Ga₂O₃ polymorphs: tailoring the epitaxial growth conditions

M. Bosi, *^a P. Mazzolini, ^b L. Seravalli ^a and R. Fornari ^{ab}

Gallium oxide is a wide bandgap n-type semiconductor highly interesting for optoelectronic applications (e.g., power electronics and solar blind UV photodetectors). Besides its most thermodynamically stable monoclinic β phase, Ga₂O₃ can crystallize in different polymorphs; among them the corundum α and the orthorhombic ε phases are the most promising ones. In this review we focus on the main aspects that promote the nucleation and stable growth of these Ga₂O₃ polymorphs. Particular emphasis is given to the ε phase since it is recently gaining increasing attention in the scientific community because of: (i) its higher lattice symmetry with respect to β -Ga₂O₃, which could favour the realization of heterostructures, (ii) the possibility to be grown on cheap sapphire substrates and (iii) its peculiar piezoelectric properties. While the growth of β -Ga₂O₃ is widely studied and understood, a thorough and comprehensive analysis of the chemical and physical aspects that allow for the stabilization of the metastable Ga₂O₃ phases with different synthesis methods is still missing. Therefore, the present review aims at filling this gap, by analysing the relevant growth parameters for several growth techniques (MOVPE, HVPE, mist-CVD, MBE, and PLD), highlighting similarities and differences, looking for a unified framework to understand the growth and nucleation of different Ga₂O₃ polymorphs. As a conclusion, we highlight practical guidelines for the deposition of the different Ga₂O₃ polymorphs with all the discussed thin film growth techniques.

1. Introduction

Metal sesquioxides are very interesting semiconducting materials that have attracted much attention in the last decade.

**M. Bosi**

The scientific activity of Dr Matteo Bosi has always been focused on epitaxial deposition by means of Metal Organic Vapor Phase Epitaxy (MOVPE) of semiconductor materials for photovoltaic, sensor and optoelectronic devices. During his career he has studied the epitaxy/synthesis of arsenides and phosphides (GaAs, InGaP, and AlGaAs), germanium, SiC, diluted nitrides (GaAsN) and III-nitrides (GaN and InGaN),

nanowires (Ge and SiC) and transition metal dichalcogenides (MoS₂), and oxides (TiO₂ and Ga₂O₃). During his career Dr Matteo Bosi has attended about 20 international conferences with several invited talks and he is author or co-author of about 100 papers in international peer-reviewed journals.

**P. Mazzolini**

Piero Mazzolini joined the group of Prof. R. Fornari as a researcher in 2020, Italy. He graduated in "Materials Engineering" at the University of Trieste in 2012. He received his PhD in "Energy and Nuclear Science and Technology" at the Politecnico di Milano in 2015 working on doped oxide thin films for transparent electronics (Ta-doped TiO₂). For his master's thesis and during his PhD he visited the Max Planck Institute for Solid State Research

of Stuttgart. As a postdoc at the Paul Drude Institute in Berlin he worked on the molecular beam epitaxial growth of Ga₂O₃/In₂O₃ thin films in the research group of Dr O. Bierwagen.

Gallium oxide (Ga_2O_3) has especially become popular because of its intrinsic properties: very wide bandgap ($E_g > 4.5$ eV) and high critical breakdown field, estimated to be about 8 MV/cm, higher than that of other wide bandgap materials like SiC and GaN.¹ This makes gallium oxide a promising candidate for high power electronics, with a field of applications complementary to the ones of SiC and GaN. Additionally, its extra-wide bandgap makes this semiconductor suitable for fabrication of solar-blind detectors for UV-C radiation (wavelength below 280 nm).

It must however be mentioned that generically talking about Ga_2O_3 can be misleading, as this material has five polymorphs of which only one is thermodynamically stable at high temperatures (β phase, monoclinic), while the others are metastable and tend to convert to β upon high-temperature treatments. The first study on polymorphism of Ga_2O_3 dates back to 1952² and reported two novel polymorphs: δ , cubic, and ϵ , hexagonal, in addition to the already known α , corundum, and γ , defective-spinel, phases. In a later crystallographic study, Playford *et al.*³ introduced also the κ polymorph, which brought the total number of explored polymorphs to six. It is to be noted that the used nomenclature follows the existing one for the more investigated aluminum oxide Al_2O_3 .

So far, most attention was concentrated on the thermodynamically stable β - Ga_2O_3 phase, essentially for one reason: it can be grown both as a single crystal and as a thin epitaxial layer, thus enabling homoepitaxy and permitting one to lower the density of structural defects. Alloys with Al or In can modulate the β - Ga_2O_3 bandgap,^{4,5} allowing for the realization of heterostructures and the formation of a modulation doped 2D electron gas (2DEG) at the heterojunction, enabling high performance electronics. However, this phase presents also evident drawbacks, essentially due to the highly-asymmetric monoclinic structure. This implies a remarkable anisotropy

of thermal conductivity⁶ and of optical properties,⁷ alongside a relatively mild anisotropy of electrical properties.⁸ Furthermore, bulk β - Ga_2O_3 is prone to cleavage and homoepitaxially-grown epilayers on certain crystal orientations – e.g., (100)⁹ – were surprisingly seen to suffer from a high density of twin lamellae, part of which may lead to incoherent twin boundaries with dangling bonds, which may act as acceptors, thus limiting the n-type doping and electron mobility. This problem could be overcome either by growing on 4–6° off-oriented (100) substrates,¹⁰ a methodology that proved to be effective but that ultimately makes the homoepitaxy less attractive, or by selecting a different substrate orientation for the homoepitaxy like (010)¹¹ or (001).^{12,13}

For the above reasons, in the past few years Ga_2O_3 research has been extended towards the two phases that present higher symmetry and easier epitaxial conditions than β - Ga_2O_3 , namely α and ϵ . Their main properties are summarized in Table 1. Both polymorphs were obtained by a variety of epitaxial techniques on different hetero-substrates, mostly sapphire, as well as on β - Ga_2O_3 . Our research team, including researchers from IMEM-CNR and Dept. of Mathematical, Physical and Computer Sciences of Parma University, has been one of the first worldwide to undertake extensive research activity on ϵ - Ga_2O_3 : we reported for the first time in 2016 on the Metal Organic Vapor Phase Epitaxy (MOVPE) epitaxial growth of single-phase ϵ -type layers on *c*-oriented sapphire, (0001)-oriented GaN and (111)-oriented cubic SiC.¹⁴ Our interest in the ϵ material at that time was mostly motivated by the easier epitaxial deposition conditions, more uniform physical properties and higher crystallographic symmetry with respect to β - Ga_2O_3 . Furthermore, we detected unusual properties, such as ferroelectricity,¹⁵ which were also theoretically confirmed by Maccioni and Fiorentini,¹⁶ and Cho and Mishra.¹⁷ Indeed, films of ϵ - Ga_2O_3 are generally deposited at much lower temperature, while their spontaneous

L. Seravalli

Luca Seravalli is a researcher at IMEM-CNR. He received a MSc in physics at Trinity College of Dublin in 2000 and a PhD in physics at the University of Parma in 2003. From 2001 he has been working on epitaxial growth, optical characterization and modelization of semiconductor nanostructures. He has authored 80 articles with over 1000 citations and he has an *h*-index of 19. His current interests include MOVPE growth of Ga_2O_3 and of Ge nanostructures and CVD growth of 2D materials.

R. Fornari

Roberto Fornari is Full Professor of Condensed Matter Physics at Parma University (Italy), where he also serves as Vice-Rector for Research. Prior to joining Parma University in 2013, he was Director of the Leibniz-Institut für Kristallzüchtung (IKZ) and professor at the Humboldt University, Berlin (2003–13), and research scientist at the Institute of Materials for Electronics and Magnetism (IMEM-CNR; 1981–2003). He has authored/co-authored over 170 articles in international journals, ten patents and several book chapters on semiconductor physics and technology. He served as President of the Intern. Organization for Crystal Growth (2010–16); in the Europ. Materials Research Society (Exec. Committee, 2011–17), and as associate editor of four scientific journals.

Table 1 Main properties of the most common Ga₂O₃ polymorphs¹

| | β-Ga ₂ O ₃ | α-Ga ₂ O ₃ | ε-Ga ₂ O ₃ |
|--|----------------------------------|----------------------------------|----------------------------------|
| Bandgap (E_g) | 4.9 | 5.2 | 4.9 |
| Structure | Monoclinic ($C2/m$) | Corundum ($R\bar{3}c$) | Orthorhombic ($P6_3mc$) |
| Dielectric constant ϵ_r | 10 | | 10 |
| a (Å) | 12.214 | 4.983 | 29.067 |
| b (Å) | 3.037 | | |
| c (Å) | 5.798 | 13.433 | 9.255 |
| β (degrees) | 103.83 | | |
| Theoretically predicted RT electron mobility ($\text{cm}^2 \text{V}^{-1} \text{s}^{-1}$) | 300 | | |

c-oriented polarization may be exploited for designing and manufacturing novel hybrid devices. This was recently confirmed by Leone *et al.*, who reported on the epitaxial growth of GaN/Ga₂O₃ and ε-Ga₂O₃/GaN heterostructures for novel high electron mobility transistors.¹⁸ ε-Ga₂O₃ alloys with In and Al were obtained with mist Chemical Vapor Deposition (mist-CVD) and Pulsed Laser Deposition (PLD),^{19,20} while a theoretical study²¹ demonstrated the possibility to form a 2D electron gas at the ε-AlGaO₃/ε-Ga₂O₃ heterointerface with higher carrier density with respect to β-Ga₂O₃ and the effect of spontaneous polarization reversal on the 2D electron gas density in ε-Ga₂O₃/ε-AlGaO₃/ε-Ga₂O₃ double heterostructures.

After the pioneering work on deposition of ε-Ga₂O₃ on sapphire, our group also dedicated much attention to the investigation of the physical properties and suitable doping procedures for this polymorph.^{22–24} After confirming that the bandgap of the ε phase is comparable with that of β-Ga₂O₃, attention was also turned to potential applications in the area of solar-blind UV photodetectors.²⁵ All this evidence provides the motivation for continuing the work on ε-Ga₂O₃ and also for the present review.

Before starting examining the growth conditions of ε-Ga₂O₃, it is however necessary to clear an ambiguity that has confused, and to some extent still confuses, the Ga₂O₃ community: what is exactly the ε phase and how does it relate to the orthorhombic κ phase? Historically the ε phase has been considered to be purely hexagonal.^{3,15,26} This is to be ascribed to the used investigation methods, neutron or X-ray diffraction, which, owing to their inherent resolution, suggested ε-Ga₂O₃ to have hexagonal crystal structure with space group P6₃mc. It was some years later that Cora *et al.*²⁷ examined the microstructure of MOVPE-grown ε-Ga₂O₃ on (0001) sapphire by high-resolution TEM: they found that the film was indeed “pseudo-hexagonal” as the apparent hexagonal symmetry actually resulted from in-plane 120° rotational nano-domains of orthorhombic Ga₂O₃. They corrected the space group to *Pna*21 and, in analogy with Al₂O₃, suggested this polymorph to be more properly named κ. More recently these findings were confirmed by Nishinaka *et al.*²⁸ In other words, it is possible to obtain phase-pure ε-Ga₂O₃ but one has to be aware that it is not single crystalline; rather it is composed of tiny (201) domains of orthorhombic Ga₂O₃ separated by 120° twins, virtually with no dangling bonds. It is the short-range order of the gallium octahedra and tetrahedra included between the oxygen planes that gives rise to such a particular arrangement. When studied by X-ray

diffraction this structure provides diffraction patterns compatible with a hexagonal structure, but it reveals an orthorhombic structure when investigated with a probe of higher resolution. The scientific community should therefore more correctly speak of “orthorhombic ε-Ga₂O₃” or rather “pseudo-hexagonal ε-Ga₂O₃”, remembering however that the intimate, microscopic structure is actually orthorhombic κ.

The other technologically important Ga₂O₃ polymorph, α, exhibits a bandgap of 5.3 eV, even higher than β-Ga₂O₃ and ε-Ga₂O₃. Ternary alloys (Al_xGa_{2–x})O₃ could be obtained in a wide range of composition, facilitating band engineering and fabrication of hetero-structured devices. α-Ga₂O₃ shares the same corundum structure as α-Al₂O₃ and it does not exhibit the rotational domain problems typical of ε- and β-Ga₂O₃.²⁹ Moreover, the possibility to obtain p-type doped α-*Ir*₂O₃ and α-*Rh*₂O₃ permits in principle the realization of p–n corundum-structured hetero-junctions on α-Al₂O₃. In terms of applications, photodetectors³⁰ and metal-oxide semiconductor field-effect transistors using a hetero-pn-junction³¹ have already been demonstrated.

Being less mature and less studied than the β phase, some physical properties of the α and ε polymorphs are still not precisely known. For example, while the maximum theoretical breakdown field of β-Ga₂O₃ is estimated to be as high as 8 MV cm^{–2},³² to the best of our knowledge no similar estimates are present for α- and ε-Ga₂O₃. Similarly, for β-Ga₂O₃ the room temperature electron mobility upper limit is theoretically predicted to be around 300 cm² V^{–1} s^{–1} (Table 1), while no clear estimates of the upper limit of the electron mobility are available for both α and ε. Therefore, even if some theoretical studies investigated the structural, electronic, and optical properties of the polymorphs,^{33,34} we believe that more effort is needed in order to unveil their full potential from both a theoretical and an experimental point of view.

We already pointed out in the previous paragraphs the possibilities given by bandgap engineering to modulate the bandgap of Ga₂O₃ with In and Al, permitting the realization of ternary alloys with bandgaps varying ideally between 3.7 (In₂O₃)⁴ and 8.8 (Al₂O₃)³⁵ eV. Heterostructures based on these alloys could dramatically expand the possibilities for the design of novel devices. However, while the technology for β-Ga₂O₃ ternary alloys is quite advanced and it was already discussed in several papers and books,^{1,36} the literature of α- and ε-Ga₂O₃ ternary alloys is still quite limited, making an in-depth discussion on this topic premature and beyond the scope of this review.

The last remark concerns the actual thermal stability of the α and ε polymorphs. By combining TEM and X-ray diffraction with differential scanning calorimetry, Fornari *et al.* demonstrated that ε -Ga₂O₃ initiates a structure modification at about 700 °C and fully converts to β -Ga₂O₃ when it is annealed at temperatures above 900 °C.³⁷ Very recently, Cora *et al.* performed TEM analysis on ε -Ga₂O₃ subjected to thermal treatments at different heating rates and they were able to detect in real time the phase transition.³⁸ Annealing experiments up to 1000 °C were performed either *in situ* in a vacuum inside the TEM chamber, or *ex situ* in ambient air. The TEM observations provided a real time view of the atomistic re-arrangement at the basis of the κ to β phase transition. Surprisingly, the *ex situ* experiments instead demonstrated the formation of an additional γ -Ga₂O₃ phase at 820 °C. The different behaviour between *in situ* and *ex situ* annealing experiments was explained in terms of the atmosphere (ambient air or high vacuum) and heating rate. Regarding α -Ga₂O₃, Lee *et al.*³⁹ demonstrated that α -Ga₂O₃ films grown at 470 °C by mist-CVD are stable until 550 °C, but are gradually changed to the β -phase after annealing in an N₂ atmosphere for 60 minutes at temperatures higher than 600 °C.

In this work, by comparing numerous experimental data from different epitaxial methods, we would like to extend the understanding of the nucleation and stable growth of Ga₂O₃ polymorphs, especially focusing on the synthesis of ε and α layers. A thorough assessment of the information published to date allows us to identify the critical parameters for phase selection. For a long time it has been indeed puzzling that growth under similar conditions did result in either α or ε films, or that a certain polymorph could be obtained with one growth technique and not with another. To the best of the authors' knowledge, no effort has been made to understand the reason for this behaviour and to critically analyse the literature on ε/α -Ga₂O₃ growth with different techniques. We believe that a deeper understanding of the growth mechanisms of Ga₂O₃ could help the progress of its different polymorphs and be therefore beneficial to the entire Ga₂O₃ community.

2. Growth of Ga₂O₃ polymorphs

In Table 2 we collected several papers related to the growth of different Ga₂O₃ polymorphs by the most common techniques: MOVPE, mist-CVD, Halide Vapor Phase Epitaxy (HVPE), Molecular Beam Epitaxy (MBE), and PLD. We included papers in which the growth parameters were explicitly mentioned and discussed, with emphasis towards the gas flows and/or the ratio of the reagents used in the deposition. We also decided to highlight articles in which different Ga₂O₃ phases were obtained by changing the synthesis parameters in different growth runs on the very same growth setup (collected in cells arranged in the same row). In the table we listed the following parameters: substrate and orientation, reagent types, and growth temperature, as well as notes for specific cases. For an overview of the above mentioned growth techniques the reader

is referred to specific reviews and books, as a detailed description of each growth process is beyond the scope of this work.^{1,40,41}

Precursors, catalyst elements, growth temperature, growth rates, mismatch between epilayers and substrates (*i.e.*, their termination and/or orientation), and background pressure are the parameters that can control and stabilize the growth of different Ga₂O₃ phases. In the next sections we will separately analyse and discuss each of them, with the goal of reaching a sound and coherent picture of the growth conditions that allow one to stabilize the ε or the α Ga₂O₃ phase. As there are several studies, books and reviews specifically focused on the growth of β -Ga₂O₃, we will generally omit the discussion and details about the synthesis of this polymorph, except when the variation of some significant parameters allows one to switch from β -Ga₂O₃ to ε - or α -Ga₂O₃.

By carefully looking at Table 2, it is possible to note that, despite peculiar differences, deposition techniques like MOVPE, HVPE and mist-CVD share some similarities: for example, HCl is used as a precursor in HVPE and is added in the mist-CVD feeding solution to dilute GaCl, while in MOVPE it can be used to control the growth rate and to stabilize the orthorhombic phase.⁴² Moreover, the temperature range in which either the α or ε phase can be obtained seems to be consistent for both polymorphs. Physical vapour deposition (PVD) techniques like PLD and MBE generally share similar growth temperatures with the CVD ones for the α phase, while, as will be later discussed in detail, the stabilization of the ε polymorph strictly requires the employment of a catalyst element like In or Sn.^{43,44}

2.1. Precursors, gas phase composition and chemistry

Since most of the available literature focuses on *c*-plane sapphire as a growth substrate for the α or ε phase, we start the discussion by considering the precursors used in the different techniques to grow α or ε -Ga₂O₃ on this substrate.

Let us start with the role of HCl in the growth of Ga₂O₃, as this is the only reagent used in comparable conditions in MOVPE, mist-CVD and HVPE.

Fig. 1 reports the Ga₂O₃ phase resulting from different Ga:Cl ratio and growth temperature (T_g) for mist-CVD and MOVPE. The values for mist-CVD are obtained from published reports^{45–51} as well as from private communications with the corresponding authors of the cited studies. In mist-CVD the Ga:Cl ratio is calculated considering the molar ratio between the gallium(III) acetylacetonate (Ga(acac)₃) and the HCl (37%) used to prepare the feeding solution. The Ga³⁺ and Cl⁻ ions and H₂O molecules are supposed to be vaporized, transported in the gas phase and able to reach the substrate with the same ratio defined in the solution.⁵² Arata *et al.*⁵⁰ used GaCl dissolved in deionized H₂O, resulting in Ga:Cl = 1. For MOVPE, the work of Sun *et al.*⁴² is the only one where HCl is added to the gas phase: in this case the Ga:Cl value results from the ratio between the TEG (triethyl-gallium) and HCl flows, privately communicated by the corresponding author of the paper.

For HVPE it is more difficult to calculate the effective Ga:Cl ratio, because the reacting species (GaCl or GaCl₃)²⁹ are obtained

Table 2 For ease of reading, the table is divided into several sections, each one collecting relevant papers related to the growth of the different Ga₂O₃ polymorphs with a single technique. In each cell we included relevant growth parameters – substrate, precursors, carrier gas, and growth temperature (T_g) – when they were explicitly mentioned in the referenced paper. Studies in which different Ga₂O₃ phases were obtained by changing the synthesis parameters in different growth runs on the same growth setup share the same table line

| HVPE | | |

by flowing HCl on liquid Ga and it is difficult to accurately estimate the yield of this reaction. Nevertheless, we can conceive that Ga : Cl is certainly less than 1. If one supposes that the yield of the reaction was 1, all the HCl would be converted either into GaCl or into GaCl₃, with Ga : Cl = 1 or 1/3. If the yield was less than unity, there would still be some HCl present, again leading to Ga : Cl < 1. For this reason, in Fig. 1 only a reasonable range for Ga : Cl in HVPE is indicated in the grey area for comparison with the other techniques.

Since it is meaningless to plot arbitrary points from HVPE in Fig. 1, it is necessary to look for an additional parameter to compare some of the HVPE data found in the literature. Therefore, Fig. 2 reports the resulting Ga₂O₃ phase from samples grown by HVPE and MOVPE depending on the O₂ : HCl flow ratios as a function of the growth temperature. The values were obtained from ref. 26, 42, 53 and 54 and from private communications with their corresponding authors.

While finding a trend between the Ga : Cl ratio and temperature is not straightforward, from Fig. 1 it can be noted that for mist-CVD Ga : Cl = 1 is the used condition, although the growth of the α polymorph is possible also with a lower Ga : Cl ratio. Mist-CVD is also more prone to provide α -Ga₂O₃ at lower temperatures. From Fig. 2 it is also evident that α -Ga₂O₃ is preferentially obtained by HVPE at lower temperatures, with the exception of the ϵ -phase obtained at 450 °C by Son *et al.*,⁵⁴ and that the ϵ phase can be stabilized on sapphire by increasing the O₂ : HCl ratio both by MOVPE and HVPE at a particular temperature.^{42,53} Higher temperatures favour the β phase, as it happens for mist-CVD.⁵⁰

Fig. 1 Ga₂O₃ phase on *c*-plane sapphire substrates as a function of the Ga : Cl ratio and temperature for the MOVPE (squares) and mist-CVD (triangles) techniques. Red symbols: ϵ -Ga₂O₃. Blue symbols: β -Ga₂O₃. Green symbols: α -Ga₂O₃. In the circle are summarized the data from ref. 42 using HCl along with O₂ and TEG; for these points the HCl flow is reported on the right y axis. The grey area represents reasonable Ga : Cl ranges for HVPE growth.

Chlorine seems to play an important role in the stabilization of different Ga₂O₃ polymorphs. A secondary ion mass spectroscopy (SIMS) investigation on different Ga₂O₃ layers⁵³ evidenced a higher amount of Cl incorporated in the ϵ -phase with respect to the α one (5×10^{17} vs. 3×10^{15} atoms per cc, respectively); this happens despite the lower O₂ : HCl ratio employed to grow the

α - Ga_2O_3 layer. Interestingly, in this work Cl seems to be confined at the Ga_2O_3 /sapphire interface for the α phase layer (Fig. 3). However, because of the unknown value of the distribution coefficient of Cl in gallium oxide, it is not straightforward to relate a volumetric SIMS measurement to a surface concentration of Cl atoms, to understand if they may indeed change the surface energy of Al_2O_3 . Density functional theory (DFT) models predict that at room temperature the saturation surface coverage of HCl on Al_2O_3 is approximately one adsorbed HCl molecule per five surface Al sites.⁵⁵ A deeper understanding of the HCl- Al_2O_3 surface interaction at higher temperature may be useful to clarify this point. It should also be noted that the presence of Cl at the outset of growth could be related to the formation of very stable Al-Cl bonds at the Al_2O_3 (0001) surface with bond dissociation energy $\Delta H_f = 495 \text{ J mol}^{-1}$. This may change both the surface energy of the sapphire and the interfacial energy between the two

oxides⁵³ and it may be one factor – but not the only one – promoting the growth of the metastable ϵ or α phases.

Other authors report incorporation of Cl throughout the whole layer, with a concentration of about 5×10^{16} atoms per cc for α - Ga_2O_3 HVPE growth at 470 °C.⁵⁴ Oshima *et al.*²⁶ found higher hydrogen and chlorine concentration for ϵ - Ga_2O_3 grown on GaN(0001), AlN(0001), and β - Ga_2O_3 ($\bar{2}01$) with respect to the one found in α - Ga_2O_3 grown on *c*-plane sapphire while maintaining the same synthesis conditions and in the same HVPE reactor (2×10^{18} vs. 7×10^{16} atoms per cc for Cl and 1×10^{18} vs. 4×10^{16} atoms per cc for H). In the same work it was observed that also H, resulting from HCl decomposition, is incorporated in the growing layer. As H is known to be a donor in Ga_2O_3 ^{56,57} this is an important element to take into consideration for its electrical properties when the growth is performed under H-based carrier gases (H_2 ¹⁴ or HCl). It is also worth mentioning that the incorporation of Cl was reported with a concentration of about 10^{16} atoms per cc in β - Ga_2O_3 grown by HVPE at 800–1050 °C,⁵⁸ indicating reasonably higher Cl desorption while increasing the deposition temperature.

For MOVPE, Sun *et al.*⁴² reported that the HCl flow does not affect the Cl concentration incorporated in the films regardless of the phase, speculating that HCl could just act as a catalyst for the growth.

Up to now, no study on the chemical details of the growth of Ga_2O_3 in the presence of HCl has been published; however, a theoretical study of the MOVPE growth of GaAs with HCl (without oxygen)⁵⁹ concluded that the interaction of TEG and HCl results in the formation of a stable GaCl molecule in the gas phase. GaCl can be adsorbed on the growth surface up to a substrate temperature of 900 °C. On the other hand, the already mentioned AlCl termination expected at the sapphire substrate- Ga_2O_3 layer interface should be more energetically stable.

MOVPE growth of α - or ϵ - Ga_2O_3 is typically obtained with the use of trimethyl- or triethyl-gallium (TMG and TEG) and water or oxygen as an oxidizing agent. By gathering several sets of data on Ga_2O_3 MOVPE growth from ref. 9, 14, 42 and 60–64, and from the same studies but considering the Ga:H₂O ratio (Fig. 1), it is possible to plot the relation between the growth temperature and the Ga:H₂O or Ga:O₂ ratio in the gas phase for the different growth methods (Fig. 4).

It should be noted that MOVPE growth with TEG and O₂ at temperatures lower than 575 °C resulted in polycrystalline β - Ga_2O_3 layers.⁶³

In MOVPE, the choice between TMG or TEG usually reflects a different growth rate and better accuracy in the gallium supply control, since TEG has a lower partial pressure with respect to TMG, allowing for easier control of lower gallium flow rates. It also produces lower carbon contamination (due to metalorganic decomposition) *via* β -hydride elimination rather than by a radical mechanism. TEG has lower stability compared to TMG and pyrolyses at significantly lower temperatures, thus allowing to grow higher purity layers at lower growth temperatures compared to TMG.⁶⁵

Another consideration should be made regarding the use of H₂O or O₂; the chemistry of the two precursors is totally

Fig. 4 (a) Ga₂O₃ phase as a function of the growth temperature (T_g) and H₂O : Ga ratio. All MOVPE points are from growth with H₂O and TMG. (b) Ga₂O₃ phase as a function of the MOVPE growth temperature (T_g) and Ga : O₂ ratio. All the growth processes are on *c*-plane sapphire substrates. Triangles: mist-CVD growth. different, as discussed by Wagner *et al.* for the growth of β-Ga₂O₃ between 750 and 850 °C.⁹ When pure O₂ is employed, the formation energy of oxygen vacancies is substantially increased, which in turn lowers their concentration. When H₂O is employed, the oxygen partial pressure is considerably lower and oxygen vacancies are expected to form spontaneously.⁶⁶ An additional mechanism can also take place: hydrogen may occupy oxygen vacancy sites by forming Ga-H species, thus reducing the surface state density. Therefore, the chemical potential of the surface will be more homogeneous and diffusion of desorbed atoms on the surface will be enhanced.⁹ Fig. 5 shows the composition of the growth atmosphere for real growth conditions using the FactSage software package, as illustrated by Wagner *et al.*⁹ The main products of the reaction between TMG and pure oxygen are solid Ga₂O₃, gaseous oxygen, water, and carbon dioxide. If water is used as the oxygen source, H₂ is present at high concentration, while O₂ molecules are not present at all, because they are fully consumed by organic species. CO₂ is also present, but at a concentration several orders of magnitude lower

Fig. 5 Calculated concentration of the main species formed during growth of Ga₂O₃ layers when using (a) oxygen and (b) water as an oxygen source. Reproduced with permission from ref. 9.

than H₂. H₂O dissociation and its chemisorption on the Ga₂O₃ surface can significantly influence the nature of the surface sites, which in turn affects the subsequent adsorption and surface mobility of other molecules. On the other hand, defects like oxygen vacancies (V_O) can affect the surface chemistry of the Ga₂O₃ surface. H₂O is preferably adsorbed in the form of molecules producing a hydrated Ga₂O₃ surface, while adsorbed CO₂ is activated and results in the formation of carbonate species with a slightly endothermic reaction.⁶⁷ In the framework of this reaction the presence of V_O on the Ga₂O₃ surface plays an important role since (i) CO₂ tends to occupy them, while (ii) H₂O spontaneously dissociates at the oxygen vacancy side.

Therefore, the choice of the precursor (*i.e.*, H₂O or O₂) can directly affect the concentration of oxygen vacancies in the deposited Ga₂O₃ layers. This is an important information, since it has been reported that the V_O concentration is related to the performances of β-Ga₂O₃ photodetectors; in particular, reducing the V_O concentration enhances the carrier drift and recombination, resulting in a higher photodetector response speed and higher photo/dark current ratio.^{68,69} If the use of H₂O leads to a different density of oxygen vacancy sites⁹ for the growth of β-Ga₂O₃, a comparison of the electrical properties of samples grown by mist-CVD and MOVPE with very different H₂O content may give some hints in the understanding of the growth mechanisms.

On the other hand, the use of O₂ or H₂O leads to completely different results with MOVPE in a wide temperature range (square symbols in Fig. 4a and b). In particular, β-Ga₂O₃ grown at temperatures lower than 575 °C with TEG and O₂ is polycrystalline, while single crystalline layers are obtained with TMG and O₂ only at T_g higher than 600 °C. The ε phase is stabilized with the use of H₂O in a wide range of temperatures between 600 and 750 °C. Nonetheless, β-Ga₂O₃ can also be grown using H₂O at higher T_g by properly tuning the growth conditions, and ε-Ga₂O₃ can be obtained at lower temperatures by using O₂ instead of H₂O. To the best of the authors' knowledge, no literature studies have been yet focused on the possibility to obtain different V_O concentrations in orthorhombic ε layers deposited with H₂O or O₂ and their possible role in photodetector performances.

From Fig. 4(a) and (b) it is evident that the use of H₂O in the gas phase instead of gaseous O₂ changes the MOVPE growth process and favours the growth of ε-Ga₂O₃. Very significant are the results obtained by Sun *et al.*⁴² (not reported in the graph): using O₂ and TEG as reagents they obtained β-Ga₂O₃ at 600 °C, but when 30 sccm of HCl was added to the gas phase, it stabilised ε-Ga₂O₃. When the HCl flow was further increased up to 60 sccm, layers of the α phase were obtained. These results confirm the important role of HCl in the stabilization of different Ga₂O₃ crystal phases. As the use of H₂O instead of O₂ in MOVPE definitely promotes the growth of ε-Ga₂O₃ over β-Ga₂O₃, one may speculate that hydrogen, alongside HCl, has also a role in stabilizing the ε phase. This does not clash with the results by Sun *et al.*;⁴² on the contrary, it would suggest that both H and Cl are active factors in stabilizing the growth of ε-Ga₂O₃. However, since pushing more HCl flow in MOVPE promotes the growth of the α phase, it is not clear why the same does not happen with high H₂O flow at similar T_g; there have been no studies reporting on the MOVPE growth of α-Ga₂O₃ with the use of H₂O or O₂ without the addition of HCl (which seems to be essential to dissolve GaCl). Nonetheless, α-Ga₂O₃ was obtained at T > 760 °C on sapphire using TMG, and N₂O as an oxidizing agent, and adding boron or nitrogen in the lattice (with triethylboron and dimethylhydrazine) to adjust the mismatch;⁷⁰ three monolayers of α-Ga₂O₃ were always observed at the interface with sapphire before the growth of β-Ga₂O₃ at 800 °C using TMG and H₂O.⁶⁰

Sun *et al.*⁴² reported DFT calculations with the relative energy difference for the formation of different polymorphs between pure Ga₂O₃ and hydrogenated gallium oxide, due to the introduction of H in the gas phase with HCl (Table 3). These DFT calculations considered the deposition of Ga₂O₃ at 600 °C in a MOVPE reactor with O₂, TEG and HCl as precursors.

From Table 3 we notice that without H in the gas phase (reflecting the absence of H in the lattice), the β phase has the lowest formation energy in agreement with the experimental data previously discussed. Therefore, H may act as a catalyst for the stabilization of metastable phases, *i.e.*, modifying the relative energy difference between the β phase and the other polymorphs and allowing, for instance, the deposition of ε layers at a T_g of 600 °C. Sun *et al.*⁴² suggested also that further

Table 3 Relative energy difference (in eV) between different Ga₂O₃ phases. Data from ref. 42

| | α | ε | β |
|---|------|------|------|
| Ga ₂ O ₃ | 0.15 | 0.04 | 0.00 |
| Ga ₄ O ₆ H | 0.07 | 0.00 | 0.02 |
| Ga ₄ O ₆ H ₂ | 0.01 | 0.00 | 0.03 |

studies regarding kinetic models may be required in order to understand the mechanism behind the crystallization process in the presence of HCl in order to: (1) fully understand the growth rate dependence on the HCl flow rates of Ga₂O₃ with the same phase, (2) consider the oversupply of HCl gas into the chamber to check the phases and growth rate, and (3) replace HCl with another gas to conduct similar studies, since increasing the HCl flow beyond a threshold results in the crystallization of α-Ga₂O₃. It is noteworthy that also Mist-CVD and HVPE show a similar tendency to obtain the α or ε phase at the growth temperatures reported by Sun *et al.*⁴² due to the presence of H₂O and HCl in the gas phase.

In the case of physical vapour deposition (PVD) techniques like PLD and MBE it is not correct to talk about precursors since usually the only elements involved in the deposition process are the ones constituting the deposited layer (excluding the unavoidable presence of impurities), *i.e.*, gallium and oxygen in the case of Ga₂O₃ growth. PVD heteroepitaxy of Ga₂O₃ on *c*-plane sapphire substrates mostly results in the formation of (201)-oriented monoclinic layers with six rotational domains.^{71–74} Nonetheless, a thin (≈ 1 nm) α-Ga₂O₃ interlayer can be usually identified at the substrate/β-Ga₂O₃ layer interface for both MBE and PLD films.⁶⁰

Particularly, for MBE the growth window for (201) β-Ga₂O₃ heteroepitaxial layers on *c*-plane sapphire is limited to relatively low substrate temperatures (T_g ≈ 500–600 °C) and/or high oxygen-to-gallium flux ratios⁷⁵ due to the high volatility of the Ga₂O suboxide which is formed on the substrate surface as a first step of its peculiar growth kinetics.⁷⁶ Outside of this growth window and with the employment of just Ga- and O-fluxes, no Ga₂O₃ layer can be deposited with MBE in either of its polymorphs on *c*-plane sapphire substrates. Notably, the stabilization of the orthorhombic ε-polymorph of Ga₂O₃ with PVD techniques like MBE and PLD specifically requires the introduction of a catalyst element during growth, *i.e.*, In⁴³ or Sn;⁴⁴ the supply of an In- or a Sn-flux together with Ga and the activated oxygen (provided *via* an oxygen plasma source) helps to widen the narrow deposition window of Ga₂O₃ on *c*-plane sapphire to both (i) higher deposition temperatures (*e.g.*, T_g = 700 °C) and (ii) lower oxygen-to-metal flux ratios. In particular, the deposition of phase-pure ε-Ga₂O₃ layers is limited to growth conditions that do not allow for any β-Ga₂O₃ formation (Fig. 6).⁴⁴ Under these synthesis conditions the catalyzing element is not incorporated to a large extent inside the deposited layer. The presence of a (201) β-Ga₂O₃ nucleation layer at the *c*-plane sapphire/ε-Ga₂O₃ interface is usually reported.^{43,44,77} As in the case of other growth techniques previously discussed in this article, also the PVD deposited

Fig. 6 Comparison of the growth rates as a function of the Ga-flux (expressed as beam equivalent pressure, BEP) during heteroepitaxial growth of Ga₂O₃ on *c*-plane sapphire substrates with and without the employment of an additional Sn flux (red triangles and black squares, respectively) via plasma-assisted MBE. The oxygen flow is kept constant at 0.5 standard cubic centimetres per minute with an oxygen plasma power of 150 W. Graph reproduced with permission from ref. 44.

ϵ -Ga₂O₃ layers on *c*-plane sapphire substrates are characterized by the presence of the same rotational domains giving rise to an (001)-oriented columnar structure.^{43,44,70}

The reasons behind the stabilization of the ϵ phase during PVD growth of Ga₂O₃ are not fully understood yet. That is why it is worth briefly describing this peculiar growth mechanism based on the collaborative effect of kinetics and thermodynamics, *i.e.*, metal-exchange catalysis (an extensive growth mechanism description is discussed in ref. 43, 44 and 78). The catalyzing element (*i.e.*, In and Sn) is (i) characterized by a higher oxidation efficiency with respect to Ga and, even though its growth kinetics (*i.e.*, In₂O₃ and SnO₂) is based on a similar 2-step process,^{75,76} (ii) its volatile suboxide (*i.e.*, In₂O and SnO) which is initially formed and adsorbed on the substrate surface has a lower vapor pressure with respect to the Ga₂O suboxide. As a matter of fact, both In₂O₃ and SnO₂ can be grown in plasma-assisted MBE at higher temperatures and with relatively lower oxygen-to-metal flux ratios with respect to Ga₂O₃.^{43,75,76} Therefore, due to its kinetic advantage, the adsorbed suboxide of the catalyst element can be further oxidized to its solid oxide form on the substrate surface (*i.e.*, In₂O₃ and SnO₂). At this stage of the growth process, Ga is replacing the catalyst element (thermodynamic advantage of Ga over In and Sn), which can be either desorbed or re-utilized in the framework of an installed catalytic cycle. In both cases, under these conditions the catalytic cycle results in very limited incorporation of the catalyst element inside the deposited Ga₂O₃ layer.^{43,44} This is true even in the presence of large catalyst fluxes (*e.g.*, In = 1/3 of the Ga-flux).⁴³ In other words, in metal-exchange catalysis the catalyst element works as an oxygen getter/reservoir for Ga₂O₃ growth, efficiently expanding its deposition window. ϵ -Ga₂O₃ layers in the presence of the catalysing element Sn were also reported for PLD grown thin films on MgO(111), SrTiO₃(111),

and yttria-stabilized ZrO₂(111) substrates.^{70,79} Notably, MBE In-mediated metal-exchange catalysis has been also applied to widen the growth window of Ga₂O₃ layers deposited on all the available β -Ga₂O₃ bulk substrate orientations [*i.e.*, (010), (100), (001), and (201)]^{12,13,80} but differently from the discussed heteroepitaxial growth; in this case the deposited layers always preserved the monoclinic structure of the substrate.

2.2. Temperature

From Fig. 1, 2 and 4 it is evident that the growth temperature T_g plays a critical role in tailoring the crystal phases of Ga₂O₃. In particular for CVD growth, high temperatures are usually necessary for the crystallization of the thermodynamically stable β -Ga₂O₃ polymorph (regardless of the deposition techniques, precursors, and gas phase composition). However, the monoclinic phase has been already reviewed in depth in the literature^{1,40} and, therefore, we will not include a discussion on β in this review. Generally, at T_g between 400 and 700 °C the driving force for the crystallization of one particular phase can be found in the kinetics of the reactions and/or in the growth process itself; for example, by simply changing the precursor from H₂O to O₂ the Ga₂O₃ switches from ϵ to β (see Section 2.1).

The growth temperature is a key factor in controlling α or ϵ phase stabilization by mist-CVD growth; in particular, $T_g \leq 500$ °C favours the deposition of α -Ga₂O₃ layers, while higher temperatures (up to $T_g < 700$ °C) result in the synthesis of ϵ -Ga₂O₃ films (Fig. 1).

With HVPE (Fig. 2) it is generally easier to crystallize the α phase in a wider temperature range compared to the mist-CVD one. ϵ -Ga₂O₃ could be obtained by HVPE at similar temperatures to mist-CVD ($T_g = 650$ °C) by appropriately tuning the gas phase composition, with the exception of one article⁵⁴ that reports the nucleation of an ϵ -Ga₂O₃ layer at a T_g of 450 °C.

Another interesting observation (Fig. 4) is that α -Ga₂O₃ is obtained by mist-CVD in a temperature range (400–550 °C) lower than the one typically used in MOVPE; one hypothesis may be related to the different kinetics of the reactions, due to the different precursors used. While in mist-CVD Ga³⁺ ions should be directly present in the gas phase so that no precursor decomposition has to occur, in MOVPE processes TMG (or TEG) may not have sufficient energy to form Ga₂O₃, and may tend to react directly with H₂O in the vapour phase without leading to Ga₂O₃ crystallization. Low MOVPE deposition temperatures (550 °C) result in polycrystalline Ga₂O₃ using H₂O and TMG. In this framework, it is worth noting that by using an ALD process instead of a standard MOVPE growth regime, crystalline ϵ -Ga₂O₃ could be obtained also at 550 °C,¹⁴ while the decomposition of the gallium precursor may have an important role in the growth process, the parasitic reactions in the gas phase between the metal-organic precursor and water may also play a role at lower temperatures. The use of water and TEG instead of TMG could be a possible route to obtain α -Ga₂O₃ by MOVPE at T_g comparable with mist-CVD without the use of Cl, as TEG has a lower decomposition temperature and prevents pre-reactions between Ga and water.⁶⁵ However, Chen *et al.*⁶⁴ reported the deposition of an ϵ -Ga₂O₃ layer

at 500 °C by using O₂ and TEG at 35 mbar. For this reason, it seems that the use of a particular Ga precursor is not sufficient to explain why mist-CVD at lower temperatures results in α -Ga₂O₃; other factors, such as the amount of H₂O (or H) or the growth pressure may also play a role in this process. A possible explanation may be that, by changing the growth temperature, the relative energy differences between the phases reported in the presence of H (Table 3) may assume different values, with the α phase more favoured than the ε one. Theoretical calculations and DFT models may help in understanding these aspects.

In the case of PVD deposition techniques, both PLD and MBE independently showed that the stabilization of the ε phase over the β one is associated with the employment of higher growth temperatures ($T_g \geq 465$ °C in PLD⁷³ and $T_g = 550$ – 700 °C in MBE^{43,44}) during the In/Sn-mediated deposition process. In the case of α -Ga₂O₃ the deposition temperature with MBE (no catalyst employed) has been so far limited to 500 °C $\leq T_g \leq 640$ °C.^{81–83}

2.3. Growth rate

HVPE, MOVPE and mist-CVD all allow for comparable Ga₂O₃ growth rates of about 500–1000 nm h⁻¹. Nonetheless, HVPE can also reach growth rates of about 10 μ m h⁻¹ by increasing the flow rates.⁵³ If comparable synthesis parameters and similar growth rates are considered, the stabilization of different Ga₂O₃ polymorphs should be discussed in light of the chemical reactions triggered by the different employed precursors (Section 2.1).

Generally, the growth rate can be related to the available time for lattice arrangement during Ga₂O₃ nucleation. In particular, a faster growth rate, typical of HVPE, may not allow the adatoms to rearrange on the layer/substrate surface, therefore not permitting the formation of the thermodynamically stable β -phase. In the case of heteroepitaxial growth on *c*-plane sapphire, the diffusing adatoms initially bonded to the oxygen and aluminium sites of the (0001) substrate surface are preferably ordering as α -Ga₂O₃ and are unable to undergo rearrangement to the β -Ga₂O₃ or ε -Ga₂O₃ phase before the next impinging atoms are adsorbed on the previously formed corundum surface; each layer of α -Ga₂O₃ is then constrained or buried by the rapidly depositing subsequent layers.⁵³ In this situation also the substrate crystallography, the eventual presence of a nucleation layer, and therefore the resulting lattice mismatch play an important role in the stabilization of the Ga₂O₃ phase (see Section 2.4).

The role of the growth rate in stabilizing the Ga₂O₃ phase is evidenced also by comparing the studies of Dang *et al.* and Kim *et al.*,^{45,84} where mist-CVD growth at the same T_g of 400 °C results in the stabilization of different Ga₂O₃ phases as a function of different growth rates. In particular, a higher growth rate of about 860 nm h⁻¹ resulted in the deposition of a phase-pure α -Ga₂O₃ layer,⁴⁵ while a lower growth rate of 260 nm h⁻¹ ended up in the synthesis of a mixed α and β phase sample as observed by bandgap measurements.⁸⁴ This supports the idea that the time given to the adatoms to rearrange on the layer surface, *i.e.*, before the atoms necessary

to cover the next monolayer are adsorbed, may influence the stabilization of a particular phase.

A similar picture can be also valid for MBE growth, since the deposition of ε -Ga₂O₃ layers is associated with a higher growth rate with respect to the β ones (Fig. 6) under similar synthesis conditions (*i.e.*, $T_g \approx 700$ °C and a low oxygen-to-metal flux ratio).^{43,44} Usually the full incorporation of the impinging Ga-flux can be obtained in such a regime, with maximum growth rates in the range of 100 to 300 nm h⁻¹. Nonetheless, it should be considered that the peculiar growth process associated with the stabilization of the ε -phase (metal exchange catalysis) specifically requires the employment of synthesis conditions where Ga₂O₃ would hardly grow without a catalyst (see Section 2.1). In fact, similar growth rates, characterized by full Ga-flux incorporation, could be obtained at lower growth temperatures and high O-flows in the case of β -Ga₂O₃ layers.

2.4. Substrate and lattice match

While in the previous paragraphs we mainly considered *c*-plane sapphire as the reference substrate to compare different growth methods, in this section we will discuss the influence of a different substrate and/or of a buffer layer.

The growth of ε -Ga₂O₃ has been demonstrated on various substrates such as gadolinium gallium garnet (GGG) (cubic), MgO(111), yttria-stabilized ZrO₂ (YSZ)(111), α -(Al_xGa_{1-x})₂O₃(0001), NiO(111), AlN, and GaN.^{26,28,85,86} The synthesis conditions that allow for a particular Ga₂O₃ polymorph strongly depend on the crystallographic mismatch between the substrate and epilayer as well as the surface crystal structure.

Some authors have reported that substrates of a cubic material (MgO and YSZ) oriented along the (111) direction allow one to obtain single phase (001)-oriented ε -Ga₂O₃ layers by mist-CVD in a wide range of deposition temperatures (400–700 °C) where typically α -Ga₂O₃ is obtained on *c*-plane sapphire.^{86,87} On the other hand, the growth on *c*-sapphire proved to be more difficult, as mixed phases are obtained in standard growth conditions by Mist-CVD, either α - ε at low temperatures or ε - β at high temperatures, due to the crystal structure of α -Al₂O₃. It is noteworthy that the addition of a small buffer layer of NiO(111) on the sapphire substrate permits one to switch from α -Ga₂O₃ to ε -Ga₂O₃ growth in the whole 400–800 °C range.⁵⁰

A lower mismatch between the substrate and the ε -Ga₂O₃ epilayer also appears to facilitate the growth of this phase; with the same HVPE growth conditions that resulted in α -Ga₂O₃ layers on *c*-plane sapphire substrates, (001)-oriented ε -Ga₂O₃ was obtained on GaN(0001), AlN(0001), and β -Ga₂O₃($\bar{2}01$), the latter exhibiting superior crystal quality.^{29,88–90} A similar trend has been reported for Mist-CVD growth, where the use of MgO(111) instead of YSZ(111) substrates (with 2.5 and 20% nominal mismatch with ε -Ga₂O₃, respectively) allowed one to obtain single-phase (001)-oriented ε layers at much lower temperatures.⁸⁶

However, a quantitative comparison of literature results based on the reported mismatch could be misleading, as the nominal lattice constant of the substrate might not be the

parameter determining the effective mismatch. Furthermore, one should consider thermal mismatch, which leads to different lattice parameters for the substrate and epilayer at different temperatures. Indeed, as discussed in the introduction, epitaxial (001) ϵ -Ga₂O₃ grows by the formation of rotational domains, effectively altering the difference in lattice spacing between the epilayer and substrate. The most obvious example is the case of *c*-plane sapphire, where the nominal mismatch between α -Al₂O₃ and (001) ϵ -Ga₂O₃ is 65%, but by the effect of 120° lattice rotations the real mismatch is 4.8%.¹⁵ In this regard, it is interesting to mention that in spite of various tested substrates (and different crystal orientations), so far just (001)-oriented ϵ -Ga₂O₃ layers were reported in the literature. As mentioned, when proper structural characterization is given, all these samples are reported to be characterized by the presence of rotational domains resulting in columnar-like growth. Even if no dangling bonds are expected at the walls of the ϵ domains (differently from the case of rotational domains in β layers),⁹¹ it should be considered that their presence could result in a barrier for in-plane electronic conduction. There can be two effective strategies for growing pure ϵ -Ga₂O₃ single crystal layers, *i.e.*, free of rotational domains: first, finding a properly matched substrate so to allow the accommodation of the orthorhombic structure of Ga₂O₃ in different crystal orientations [*e.g.*, (010)] or, second, employing a proper in-plane substrate offcut, *i.e.*, inducing the formation of properly spaced terraces whose kinks act as properly spaced nucleation sites (as already demonstrated for the growth of β layers on *c*-plane sapphire).⁹²

As discussed in the previous section, heteroepitaxy of ϵ -Ga₂O₃ and α -Ga₂O₃ on sapphire may be favoured over the growth of β -Ga₂O₃ at lower temperatures due to reduced kinetical effects, allowing for the growth of a phase that is better lattice-matched to the substrate. In MOVPE, the growth on α -Al₂O₃ oriented along (1120), (1010), and (0112) allows for the growth of α -Ga₂O₃⁷⁰ at 700 °C using TEG and NO₂ as an oxidizing agent.

ϵ -Ga₂O₃ was obtained by mist-CVD on an α -(Al_{0.4}Ga_{0.6})₂O₃ buffer at temperatures lower than 600 °C, while the α phase was observed at higher temperatures, conceivably due to the lower lattice mismatch of 1.2% for the ϵ phase and 2.2% for the α phase. This effect was interpreted as due to a stepped surface: if the diffusion of adatoms is sufficiently high to reach step edges, the epitaxial layer grows with the α crystal structure of the buffer; if the growth temperature is not high enough, the lower-mismatch ϵ -Ga₂O₃ is favoured.⁴⁸ Therefore, not only the substrate and its intrinsic mismatch with the relative polymorph lattice of the growing Ga₂O₃ layer should be considered as a growth parameter, but also its in-plane offcut and the associated terrace length. In this regard, the possible role of anisotropic diffusion lengths of the adsorbed species along different in-plane directions should also be considered, meaning that also the in-plane direction of the substrate offcut should be taken into account (*i.e.*, both the terrace length and diffusion length along the offcut direction determine if the adsorbed species are able to reach the step edges and thus allow a step-flow growth mechanism), as already evidenced for β -Ga₂O₃.⁹³

The indication that the α phase stabilization could be mainly driven by the mismatch with the underlying substrate lattice is also suggested by the MBE literature. In particular, corundum gallium oxide shares the same crystalline structure as sapphire and, therefore, it can in principle allow the growth of α -Ga₂O₃ along different sapphire orientations. In this case, the substrate–layer mismatch affects the maximum thickness that can be obtained: for *c*-plane sapphire (4.6% mismatch) only about a nanometer of α -Ga₂O₃ is achievable, while for *a*-plane sapphire layers of up to 10 nm were grown (3.4% mismatch).⁸¹ Nonetheless, the deposition of a Nd-doped α -Ga₂O₃ layer as thick as 100 nm has also been reported,⁸³ suggesting that the presence of a dopant could affect the critical thickness of the layer on this orientation. Nonetheless, the thickest α -Ga₂O₃ films were obtained on *r*-plane sapphire:⁸² in this case a phase change to β -Ga₂O₃ was recorded after about 200 nm of α -Ga₂O₃, due to the formation of large exposed *c*-facets which favour subsequent monoclinic phase nucleation. Being the formation of facets also related to the chemical potential during the thin film deposition,⁹⁴ we can argue that in the case of α -Ga₂O₃ layers on *r*-plane sapphire substrates the thickness limitation for the obtainment of phase-pure layers could be overcome by properly tuning the Ga-to-O flux ratio.

However, in the case of ϵ -Ga₂O₃ layers obtained *via* PVD techniques like MBE and PLD, the role of the substrate and the relative mismatch with the layer is less clear; there have been reports of layers grown on *c*-plane sapphire *via* MBE^{43,44} and PLD,⁷³ while growth on substrates with a cubic structure [MgO(111), SrTiO₃(111), and YSZ(111)] has just been reported for PLD.⁷⁹ A buffer layer of β -Ga₂O₃ between *c*-sapphire and ϵ -Ga₂O₃ is usually present and evidenced by XRD and TEM. This could be an indication that an interlayer could be needed in order to accommodate the substrate–layer strain. The presence of a β -Ga₂O₃ buffer layer was observed also in the recent reports of ϵ -Ga₂O₃ layers on ITO/YSZ(111)⁸⁷ and of van der Waals epitaxy of ϵ -Ga₂O₃ on synthetic mica,⁹⁵ both *via* mist-CVD. In particular, the van der Waals epitaxy report of ϵ -Ga₂O₃ might hint at the fact that, in conditions with very weak chemical bonding between the substrate and epilayer, the growth of an initial layer of the most thermodynamically stable material in the β phase is needed, before obtaining epitaxial ϵ -Ga₂O₃. Moreover, the presence of an α -Ga₂O₃ buffer layer prior to ϵ -Ga₂O₃ deposition on *c*-plane sapphire has been reported for HVPE with the presence of Cl and interpreted to be related to semi-coherent growth of the α -phase, followed by ϵ -phase island nucleation and growth.⁵³ Nonetheless, for both MBE and PLD where ϵ -Ga₂O₃ can be just obtained by In or Sn-mediated catalysed growth (see 2.1), also the crystal structure of the respective catalyst oxides (In₂O₃ or SnO₂) – *i.e.*, their oxygen atom distribution/coordination on the sample surface – could be at least partially responsible for the orthorhombic phase stabilization.

Moreover, it is worth mentioning that In-mediated MBE growth on (201) β -Ga₂O₃ single crystalline substrates under growth conditions that would otherwise allow for the synthesis of ϵ layers on *c*-plane sapphire substrates results in the preservation

of the underlying substrate monoclinic structure.^{12,13} This is surprising considering that (i) the growth of ϵ -Ga₂O₃ on *c*-plane sapphire substrates is usually happening on top of ($\bar{2}01$) β -Ga₂O₃ interlayers, and (ii) the deposition of ϵ -Ga₂O₃ layers has been already previously reported on top of β -Ga₂O₃ bulk substrates *via* HVPE.²⁶ One possible explanation relies on the formation of wide facets [*i.e.*, different surfaces not parallel to the ($\bar{2}01$) one] during MBE ($\bar{2}01$)-homoepitaxy,^{12,13} which could favour the stabilization of the monoclinic polymorph, similarly to what has been previously discussed in the case of α -Ga₂O₃ on *r*-plane sapphire substrates.⁸²

An interesting contribution about the role of the substrate in the nucleation of the α or ϵ phase is given in ref. 90 and 96, using HVPE to grow Ga₂O₃ on column-patterned sapphire. While the standard deposition on bare *c*-plane sapphire results in α -Ga₂O₃ with good crystallinity, the film on patterned substrates gives a mixture of α and ϵ -Ga₂O₃, with α -Ga₂O₃ vertical columns originating from the cones on the sapphire substrate, protruding up to the surface and capped with an irregular shape faceted pyramid on top. The ϵ -phase was located between these columns and had poorer crystallinity.

2.5. Pressure

Considering different deposition techniques that work in totally different pressure regimes (CVD *vs.* PVD) and with different oxidizing agents, a unified view towards the effect of pressure on the stabilization of Ga₂O₃ polymorphs is challenging. Nonetheless, internal comparisons among different pressure regimes (*i.e.*, oxygen partial pressures) in the framework of the same deposition techniques can allow one to critically discuss this point.

As a starting point, a simple consideration would be that MOVPE processes are usually performed at pressures from some tens up to some hundreds of mbar, while mist-CVD and HVPE generally use atmospheric pressure. As discussed above, by considering Fig. 1 and 2 it can be noticed that α -Ga₂O₃ is obtained by both HVPE and mist-CVD at low temperatures (up to 500–600 °C), while β or ϵ Ga₂O₃ is generally obtained in the same temperature range by MOVPE.

Regarding MOVPE with H₂ and TEG, it was observed that a high pressure regime (>100 mbar) favours the nucleation of β -Ga₂O₃ in the gas phase, resulting in films with a mosaic surface, while ϵ -Ga₂O₃ is obtained at lower pressures, as already discussed in Section 2.3.⁶⁴

For PLD, a flux of molecular oxygen is employed for the growth of oxide layers; for Sn-mediated growth of Ga₂O₃ it has been shown that the stabilization of the ϵ phase over the β one requires lower oxygen fluxes ($p_{\text{O}_2} \leq 1 \times 10^{-2}$ mbar).⁷⁹ For MBE growth it is complicated to discuss absolute oxygen partial pressure values; in fact, as this deposition technique must work at significantly lower pressure regimes during deposition processes ($\leq 10^{-5}$ mbar), it therefore requires a flow of highly reactive oxygen so to allow for oxide layer deposition. This can be obtained either by an O-plasma source or by ozone, whose efficiencies are strongly dependent on every single experimental apparatus (*e.g.*, distance of the sources from the substrate, purity of the provided ozone flux, efficiency of the

O-plasma source). As already mentioned in Section 2.1, and consistently with the discussed PLD data, the stabilization *via* MBE of the ϵ phase over the β one requires lower oxygen-to-metal flux ratios.⁴⁴ In both PLD and MBE, growing phase-pure ϵ -layers through metal-exchange catalysis (see Section 2.1) not only requires the presence of the catalyst element during growth, but also the employment of synthesis conditions that would not otherwise allow for β -Ga₂O₃ deposition (*i.e.*, substrate temperatures >550 °C coupled with low oxygen fluxes). Otherwise, the competition between the normal growth regime (*i.e.*, without a catalyst) and the catalysed one would result in mixed β - ϵ phase formation (see Fig. 6).⁴⁴ Moreover, higher oxygen-to-metal flux ratios in MBE growth lead to remarkable incorporation of the catalyst element in the Ga₂O₃ layer, even though it is not clear if the incorporation can also be affected by the actual crystalline phase (*i.e.*, ϵ or β).^{12,97}

Differently from the ϵ -phase, the stability of α -Ga₂O₃ layers is apparently only weakly affected by different oxygen-to-metal flux ratios, as shown for heteroepitaxial growth by MBE on *r*-plane sapphire substrates.⁸²

3. Conclusions

In this work we critically discussed the main aspects that rule the stabilization of different Ga₂O₃ polymorphs during growth. We considered and discussed all the main chemical and physical vapour phase deposition techniques and identified that the use of different precursors/catalysts (2.1), the deposition temperature (2.2), the growth rate (2.3), the substrate/nucleation layer (2.4), and the partial pressure of the processes (2.5) are all key parameters to be carefully considered for the synthesis of β , α , or ϵ Ga₂O₃ thin films. Naturally, it is very complicated to disentangle the effect of one single variable, but we were nevertheless able to highlight and critically examine several chemical/physical reasons behind different observations reported in the vast literature on Ga₂O₃ growth.

In particular, we can here briefly summarize guidelines for the stabilization of different Ga₂O₃ polymorphs prepared by different deposition techniques (limited to growth on sapphire substrates for simplicity):

- Chemical vapour deposition techniques (HVPE, MOCVD, and Mist-CVD) on *c*-plane sapphire: β -Ga₂O₃ can be usually obtained at growth temperatures above 500 °C with O₂ as a precursor, while at higher growth temperatures ($T_g > 700$ °C) it can be obtained also with H₂O. ϵ -Ga₂O₃ can be grown (i) with an H₂O precursor in a temperature window from 600 °C to 750 °C or (ii) if Cl is added at temperatures in the 600 °C range; however, the absolute T_g depends on the growth technique (*e.g.*, MOVPE allows one to grow at lower T_g than MIST-CVD). α -Ga₂O₃ is generally grown at lower temperatures. In particular, MIST-CVD, which generally uses a high content of H₂O precursor, allows for lower growth temperatures (400–550 °C) than MOVPE (600 °C); in HVPE, which makes use of O₂, the addition of Cl favours the stabilization of this phase at temperatures up to 650 °C.

• Physical vapour deposition techniques (MBE and PLD): referring to *c*-plane sapphire substrates, $(\bar{2}01)$ -oriented β -Ga₂O₃ can be usually synthesized at low substrate temperatures (*e.g.*, $T_g \leq 600$ °C) and/or at high oxygen-to-metal flux ratios (oxygen-rich regime). Single phase (001)-oriented ε -Ga₂O₃ can be deposited under growth conditions where the β polymorph would not grow – *i.e.*, higher substrate temperatures (600 °C $\leq T_g \leq 700$ °C) and lower oxygen-to-metal flux ratios (metal-rich regime) – through the employment of a catalyst element (In and Sn) provided during the deposition process. α -Ga₂O₃ layers can be obtained on *c*-plane sapphire substrates just with limited thickness (≈ 3 nm), while on *a*-plane and especially *r*-plane sapphire substrates single phase thicker films can be deposited (maintaining the substrate orientation); no catalyst element is needed, T_g can be in the range of 500 °C to 650 °C, and no limitations on the oxygen-to-metal flux ratio are reported.

From a fundamental point of view, some questions arise about the exact chemical mechanisms that result in the stabilization of the ε phase, in particular concerning the role of additional elements involved in the growth process such as Cl and H (for CVD techniques) and Sn and In (PVD techniques). Additional insight into these processes could allow one to expand the range of useful elements to stabilize ε -Ga₂O₃ and other metastable polymorphs.

The role of the growth kinetics in the stabilization of the phase is also an important topic, if one aims to optimize the synthesis conditions. Indeed, some results indicate that the growth rate might be an important parameter to control the nature of the polymorphs; with its higher growth rate, HVPE could be the most convenient solution to stabilize α -Ga₂O₃ in a wide range of temperatures.

Moreover, despite the different substrates adopted for Ga₂O₃ heteroepitaxy, just (001) oriented ε -Ga₂O₃ and $(\bar{2}01)$ oriented β -Ga₂O₃ layers were so far deposited. For both polymorphs these particular growth orientations result in the formation of domains which lead, in the case of β , to the formation of dangling bonds at the domain interfaces, while, in the case of ε , even without dangling bonds there could be negative effects on the transport properties of the layers. The use of different substrates and/or of proper offcuts could allow one to investigate this issue.

The identification of a well-defined growth window (*e.g.*, oxygen- or metal-rich) and the employment of different precursors or catalysts for any particular polymorph can generate different point defects during growth, with a possible great impact on electronic devices (*e.g.*, higher photodetector response speed and higher photo/dark current ratio).

As a final remark, we believe that particular effort should be made in the direction of the clear determination of the physical properties of the α and ε polymorphs, from both a theoretical and experimental point of view.

Therefore, we believe that this work could represent a landmark for the synthesis of different Ga₂O₃ polymorphs, which could help to unveil the full potential of this material for future applications.
