different
549 extents²⁸. Results of microbial community structure analysis
550 are very similar to previously published work which reports
551 some decreases in alpha diversity and beta diversity along the
552 treatment zone^{41,49,50}. The results of this experiment show
553 that the combined biotic and abiotic mechanisms of EK-Bio can
554 result in improved remediation over traditional
555 bioaugmentation methods. These two mechanisms can act
556 synergistically with microbial reductive dechlorination
557 consuming acetate to prevent electrochemical generation of
558 the carcinogen chloromethane and with abiotic formation of
559 acetylene from TCE acting as a fermentable substrate for
560 microbial reactions. Results of this work demonstrate EK-BIO
561 can be considered a feasible remedy for chlorinated solvent
562 contaminated environments with transport limitations and
563 geochemical challenges, thus extending much needed
564 treatment to a great number of impacted water sources.

3 DOI: 10.1039/x0xx00000x
4

11 Chlorinated solvents are some of the most pervasive pollutants found in groundwater and drinking water sources in the
12 United States (U.S.). In the early 2000s, bioremediation emerged as a novel and effective technology, but was limited by
13 challenges to delivery and transport of nutrients and microbes. Electrokinetic bioremediation (EK-Bio) has since emerged as
14 a promising alternative to solve these limitations, delivering successful results at the lab and pilot scale. EK-Bio can be
15 applied at sites where traditional bioaugmentation, the transformation of pollutants via an added microbial culture, is
16 transport limited. The application of direct current *in situ* in electrokinetic (EK) remediation facilitates transport of the
17 microbial culture and substrate in the subsurface. Despite this recent surge in interest surrounding EK-Bio, it is not clear
18 how this technology would perform at a site with elevated levels of alternative electron acceptors, another common barrier
19 to successful bioremediation. Our objectives were to use bench scale reactors to 1) determine which reactions and
20 processes would dominate when using EK-BIO to treat TCE contamination at a site with high levels of the alternative electron
21 acceptor sulfate, 2) compare EK-Bio to a traditional bioremediation application without electrokinetics, and 3) understand
22 the effect of EK-Bio on the microbial community under these conditions. Our results showed complete transformation of
23 TCE to ethene and acetylene by EK-Bio, while only 15% of TCE was transformed to cis-DCE and VC via traditional
24 bioaugmentation. Instead, the majority of the TCE was converted to acetylene, likely due to its electrochemical reduction
25 at the cathode. EK-Bio out performed traditional methods as it facilitated TCE biotic and abiotic transformation. Next
26 generation sequencing analysis showed the microbial community in the EK-Bio reactor was highly enriched by the
27 bioaugmentation culture, and community structure and diversity were minimally affected by the electrokinetic application.
28 These results demonstrate that EK-Bio is an effective and promising remedy for treating chlorinated solvent contamination
29 at transport limited sites with high concentrations of competing electron acceptors. This combined treatment strategy can
30 be used to extend traditional bioaugmentation to a greater number of polluted sites, restoring more contaminated water
31 systems for beneficial use.

32 Water Impact Statement

33
34 Trichloroethene (TCE) is one of the most widespread
35 contaminants in groundwater affecting an estimated 4.5-18%
36 of drinking water sources in the United States. Combined
37 remediation technologies are required to address the
38 increasingly complex sites which remain polluted. Here, we
39 present a combined bioelectrochemical approach which
40 improves treatment outcomes and extends applications of
41 traditional technologies.

42 1. Introduction

43
44 Chlorinated solvents like perchloroethylene (PCE) and
45 trichloroethylene (TCE) are common groundwater
46 contaminants throughout the United States (U.S.) which cause
47 concern due to their toxic properties and widespread
48 occurrence^{1,2}. Previously used as dry cleaning and degreasing
49 agents, these chemicals entered the watershed due to
50 accidental spills and improper disposal^{3,4}. PCE has been
51 detected in 4% of aquifers tested by the U.S. Geological Survey
52 (USGS), and TCE has been measured in 4.5-18% of the country's
53 drinking water supply sources^{5,6}. Health issues associated with
54 PCE and TCE range from damage to the nervous system, liver,
55 kidney, and reproductive systems, to developmental issues,
56 and possibly cancer^{5,6}. PCE and TCE daughter product vinyl

57 chloride (VC) is a known carcinogen⁷. Given the health effects
58 associated with these compounds and their daughter products,
59 complete removal or transformation to non-toxic ethene is
60 required to protect human health⁸.

61 One commonly used method for treating chlorinated
62 solvent contamination is bioaugmentation, the *in situ* addition
63 of a bacterial culture capable of dechlorinating PCE and TCE to
64 ethene^{9,10}. The key bacteria, *Dehalococcoides*, removes one
65 chlorine atom at time and replaces them with hydrogen in a
66 process known as microbial reductive dechlorination,
67 transforming PCE to TCE, TCE to cis-dichloroethene (cis-DCE), cis-
68 DCE to VC, and VC to ethene¹¹. *Dehalococcoides*, are strict
69 anaerobes that use H₂ as an electron donor and acetate as a
70 carbon source⁹. They require moderate temperatures (25-
71 40°C) and neutral pH conditions¹¹. In the subsurface, H₂ and
72 acetate can be delivered to *Dehalococcoides* through anaerobic
73 fermentation of substrates like lactate¹². Bioaugmentation
74 using cultures with *Dehalococcoides* was developed as a
75 treatment strategy in the 1990's, and hundreds of sites have
76 since been successfully treated with this remedy¹³. Despite this
77 success, there remain challenges to bioaugmentation efficacy.
78 Two of the most substantial challenges to anaerobic
79 bioremediation of chlorinated solvents are microbial
80 competition from native soil bacteria and transport of
81 bioaugmentation cultures and substrates *in situ*¹⁴.

82 One of these challenges, transport limitations, can be
83 addressed by pairing traditional bioaugmentation with
84 technologies that improve delivery of nutrients and microbes,
85 like electrokinetics (EK)¹⁵. EK is the application of direct
86 current to the subsurface to induce transport *in situ*. Soluble
87 molecules may be transported via movement of fluid through
88 pore spaces (electroosmosis) and ions or other charged
89 molecules may move to the oppositely charged electrode
90 (electromigration and electrophoresis)¹⁵. When EK is

91 combined with bioaugmentation (EK-Bio), the bioaugmentation
 92 culture and electron donor are added to the subsurface via
 93 traditional injection wells and transported via electrokinetic
 94 mechanisms in addition to the natural advective gradient¹⁵. It
 95 is important to note that the application of current causes
 96 electrochemical reactions at each electrode, namely production
 97 of oxygen gas at the anode and hydrogen gas, H₂, at the
 98 cathode according to the reactions below¹⁶.

102 Further, these reactions generate a pH gradient with acidic
 103 conditions at the anode and basic conditions at the cathode¹⁶.
 104 Both the extreme pH fronts and the oxygen produced by the
 105 anode must be carefully managed at sites where microbial
 106 reductive dechlorination is employed to maintain the specific
 107 conditions required by *Dehalococcoides*.

108 Microbial competition for H₂ in the subsurface
 109 between *Dehalococcoides* and native soil bacteria is caused by
 110 high concentrations of alternative electron acceptors, like
 111 sulfate. High levels of sulfate are often found in PCE and TCE
 112 plumes due to natural sources, like atmospheric deposition,
 113 sulfate mineral dissolution, and sulfide mineral oxidation, or
 114 anthropogenic sources, like coal mines, power plants, and
 115 refineries^{17,18}. Like microbial reductive dechlorination,
 116 microbial sulfate reduction is carried out with H₂ as an electron
 117 donor, leading to competition between sulfate reducing
 118 bacteria (SRB) and dechlorinating bacteria for the limited H₂
 119 available *in situ*¹⁷. Further, sulfide inhibition of dechlorination
 120 also occurs at high concentrations (greater than 5mM) due to
 121 the toxicity of the sulfide species (H₂S and HS⁻) produced from
 122 sulfate reduction¹⁷. These inhibitory effects are further
 123 exacerbated in the field when sites are flooded with electron
 124 donor as toxic sulfide species accumulate¹⁷. It is not clear how
 125 EK-Bio would perform at a site with elevated levels of
 126 alternative electron acceptors. Electrokinetic bioaugmentation
 127 of chlorinated solvents at sites with high concentrations of
 128 sulfate has not been extensively studied. It is possible that EK
 129 transport of substrate could favor SRB who can out-compete
 130 *Dehalococcoides* for H₂¹⁹. This scenario could cause a stall of
 131 microbial reductive dechlorination or generation of a reactive
 132 metal sulfide species capable of abiotic dechlorination²⁰⁻²². A
 133 mixture of biotic and abiotic reactions could occur, including
 134 some electrochemical transformations of TCE which have been
 135 reported in closed recirculation systems with Pt, Pd, iron, and
 136 graphite electrodes²³⁻²⁵. Our objectives were to 1) determine
 137 which reactions and processes would dominate at a TCE
 138 contaminated site with high levels of the alternative electron
 139 acceptor sulfate, 2) compare EK-Bio to a traditional
 140 bioremediation application without electrokinetics, and 3)
 141 understand the effect of EK-Bio on the microbial community
 142 under these conditions.

143 2. Materials and methods

144 **2.1 Reactor Design and Set-up** This experiment featured a
 145 combined electrokinetic bioaugmentation (EK-Bio) reactor and
 146 a traditional bioaugmentation reactor (Bio). The Bio reactor
 147 was operated with traditional bioaugmentation methods where

148 diffusion is the main processes for mass transfer. No current
 149 was applied to the Bio reactor. The EK-Bio reactor was
 150 operated with a combined electrokinetic and bioaugmentation
 151 approach. Direct current was delivered to the EK-Bio reactor
 152 via power supply (Rigol DP832). Each of the two reactors was
 153 constructed from acrylic, consisting of a central soil
 154 compartment (40 cm long, 8 cm wide, 20 cm high; 6.4 L)
 155 between two electrode chambers (10 cm long, 8 cm wide, 20
 156 cm high; 1.6 L). The soil and electrode compartments were
 157 divided with a plastic porous separator (Midland Scientific Inc,
 158 HDPE, 1.6mm, medium grade porosity). A grid of nylon
 159 Swagelok sampling ports fitted with rubber septa covered the
 160 top and front face of each soil chamber. Porous metal tubes
 161 made of rolled screening (nickel 200, wire mesh 70 x 70) were
 162 inserted into all the ports to allow collection of porewater for
 163 sampling. Graphite electrodes (Fine extruded rod, 1.27 cm OD,
 164 Graphite Store) were used for both the anode and cathode.
 165 Once the electrodes were in place, the electrode chambers
 166 were filled with glass beads (11mm OD) to decrease the
 167 electrode compartment volumes to approximately 280 mL. A
 168 gas bag (5L, PVF Tedlar bag, Cole Parmer) was fitted on top of
 169 the electrode chambers of each reactor to allow release of
 170 gases created during electrolysis and microbial reactions. In
 171 the EK-Bio reactor, a peristaltic pump (Masterflex L/S) was used
 172 to recirculate electrolyte between the anode and cathode
 173 compartment at 1mL min⁻¹ to manage the pH gradient formed
 174 from electrokinetic reactions, an approach commonly used in
 175 the field²⁶.

176 The soil used for this experiment was a mixture of local
 177 Arizona clay topsoil and F85 sand. Soil was added to the
 178 central chamber in several layers and compacted with a 0.100
 179 kg hammer with rubber tips. Approximately 6.9 kg of soil were
 180 added in total.

181 The electrolyte was synthetic groundwater at a pH of 8.5
 182 made according to the recipe outlined in previous work
 183 modified to include 10 mM sodium bicarbonate, 11.45 mM
 184 sulfate, and 2 mM TCE²⁷. This synthetic groundwater, free of
 185 TCE and sulfate, was periodically added to the EK-Bio reactor
 186 through the experiment as electrolyte levels decreased due to
 187 electrolysis reactions occurring at the electrodes.

188 **2.2 Reactor Operation** After the addition of soil into each
 189 reactor, an injection well was created by coring out a 12 mm
 190 OD (outer diameter) cylinder with metal tubing and inserting a
 191 piece of 6mm OD Teflon tubing with 1mm sized pores. The
 192 electron donor, lactate (sodium DL-lactate, 60% syrup, Sigma-
 193 Aldrich), was added to each via the injection well to a final
 194 groundwater concentration of 10 mM. An incubation stage of
 195 21 days followed this addition to allow anaerobic conditions to
 196 be reached. In the case of the EK-Bio reactor, a potential of 30
 197 V was applied to distribute the lactate during this time leading
 198 to a current that stabilized around 10 mA. With the electrodes
 199 40 cm apart and just under 20 cm in length, this results in a
 200 current density of 0.0125 mA cm⁻². This current density is in
 201 line with work conducted in the field with a current density of
 202 approximately 0.0184 mA cm⁻² (26). According to Cox et al.
 203 (2008), this 150 m² field site was treated successfully over 14
 204 months with power requirements equivalent to that of two
 205 100-watt light bulbs. This value is relatively low, especially
 206 when compared to other remedial technologies, like thermal
 207 treatments (26).
 208

209 Once anaerobic conditions were reached, as
210 quantified by measurements of oxidation reduction potential
211 (ORP), a bioaugmentation culture known as ZARA-10 was
212 injected into the reactors. The culture was enriched as outlined
213 in Delgado et al.²⁸. In the EK-Bio reactor, the current was
214 paused during the addition of the culture to allow the culture
215 to acclimate and was resumed after 14 days. A second dose of
216 lactate was added after this time. Both reactors were operated
217 for a total of 11 weeks. Samples were taken approximately
218 weekly to monitor pH, ORP, and concentrations of chlorinated
219 solvents, sulfate, sulfide, lactate, and fermentation products.
220

221 **2.3 Chemical Analysis** After pore-water samples were extracted
222 with a glass syringe, the oxidation reduction potential (ORP)
223 and pH of the samples were measured with probes (Sartorius
224 pHCore). High performance liquid chromatography (HPLC) and
225 ion chromatography (IC) were used to measure lactate and
226 volatile fatty acid (VFA) concentrations and sulfate
227 concentrations after filtration through a 0.2µm PVDF filter. The
228 instruments used were a Shimadzu HPLC (LC 20-AT) with an
229 Aminex HPX-87H (Bio-Rad) column and photodiode-array
230 detector (210nm) and a Metrohm 930 Ion Chromatograph with
231 a Metrosep A Supp 5-150/4.0 column and A Supp 5 100x
232 carbonate based eluent. Total soluble sulfides were measured
233 with the HACH kit TNT861, and hydrogen sulfide gas was
234 measured with Draeger tubes (MSI-Mid State Instruments LLC).
235 A gas chromatograph (GC) (Shimadzu) equipped with a flame
236 ionization detector (FID) with a packed column (Restek Rtx-624)
237 was used to measure TCE and daughter products. Liquid
238 samples of 1 mL were withdrawn from each port and placed in
239 a 2mL capped vial. After 24 hours of shaking, headspace
240 samples were withdrawn from the vials with a 500 µl gas-tight
241 syringe, and 200µl of gas was injected into the GC for analysis.
242 Scanning electron microscopy energy dispersive X-ray
243 spectroscopy (SEM-EDX) (Nova 200 NanoLab) at the Arizona
244 State University (ASU) Eyring Materials Center was used to
245 detect insoluble mineral compounds present in the soil at the
246 end of the experiment.
247

248 **2.4 Microbial Community Analysis** At the end of the
249 experiment, vertical soil cores were taken along each sampling
250 port. DNA was extracted from the soil samples using the
251 MoBio Powersoil® DNA isolation kit. The Qiagen DNeasy
252 PowerClean Pro Cleanup kit was then used to further improve
253 the quality of the DNA.
254

255 The barcoded primer set 515/806R was used to
256 perform sample sequencing on the V4 region of the 16S rRNA
257 gene^{29,30}. Library preparation was conducted using a protocol
258 from the Earth Microbiome Project at the Microbiome Analysis
259 Laboratory in the Biodesign Swette Center for Environmental
260 Biotechnology, Arizona State University³¹. A MiSeq Illumina
261 sequencer (Illumina Inc., Dan Diego, CA) was used for the
262 sequencing via the chemistry version 2 (2 x 150 pair-end).
263 Demultiplexed paired-end fastq files produced by CASAVA
264 (Illumina) were used as inputs to QIIME2 version 2020.2 for
265 evaluation^{32,33}. Fastq files were quality filtered, trimmed,
266 denoised, and merged with the DADA2 software package
267 wrapped in QIIME2³⁴. Sequences were truncated at 250
268 basepairs due to a decline in quality of reverse reads that point.
269 The QIIME2 feature-classifier plugin and the Naïve Bayes
270 classifier trained on the Greengenes 13.8 99% OTU full-length
sequences were used to assign taxonomy. Alpha and beta-

271 diversity analysis was completed with the QIIME2 q2-diversity
272 plugin at a sampling depth of 8,750. A pairwise PERMANOVA
273 test of beta diversity significance using weighted unifrac
274 distance was run in Qiime2 using the beta-group-significance
275 command, and the Kruskal-Wallis test of alpha diversity
276 significance was run in Qiime2 using the alpha-group-
277 significance command. Raw sequences for this project are
278 available in the NCBI SRA under the BioProject ID
279 PRJNA631539.

280 3. Results and discussion

281 3.1 EK-Bio Treatment Outperformed Traditional Bio Method

282 Figure 2 shows the transformation of TCE to daughter products
283 across the Bio and EK-Bio reactors over the 11-week
284 experiment. In the Bio reactor, products of microbial reductive
285 dechlorination, cis-DCE and VC, appeared by week 4. Trace
286 amounts of non-toxic ethene, 2.1-4.6 µM, appeared by week 8,
287 but the largest concentration of daughter products remained
288 cis-DCE and VC with average concentrations across the reactor
289 of 86.5 µM (58.4% deviation) and 17.5 µM (52.0% deviation)
290 respectively. Hindrance of microbial reductive dechlorination
291 leading to cis-DCE accumulation has been reported in cultures
292 where *Dehalococcoides* is out competed by other microbes for
293 H₂²⁸.

294 In the EK-Bio reactor, microbial reductive
295 dechlorination products appeared at week 4, similar to the Bio
296 reactor. There was also an initial spike in TCE at week 2, likely
297 due desorption caused by electroosmosis³⁵. Minimal amounts
298 of the reductive dechlorination daughter product cis-DCE were
299 observed in the EK-Bio reactor, but spikes of VC, 17.7 µM, were
300 detected by week 11. Near the end of the experiment at week
301 9.5, ethene concentrations in the EK-Bio reactor (28.3 µM)
302 were higher than the Bio reactor (4.6 µM). Acetylene, a TCE
303 daughter product formed through reaction with mineral
304 compounds or cathodic reduction, appeared in the cathode
305 chamber of the EK-Bio reactor early on in the experiment at a
306 concentration of 1.2 mM and reached 1.4 mM and 1.9 mM at
307 ports 1 and 2 by week 11. By the end of the experiment
308 acetylene concentration across the reactor averaged 824.0 µM
309 (45.5% deviation). These results suggest both biological and
310 chemical transformation of TCE occurred in the EK-Bio reactor
311 as acetylene is the signature product of abiotic reaction while
312 VC is a signature daughter product of microbial reductive
313 dechlorination found infrequently in abiotic reactions²⁰.
314

315 3.2 Conditions for Microbial Reductive Dechlorination

316 **Eventually Achieved in Both Reactors** Differing dechlorination
317 results can be attributed to variations in substrate transport
318 rates and operating conditions in each reactor. In the Bio
319 reactor, conditions for microbial reductive dechlorination were
320 reached at a slower pace than in the EK-Bio reactor. A negative
321 ORP reflective of anaerobic conditions was achieved in the
322 cathode side of the Bio reactor near the injection port by week
323 3, prior to injection of bioaugmentation culture, but reducing
324 conditions were reached in the anode side only by week 9.
325 Acetate, the fermentation product of lactate and an indication
326 of anaerobic conditions, was not measurable in the Bio reactor
327 until week 6. Concentrations of acetate remained low, < 13
328 mM, until week 10 when increased concentrations were
329 measured in the anode and cathode chambers, 43.9 and

330 38.5mM respectively. While more time was required to reach
331 reducing conditions and transport substrate, pH remained near
332 neutral in the Bio reactor for the duration of the experiment.

333 Contrastingly, in the EK-Bio reactor conditions for
334 microbial reductive dechlorination were reached quickly,
335 though with greater challenges for pH control. A negative ORP
336 was achieved by week 2, immediately following injection of
337 lactate in week 1. Detection of lactate was delayed until week
338 8, but once measurable, was present at high concentrations,
339 approximately 1-2mM, and evenly distributed throughout the
340 contaminated soil. Concentrations of acetate peaked at week
341 10, around 60 mM. This increase in acetate, seen in both
342 reactors at week 10, may have been due to uneven flow paths
343 leading to areas of high concentration or to acetate produced
344 via inorganic carbon and hydrogen via acetogenesis (Figure 4).
345 Particularly in the EK-Bio reactor, the high relative abundance
346 of these genera at port 4 corresponds to acetate peaks at week
347 10 near the anode chamber port 4. A large pH gradient
348 developed in the EK-Bio reactor by week 2 (Figure 5) but was
349 neutralized by slightly increasing the rate of recycle between
350 the anode and cathode. This gradient reappeared by week 10
351 suggesting an even greater recycling rate or added buffer might
352 be needed. While pH management was more difficult in the
353 EK-Bio reactor, reducing conditions were achieved earlier due
354 to better distribution of lactate, creating conditions that were
355 more amenable to microbial reactions than in the Bio reactor.
356

357 3.3 Sulfate Transport and Abiotic Reactions Effect Treatment

358 **Performance** Despite eventually reaching reducing conditions
359 and diffusion of electron donor throughout the reactor,
360 microbial reductive dechlorination stalled in the Bio reactor at
361 cis-DCE and VC between weeks 9 and 10. This stall can be
362 attributed to competition between Dehalococcoides and SRB
363 due to sulfate transport limitations. As seen in Figure 6, in the
364 Bio reactor, sulfate remained distributed throughout the soil
365 for the duration of the experiment. By the end of the
366 experiment, concentrations of sulfate remained over 3 mM at
367 some locations possibly leading to competition for H₂ by SRB.
368 The competition facing *Dehalococcoides* was further
369 confounded by with increasingly inhibitory concentrations of
370 sulfide, already at soluble concentrations of up to 0.2mM¹⁷.
371 Contrastingly, by week 3 in the EK-Bio reactor sulfate nearly
372 disappeared except in the anode and cathode chambers. With
373 an expected rate of electromigration of 1.2 x 10⁻⁶ m s⁻¹, sulfate
374 would be transported the length of the reactor in 4.5 days
375 (calculations in SI). The accumulation of sulfate in the anode
376 and cathode chambers by week 3 is reflective of this quick
377 migration rate. Competition for H₂ between SRB and
378 *Dehalococcoides* was quickly eliminated, allowing microbial
379 reductive dechlorination to ethene to proceed uninhibited.
380

381 The reduction of sulfate in the EK-Bio reactor may have
382 also contributed to formation of TCE daughter product
383 acetylene. Hydrogen sulfide generated from microbial sulfate
384 reduction (equation 3) can react with iron oxide/hydroxide
385 species to form elemental sulfur and iron (II) sulfide (equation
386 4). The iron (II) sulfide subsequently reacts with TCE to form
387 acetylene (equation 5), as outlined in the reactions below³⁶.
388 Sulfate removal of up to 75%, along with low soluble sulfide
389 concentrations measured (Figure 6), suggest precipitation of
390 metal sulfides. Transformations of chlorinated ethenes via this
391 biogeochemical pathway have been reported in lab studies and
in the field through monitored natural attenuation schemes or

392 engineered systems³⁶⁻³⁸. Measurements of insoluble iron
393 species by the SEM-EDX averaged 3.8% by weight, indicating a
394 high enough concentration to transform available TCE to
395 acetylene.

400 Generally, the rate of microbial reductive dechlorination has
401 been reported to be much faster than abiotic reaction with iron
402 minerals²⁰. However, the rate of abiotic reaction can be
403 significantly increased at sites with favorable environmental
404 conditions which increase reactant loading, as occurred in the
405 EK-Bio reactor²⁰. In addition to high concentrations of organic
406 carbon, iron, or sulfate, the abiotic reaction rate can be
407 accelerated with increases in pH³⁹. Weerasooriya and
408 Dharmasena³⁹ demonstrated a monotonic increase in reaction
409 rate between iron (II) sulfide and TCE from 0.03 h⁻¹ at pH 8 to
410 over 0.05 h⁻¹ at pH 10. While the pH spikes in the EK-Bio
411 reactor were detrimental to microbial reductive dechlorination,
412 they may have aided reaction rates of biogeochemical
413 transformation. While both the EK-Bio and Bio reactors had
414 high levels of sulfate and iron needed to generate the reactive
415 chemical species, but quicker attainment of reducing conditions
416 and more uniform organic carbon substrate distribution in the
417 EK-Bio reactor may have better facilitated biogeochemical
418 reduction of TCE.

419 Alternatively, acetylene can be generated through
420 direct cathodic reduction of TCE. Cathodic reduction of
421 chlorinated solvents has been investigated previously with Pt,
422 Pd, iron, and graphite electrodes in closed recirculation
423 systems²³⁻²⁵. TCE can follow several abiotic dechlorination
424 pathways with multiple daughter products, but the appearance
425 of acetylene indicates β-elimination was likely the mechanism.
426 The use of a graphite electrode has been reported to lead to
427 the by-product chloromethane, a known carcinogen, through
428 the combination of chloride and methyl radicals created
429 through the Kolbe reaction of acetate²⁵. No chloromethane
430 was detected in this experiment, likely as acetate was
431 consumed by SRB or dechlorinating bacteria.

432 Under similar conditions in a soil free reactor with a
433 granular graphite electrode and the application of 15 V, Al-
434 Abed and Fang (2007) measured transformation of 76% of TCE
435 to ethene and ethane in 25 hours. In this EK-Bio experiment,
436 acetylene may have been the primary reaction product rather
437 than ethene or ethane as it volatilized out of solution into the
438 gas bag, preventing further reaction with the cathode or iron
439 species in the soil. The early appearance of acetylene in the
440 cathode chamber of the EK-Bio reactor and the complete
441 absence of acetylene in the Bio reactor suggest cathodic
442 reduction was the primary, or at least initial, abiotic
443 transformation mechanism of TCE in this experiment²⁵. The
444 rate of electroosmosis, the primary transport mechanism for
445 acetylene, is 2.9 x 10⁻⁷ m s⁻¹ (calculations in SI). At this rate,
446 which is similar to those previously reported, acetylene
447 generated in the cathode chamber by cathodic reduction could
448 travel to the anode chamber in approximately 16 days⁴⁰. The

449 appearance of acetylene in the anode chamber at week 6 could
450 be due to cathodic reduction in earlier weeks and subsequent
451 electroosmotic transport throughout the experiment. Thus,
452 the presence of acetylene throughout the reactor does not

458 **3.4 Microbial Community Analysis Reveals Large Shift in EK-
459 Bio Reactor** Analysis of the final resulting microbial community
460 structures shows differences between the native microbial
461 community, the Bio reactor samples, and the EK-Bio reactor
462 samples. The initial soil samples are very similar to those in the
463 Bio reactor. The samples from the EK-Bio reactor are very
464 different from the initial soil samples ($P = 0.020$) or the
465 samples from the Bio reactor ($P = 0.001$), especially near port 4.
466 These data and the matrix distances can be seen in the
467 weighted unifracs beta (between sample) diversity plot in
468 Figure 7A. In weighted unifracs analysis, the most abundant
469 taxa drive differences between the distance matrices. The
470 differences between samples from the EK-Bio reactor and
471 others is likely due to the larger increase in fermentative and
472 sulfate reducing bacteria, this is illustrated in more detail by
473 our taxonomic analysis in Figure 8. Further, the microbial
474 community appeared to be most different at port 4 of the EK-
475 Bio reactor, which is consistent with the taxonomy data
476 showing an increase in phylotype similar to Bacilli at this
477 location (Figure 8).

478 Alpha (within sample) diversity in the Bio reactor was
479 largely unchanged from that of the initial soil microbial
480 community ($P = 0.79$; Kruskal-Wallis test), but significantly
481 decreased in the EK-Bio reactor ($P = 0.038$; Kruskal-Wallis test),
482 especially near ports 1 and 4 (Figure 7B). Average operational
483 taxonomic units (OTUs) in the initial soil sample were 803
484 versus 842 in the Bio reactor and 449 in the EK-Bio reactor.
485 This type of decrease in alpha diversity has been previously
486 reported in the literature and attributed to secondary effects of
487 EK like changes in pH, which is consistent with chemical data
488 reported here in week 10 (Figure 5)⁴¹⁻⁴³. This drop can also be
489 linked to the enrichment and increased abundance of one
490 microbe, in this case, phylotypes most similar to the class
491 Clostridia.

492 Assessment of the microbial community members
493 shows many similarities between the Bio and EK-Bio reactors²⁸.
494 Both reactors displayed comparable levels of the phylotype
495 most similar to dechlorinating bacteria, though phylotypes
496 most similar those found in the overall enrichment culture
497 were slightly more elevated in the EK-Bio reactor. The
498 microbial community of the enrichment culture was previously
499 described in Delgado et al. 2014 and includes, among others,
500 Clostridia, Bacteroidia, Anaerolineae, and Dehalococcoidetes²⁸.
501 Clostridia, Bacteroidia, and Anaerolineae are known to contain
502 fermentative bacteria and are frequently found in the
503 environment⁴⁴⁻⁴⁶. The class Clostridia is also known to contain
504 species of SRB⁴⁷. Phylotypes similar to the classes Clostridia,
505 Bacteroidia, and Anaerolineae, constituted on average, 27% of
506 the community in the Bio reactor and 43% of the community in
507 the EK-Bio reactor (Figure 8). Phylotypes similar to the class
508 Dehalococcoidetes, which contains the TCE dechlorinating
509 *Dehalococcoides*, made up 0.1% or less of each community in
510 both reactors, but were slightly more abundant in the Bio
511 reactor. Both reactors also displayed similar levels of the
512 phylotype most similar to the class Deltaproteobacteria, which
513 is known to also contain SRB and iron reducing bacteria⁴⁷.
514 Unlike the Bio reactor, there was also a significant enrichment

453 necessarily imply a production through FeS minerals. In fact,
454 the early appearance of acetylene within the cathode chamber
455 suggests that cathodic reduction was likely the primary, if not
456 sole, abiotic transformation mechanism.

515 of phylotypes most similar to the class Bacilli near port 4 of the
516 EK-Bio reactor. Analysis on a genus level (not shown) indicates
517 this was most similar to the phylotype *Ammoniphilus*, an
518 aerobic haloalkalitolerant organism⁴⁸. Enrichment of this
519 organism near port 4 may have been due oxygen production
520 near the anode. The relative abundance of phylotypes most
521 similar to genera known to have homoacetogenic metabolisms
522 can be seen in Figure 4. Overall, these microbial community
523 results support the chemical data which indicate microbial
524 reductive dechlorination facilitated by a bioaugmentation
525 culture occurred in both reactors.
526

527 4. Conclusion

528 Electrokinetic and traditional bioremediation approaches both
529 resulted in transformation of TCE in a clay soil matrix with high
530 sulfate concentrations. Microbial reductive dechlorination was
531 the primary mechanism in the Bio reactor with a traditional
532 bioremediation approached. These microbial reactions stalled
533 at the end of the experiment, likely due to competition for H_2
534 caused by SRB or inhibitory effects of the sulfate reduction
535 product sulfide¹⁷. Greater transformation of TCE occurred in
536 the EK-Bio reactor, where acetylene was the primary daughter
537 product, indicating the dominance of an abiotic mechanism,
538 either biogeochemical reaction or direct cathodic reduction.
539 The production of acetylene near the cathode during the first
540 few weeks of experiment in the EK-Bio reactor strongly suggest
541 that electrochemical reduction was the major mechanism of
542 TCE reduction. The appearance of VC and ethene in the EK-Bio
543 reactor indicates microbial reductive dechlorination occurred
544 as well, though as a secondary transformation mechanism.
545 Taxonomic analysis showed enrichment of phylotypes similar to
546 those reported in the dechlorinating inoculum in each reactor,
547 supporting the conclusion that microbial reduction
548 dechlorination occurred in both reactors, though to different
549 extents²⁸. Results of microbial community structure analysis
550 are very similar to previously published work which reports
551 some decreases in alpha diversity and beta diversity along the
552 treatment zone^{41,49,50}. The results of this experiment show
553 that the combined biotic and abiotic mechanisms of EK-Bio can
554 result in improved remediation over traditional
555 bioaugmentation methods. These two mechanisms can act
556 synergistically with microbial reductive dechlorination
557 consuming acetate to prevent electrochemical generation of
558 the carcinogen chloromethane and with abiotic formation of
559 acetylene from TCE acting as a fermentable substrate for
560 microbial reactions. Results of this work demonstrate EK-BIO
561 can be considered a feasible remedy for chlorinated solvent
562 contaminated environments with transport limitations and
563 geochemical challenges, thus extending much needed
564 treatment to a great number of impacted water sources.

Water Impact Statement

Trichloroethene (TCE) is one of the most widespread contaminants in groundwater affecting an estimated 4.5-18% of drinking water sources in the United States. Combined remediation technologies are required to address the increasingly complex sites which remain polluted. Here, we present a combined bioelectrochemical approach which improves treatment outcomes and extends applications of traditional technologies.
