As a new member of the carbonaceous nanomaterial family, carbon dots (CDs) have been recognized as promising candidates in nanotheranostics for simultaneous bioimaging and cancer treatment because of their unique optical properties and intrinsic theranostic properties. In this short review, we aim at summarizing the recent advances and future prospects of CDs as nanotheranostic agents for anticancer applications. Initially, we discuss CDs for fluorescence imaging, photoacoustic imaging and magnetic resonance imaging. Subsequently, we highlight CDs for photodynamic therapy, photothermal therapy, multimodal therapy, and tumor microenvironment stimulus-responsive cancer treatment. Lastly, we discuss the present challenges and future prospects of CDs as versatile nanotheranostic agents for cancer treatment.

1. Introduction

Cancer has become a primary health burden in the world due to its high incidence and mortality. Despite remarkable efforts in cancer treatment, the overall 5 year survival rate of patients with cancer is still very low.¹ Around 18 million new cancer cases and approximately 9.6 million deaths from cancer reported in 2018,

and the annual number of cancer cases will have increased to 22 million in the next two decades. Therefore, new medicines and techniques must be developed for precise and efficient cancer therapy.

Nanotheranostics that integrate diagnosis and therapy into a single nanoplatform have attracted increasing interest for cancer treatment.^{2–5} In comparison with traditional anticancer models, the combination of diagnosis and therapy can collect more detailed information for precise, high-sensitivity, and low-interference cancer treatment. The integration also can monitor the metastasis and relapse of tumor to obtain high therapeutic efficacy. Hence, a large variety of nanotheranostic agents based on multicomponent inorganic, organic, or inorganic/organic nanostructures that combine two or more imaging functions (e.g., fluorescence (FL)/photoacoustic (PA) imaging, FL/magnetic resonance (MR) imaging, MR/positron emission computed tomography (PET) imaging, or FL/MR/PET imaging) and therapeutic modalities (e.g., chemotherapy (CHT)/radiotherapy (RT), gene therapy (GT)/photodynamic therapy (PDT), CHT/photothermal therapy (PTT), and PDT/PTT/CHT) have been studied in quantities, and many interesting results have been obtained in preclinical animal experiments on various tumor models.^{6–10} Although these techniques have gained prominence, each type of nanotheranostic agents has unique properties and intrinsic limitations. Inorganic nanoparticles, such as transition metal chalcogenide or selenide nanoparticles and upconversion nanoparticles, often have unique physicochemical properties that allow applications in simultaneous imaging and therapy of cancer. Unfortunately, the use of these particles in clinical settings is impeded by the long-term safety of heavy metal atoms associated with these nanoparticles. Research on nanotheranostics

Qingyan Jia

Qingyan Jia is an associate professor at Northwestern Polytechnical University in China. He received his PhD degree from Technical Institute of Physics and Chemistry (TIPC) in 2018. In 2018, he joined the Institute of Flexible Electronics (IFE) at Northwestern Polytechnical University. The primary goal of his research team is to develop novel nanomaterials and innovative strategies for cancer and infection treatments.

derived from low toxicity materials is still in infancy, and using fewer components to develop new and safe/biocompatible “one for all” theranostic features for clinical multimodal imaging and therapeutic modalities remains a major challenge.

In the past decade, carbon dots (CDs) have attracted considerable attention in different fields, including bioimaging, photocatalysis, light-emitting diodes, and plant growth promotion, because of their remarkable nanostructures and favorable electronic, mechanical, optical, thermal, and safe/biocompatible properties.^{11–17} CDs were first discovered accidentally in 2004 by Xu and coworkers, and then Dr Sun named them CDs or carbon quantum dots (CQDs) based on their spectral features and properties that are similar to those of the widely studied silicon QDs at that time.^{18,19} The preparation methods of CDs are currently divided into bottom-up and top-down approaches. The bottom-up approach uses a variety of technologies, such as template method, pyrolysis, microwave, solvothermal, *etc.* to carbonize organic molecules or biomass containing organic molecules to obtain emitting CDs. The top-down approach is to prepare smaller luminescent CDs with large bulk carbon

materials, such as graphite, carbon fiber, carbon nanotubes, graphene, *etc.* as precursors by using laser ablation, electrochemistry, arc discharge, and other technologies.^{20,21} According to the reported literature, CDs mainly include CQDs, graphene quantum dots (GQDs), polymer carbon nanodots, and carbon nanodots.^{22–25} CDs can effectively overcome the metal toxicity of traditional II–VI QDs; thus, they can be applied as highly stable/biocompatible fluorescence probes and biological tracers *in vivo*. Moreover, fluorescent CDs are superior to organic dyes in terms of photoluminescence stability, fluorescence tunability, surface group richness, strong hydrophilicity, low toxicity, good biocompatibility, rich carbon source, and simple preparation. Therefore, CDs have been recognized as smart candidates for the diagnosis of cancer.

In addition to the use of FL imaging, a variety of CDs have been studied for PA imaging, MR imaging, *etc.* for cancer diagnosis. Some CDs also have inherent anticancer properties, including PDT and PTT.^{26–29} PDT is mainly to use photosensitizers (PSS) to produce reactive oxygen species (ROSS) under proper light illumination, and then generate oxidation

Ziyu Zhao, Ke Liang, Fuchun Nan, Ye Li, and Jian Wang are students at Key Laboratory of Photochemical Conversion and Optoelectronic Materials and CityU-CAS Joint Laboratory of Functional Materials and Devices of Technical Institute of Physics and Chemistry of Chinese Academy of Sciences. Ye Li and Ziyu Zhao are studying for their Master's degree. Ke Liang, Fuchun Nan, and Jian Wang are pursuing for their PhD degree. They are focusing on the development of carbon nanomaterials for biomedical, energy, and environmental applications.

Jiechao Ge

Jiechao Ge is currently a professor at the TIPC, Chinese Academy of Sciences. He received his PhD degree from Shandong Normal University in 2008 under the guidance of Prof. Bo Tang. During 2008 and 2009, he joined the group of Prof. Harry Dorn and worked as a postdoctoral researcher at Virginia Polytechnic Institute & State University. He joined TIPC in 2010. His research interests mainly focus on the design and synthesis of carbon nanomaterials as cancer theranostics and photocatalysts.

Pengfei Wang

Pengfei Wang is a professor at TIPC. He received his PhD degree in organic chemistry from the Institute of Photographic Chemistry, CAS, in 1993. After completing professional experience at Laboratoire PPSM of CNRS of France as a visiting researcher, at the National Institute of Materials and Chemical Research (NIMC) in Japan as a COE fellow, and at the Department of Applied Physics and Materials Science in City University of Hong Kong as a senior research fellow, he joined TIPC in 2005 as a professor. His current research interests include chemosensors and phototheranostic agents based on organic/inorganic materials.

reaction with biological macromolecules in cancer cells, resulting in cell toxicity; PTT is usually to absorb photon energy through photothermal agents, and then release heat in the tumor site inducing irreversible damage to cancer cells. The light illumination in PDT and PTT are able to be spatially controlled to irradiate only the tumor lesion without damaging normal tissues. Such selectivity offered by PDT and PTT can significantly reduce the systemic toxicity compared with the traditional chemotherapy and radiotherapy.^{30,31} Thus, the CDs with intrinsic phototheranostic properties have shown considerable potential for application in tumor treatment. Although several articles have reviewed CD syntheses and applications, including imaging, diagnosis, and cancer treatment,^{32–35} in the present review, we aim at summarizing the recent advances mainly reported in both 2018 and 2019 and the future prospects of CDs as nanotheranostic agents for anticancer applications. Initially, we discuss the present progress in the use of CDs for FL imaging, PA imaging as well as MR imaging. Subsequently, we highlight the recent advances in CD-based cancer nanotheranostics in branches of PDT, PTT, multimodal therapy, and tumor microenvironment stimulus-triggered therapy. Lastly, we present the current challenges and future prospects of CDs as versatile nanotheranostic agents for cancer treatment.

2. Carbon dots for cancer diagnosis

2.1 Carbon dots as fluorescence imaging probes

Fluorescent CDs have been widely used in bioimaging because of their excellent and tunable multicolor emission. For FL imaging probes, red or near-infrared (NIR) emissive CDs (>600 nm) are favorable due to their deep tissue penetration, minimal tissue absorption, minimal photodamage, and low autofluorescence interference to biological samples.^{34,36} However, prior to 2014, the reported CDs were mainly concentrated at a wavelength range of blue to yellow and generally excited using a short-wavelength light of less than 500 nm, which is outside the biological optical window (650–900 nm); as a consequence, these CDs would be strongly absorbed by biological tissues, limiting light penetration in tissues.^{37,38} Therefore, the use of CDs as FL imaging probes for the *in vivo* diagnosis of cancer is hindered. In 2014, our group reported a novel N- and S-doped CD prepared from polythiophene derivative termed as PT2, which is a well-defined conjugated polymer molecular precursor. The CDs exhibit a broad absorption in the UV-visible region and a strong red emission peak at 680 nm.³⁹ Subsequently, we designed various functional precursors based on polythiophene derivatives to prepare CDs with tunable emissions ranging from blue to NIR (Fig. 1a and b).⁴⁰ We also proposed a tunable photoluminescence mechanism resulting from variations in the surface state and N doping (Fig. 1c). The introduction of N atoms leads to a decrease of energy levels of the CDs' surface state. Moreover, the S atom introduction likely enhances the effect of N atoms on the properties of CDs. These findings further prove that is an available way to improve the fluorescent properties and other

physicochemical properties of CDs.^{41–43} Thus far, various heteroatoms, such as N, S, and F, with different doping methods have been utilized to explore CDs as bioimaging probes in the red/NIR emissive region (Table 1). For example, in 2016, Lin's group prepared highly efficient red emissive CDs by using citric acid and formamide as precursors.⁴⁴ The red emissive CDs exhibit excellent properties, including high quantum yield (QY) of 22.9% and red emission (maximum emission at 640 nm). They found that formamide plays an important role in the favorable realization of red emissive CDs and concluded that the surface states/defects of CDs and N/O codoping possibly cause the intense red emission. In 2017, Xiong *et al.* prepared red emissive CDs with a high QY of 28% in water by using pulp-free lemon juice.⁴⁵ The red emissive CDs are monodispersed with an average diameter of 4.6 nm and exhibit excitation-independent emission with peak at 631 nm. Further investigations have suggested that the surface states of CDs and the N-derived structures of CD cores synergistically cause the intense red emission. Subsequently, they prepared red emissive CDs with a high QY of 53% by heating citric acid and ethylenediamine in a formamide solution, thereby improving the wide applications of CDs in bioimaging.⁴⁶ Fan's group also reported multicolored N-doped CDs by controlling the fusion and carbonization of an ethanol solution of citric acid and diamionaphthalene (DAN) with a suitable amount of H₂SO₄.⁴⁷ Given the large N-doped sp² cluster of precursor DAN, the surface of CDs can be highly passivated and crystallized for yielding strong emission. Yang and coworkers fabricated one fluorine-doped CD with red photoluminescence *via* a simple and eco-friendly microwave-assisted method.⁴⁸ The red-shift emission of CDs is mainly attributed to the doped fluorine, which increases the delocalized π -electron and then narrows the energy gap of the surface states of CDs. Additionally, Ding's group synthesized an NIR-emitted CD by using low-cost lemon juice as a precursor *via* a solvothermal reaction.⁴⁹ The as-prepared CDs show excitation-independent emission with the

Table 1 Heteroatom doped red emissive CDs prepared from different carbon sources and their emission properties

Carbon source	Method	Doping	Emission (nm)	QY (%)	Ref.
Polythiophene derivatives	Hydrothermal	N, S	680	5.4	39 and 40
Citric acid, formamide	Microwave	N	640	22.9	44
Pulp-free lemon juice	Solvothermal	N	631	28	45
Citric acid, ethanediamine, formamide	Solvothermal	N	627	53	46
<i>N,N</i> -Dimethyl-, <i>N,N</i> -diethyl-, and <i>N,N</i> -dipropyl- <i>p</i> -phenylenediamine	Solvothermal	N	637, 642, 645	86	47

Pulp-free lemon juice, formamide	Solvothermal	N	704	31	49

highest fluorescent peak at 704 nm and a fluorescence QY of up to 31%.

Surface functionalization is another effective strategy to improve the fluorescence of CDs.^{50–54} In 2018, Sun's group reported multiple-color-emission CDs from blue to red by controlling their surface graphitization and functionalization (Fig. 2a).⁵⁵ The XRD (Fig. 2b) and Raman spectra (Fig. 2c) demonstrate that the graphitization degree of R-CDs is higher than those of B- and G-CDs. Fig. 2d shows that the –COOH content significantly increases from B- and G-CDs to R-CDs. Therefore, the emission peak of CDs can be tuned to 630 nm by regulating the thermal pyrolysis temperature and reactant ratio of citric acid and urea (Fig. 2e). The relative photoluminescence QYs of CDs with red emission can reach 12.9%. Another notable progress was revealed by Qu and Rogach *et al.*, who prepared NIR CDs by modifying polymers or molecules on their surface.⁵⁶ For instance, they bound poly(vinylpyrrolidone) with electron-acceptor groups, such as S–O and C–O, to the outer layers and edges of CDs to facilitate the electron transitions between optical band gaps of CDs for NIR excitation and emission (Fig. 2f).

In most cases, PL enhancement with multistep modification is less than 10-fold; processes are often time consuming, requiring toxic chemicals, and unfeasible on a large scale, thereby hindering further imaging applications.⁵⁷ Aggregation-induced emission (AIE) regulates the fluorescent properties of CDs.^{58–60} Recently, Hu *et al.* prepared hydrophobic CDs (H-CDs) with excellent AIE properties by using melamine and dithiosalicylic acid/acetic acid (Fig. 3a).⁶¹ H-CDs display blue fluorescence in a dispersed state, but red emission in an aggregated state by the introduction of water to the solution (Fig. 3b). These interesting properties are ascribed to AIE induced by the π - π stacking interactions of carbonized cores and the restriction of CD surfaces' intramolecular rotation around disulfide bonds. We also showed that the FL intensity of CDs is enhanced up to 69 times by ionic and nonionic surfactants. The effects of ionic and nonionic surfactants on the FL emission of CDs have been explored for the first time, subsequently improving the sensitivity of CDs for bioimaging.⁵⁷

Compared with visible/NIR-I light-based bioimaging, FL imaging in the NIR-II region (1100–1600 nm) shows substantially reduced scattering losses, enabling the observation of deeper tissues with an enhanced spatial resolution.^{62–64} Hence, nanomaterials

with NIR-II emission should be explored to improve their competitiveness for further biomedical applications, especially bioimaging. Currently, QDs, carbon nanotubes, rare-earth-element-doped nanoparticles, small-molecule-containing NPs, and conjugated polymer NPs have been investigated as NIR-II contrast agents for imaging biological systems.^{65–68} Although some impressive advances in nanoparticle-based NIR-II imaging probes have been achieved, reports on the NIR-II emission of CDs as FL imaging probes remain few. Hao and coworkers first reported a new type of CDs with NIR-II emission by using environment-friendly watermelon as a precursor *via* a one-step hydrothermal reaction.⁶⁹ The obtained CDs display an emission peak of 900–1200 nm with a QY of 0.4% under 808 nm laser irradiation. Then, they performed *in vivo* NIR-II FL imaging with CDs in the range of 1000–1400 nm. As shown in Fig. 3c, strong NIR-II FL signals are observed in the kidney within 1 min post-*i.v.* CD injection. The signal further enhances at 0.5 h and decreases after 1 h of injection. The FL signal in the kidney weakens after 6 h of injection, indicating the effective excretion of CDs from the body through renal clearance. In a supine-positioned mouse, FL signals in the bladder are intense, whereas signals in the liver are relatively weak. These findings further indicate the primary renal excretion of CDs. The renal clearance of CDs is also evaluated on the basis of emission intensity of CDs in urine. Experimental results reveal that 65% of CDs can be excreted through urine (Fig. 3d). These results show that the NIR-II emitted CDs with renal excretion are desirable bioimaging probes. Wang's group prepared N- and B-doped CDs with 3-aminophenylboronic acid monohydrate as a precursor.⁷⁰ N-B-CDs show a broad absorption band at 650–950 nm and a photoluminescence at 950–1100 nm with a peak at 1000 nm. They also possess good water solubility, photostability, biocompatibility, and low cytotoxicity. Given these fine optical and physicochemical properties, N-B-CDs are desirable agents for the NIR-II imaging of internal organs and blood vessels.

Two-photon FL imaging (TPFI), which commonly uses NIR femtosecond pulse lasers as light sources, has also received considerable attention in basic biological research and clinical diagnostics because of its large penetration depth, minimized tissue fluorescence imaging with advantages of autofluorescence background, and reduced photodamage in biotissues.^{71–74} To date, various CDs have been widely constructed as two-photon reagents. In 2007, Sun *et al.* first used surface-passivated CDs with a high two-photon absorption cross-section of 39 000 Göppert-Mayer (GM) units for multiphoton imaging.⁷⁵ Subsequently, Yang and coworkers reported TPFI by using CDs for cell labeling in 2012.⁷⁶ During this period, no studies explored the application of CDs as TPFI probes. In 2013, Gong and coworkers first reported biocompatible N-doped CDs with QY of 0.31 as effective TPFI probes for cellular and deep-tissue imaging.⁷⁷ N-Doped CDs are synthesized by using dimethylformamide as nitrogen source and solvent. The two-photon absorption cross-section of N-doped CDs reaches 48 000 GM, thereby achieving the highest value ever reported for carbon-based nanomaterials and surpassing that of organic dyes. A large penetration depth of 1800 μm can be achieved by N-doped CDs in a tissue phantom, significantly

Fig. 4 (a) Schematic of the setup applied for TPFI of N-GQDs in a tissue phantom with varying thicknesses. (b) Penetration depth of N-GQDs for TPFI and OPFI in the setup of (a). extending the fundamental TPFI depth limit (Fig. 4a and b). Therefore, N-doped CDs are attractive TPFI probe candidates in biological applications. In 2016, NIR emissive CDs with emission peak at 683 nm and a high QY of 16.8% were first reported by Lin's group.⁷⁸ Further investigations have revealed that the emission of NIR CDs is derived predominantly from a surface molecular state mechanism. As shown in Fig. 4c, NIR CDs emit deep-red light with excitation-independent properties. Similar to one-photon fluorescence, excitation-independent emission with $\lambda_{\text{max}} \approx 683$ nm is observed under a femtosecond pulse laser with wavelengths varying from 800 nm to 1000 nm, with ~ 850 nm as the optimum (Fig. 4d). As seen in Fig. 4e, deep-red light images from MCF-7 cells can be achieved under one- and two-photon modes *via* confocal imaging, suggesting the capabilities of NIR CDs as one-photon FL imaging (OPFI) and TPFI agents. Zhang and Wang reported two-photon excited S, Se-codoped CDs with peaks at 731 and 820 nm for fluorescence imaging.⁷⁹ Yang and coworkers prepared NIR-emissive polymer carbon nanodots (710 nm, QY 26.28%) for TPFI.²⁵ They were the first to report polymer carbon nanodots with such long-wavelength emission and two-photon fluorescence. Further studies have revealed that a specific D- π -A structure with a large conjugated rigid sp^2 domain may be responsible for a large two-photon absorption cross-section. Qu and Rogach *et al.* described efficient NIR emissive CDs ($\lambda_{\text{abs}} \approx 715\text{--}724$ nm, $\lambda_{\text{em}} \approx 750\text{--}760$ nm) through the surface engineering of molecules or polymers rich in sulfoxide/carbonyl groups.⁵⁶ They were also the first to present two-photon- and three-photon-induced red emission simultaneously observed in CDs. All these works have demonstrated the attractive optical features and promising applications of CDs in the NIR region and

provided a rational design method for exploiting the two-photon-induced fluorescence of CDs as deep-tissue imaging probes.

2.2 Carbon dots as photoacoustic imaging probes

Each imaging modality has unique advantages and intrinsic limitations. Although FL imaging technique shows high sensitivity, spatial resolution is unsatisfactory because of the limited penetration depth.^{80,81} PA imaging, which combines the advantages of ultrasound imaging and optical imaging, is a new emerging bioimaging technique with rich contrast, high resolution, and deep-tissue penetration.^{82,83} This hybrid technique relies on the photoacoustic effect, which refers to the generation of acoustic waves as light converted to heat following optical absorption (Fig. 5a).⁸⁴ Given unusual optical properties, various extrinsic endogenous contrast agents, *e.g.*, oxyhemoglobin and deoxyhemoglobin, and exogenous contrast agents, *e.g.*, organic dyes and nanoparticles, have been employed as PA imaging probes to visualize hierarchical biostructures, including organelles, cells, and organs, especially in cancer diagnosis.^{85–88} Among these agents, CDs have been widely studied as PA imaging probes. In 2015, our group developed a new CD by using polythiophene phenylpropionic acid (PPA), a conjugated polymer synthesized as a precursor in our laboratory.⁸⁹ The as-prepared CDs show a broad absorption band in the visible region to the NIR region (from 400 nm to 800 nm with a peak at 470 nm) with red emission peaked at 640 nm with excitation-dependency. The PA spectrum of CDs in an agarose gel phantom reveals obvious

signals in the range of 700–950 nm with a peak at approximately 710 nm (Fig. 5b), and PA signals increase with CD concentration (Fig. 5c). Significantly, red emissive CDs can simultaneously act as FL/PA imaging agents. FL imaging offers high sensitivity and PA imaging provides high-spatial resolution for accurate tumor detection (Fig. 5d and e). We further prepared another CD with *Hypocrella bambusae* (HB), a parasitic fungus in bamboo, as a raw carbon source *via* the solvothermal method.⁹¹ The HBCDs have good water solubility, broad absorption, red emission, and excellent biocompatibility. They can be used as bimodal FL/PA imaging agents to guide tumor therapy. Similarly, a clear tumor microstructure with high spatial resolution and deep penetration is obtained using HBCDs. In comparison with polythiophene-derived CDs, HBCDs are prepared using natural biomass as raw carbon sources, which can effectively resolve problems on complex synthetic routes and high cost. However, these described CDs exhibit weak absorption in the red to NIR region. Qu and his coworkers prepared supra-CDs by using citric acid and urea as carbon sources.⁹² The obtained aqueous supra-CD solution exhibits a broad absorption band from 500 nm to the NIR region with maximum absorption at 670 nm. This result indicates that supra-CDs can be used as an efficient NIR light-responsive contrast agent for PA imaging at relatively high irradiating power densities (1 W cm^{-2}). To enhance the PA signals of CDs in tumors, Wu *et al.* modified the surface of porphyrin-implanted CDs with cetuximab, which can recognize and target specific cancer cells overexpressing of epidermal growth factor receptor so that they can actively target tumors.⁹³ The as-prepared CDs can enhance PA amplitude signals and maintain a strong signal for 12 h in the bodies of mice. Thus, these CDs can provide a long-term and accurate guidance for the efficient PDT of breast cancer. Kim and coworkers synthesized N-doped CDs with citric acid as a carbon source and nitric acid as a N source.⁹⁰ N-CDs have a strong absorption in the NIR region and are responsible for apparent PA signals. Whole-body PA imaging is performed after N-CDs are subcutaneously injected to determine the bodily distribution and clearance behavior. As shown in Fig. 5f, the PA signal in the bladder increases and generally enhances up to 450 min, demonstrating the efficient removal of N-CDs from the body through renal clearance.

2.3 Carbon dots as magnetic resonance imaging probes

As a non-invasive imaging mode, MR imaging has been widely used to provide anatomical, physiological, and even molecular information of the body in clinical settings. Given an ability to provide high-contrast images of soft tissues and appropriate penetration depth to visualize the entire human body, MR imaging is often used to verify whether tumors should be surgically removed.^{94–96} To date, two methods have been mainly applied to adopt CDs for MR imaging applications: (1) incorporation of metal ions in CDs and (2) use of metal-free CDs.^{97,98} For example, Chen *et al.* prepared Gd@GCNs *via* a solvothermal process as shown in Fig. 6a.⁹⁴ The high resolution transmission electron microscopes (HRTEM) images (Fig. 6b) show that Gd@GCNs are relatively monodispersed and highly crystalline. Element mapping analysis

(c) T_1 and T_2 MR images of Gd@GCNs at different Gd concentrations. (d) *In vivo* MR images of the tumor after i.v. injection of Gd@GCNs. Reproduced with permission from ref. 94. Copyright 2018, Wiley-VCH.

also demonstrates that Gd@GCNs have a high Gd content of 37.6 wt%, which provides excellent T_1 and T_2 MR imaging effects (Fig. 6c). After i.v. injection of Gd@GCNs into SCC-7 tumor-bearing mouse, the signals on the T_1 -weighted images of tumors significantly enhance upon scanning times on a 7 T system (Fig. 6d). Fernandez's group also developed new multimodal contrast agents based on CDs.⁹⁹ They used citric acid and Gd^{3+} and Yb^{3+} inorganic salts (doping ions) as a precursor to prepare CDs codoped with N, Gd, and Yb, producing a single multimodal contrast agent through a facile and low-cost one-pot microwave-assisted hydrothermal method. The as-prepared CDs exhibit intense and stable FL emission with high QYs ($66\% \pm 7\%$). Moreover, Gd^{3+} doping can provide CDs with MR contrast capability. The measured r_1 and r_2 are 5.02 and $14.45 \text{ mm}^{-1} \text{ s}^{-1}$, respectively, providing r_2/r_1 of 2.88, which indicates that these co-doped CDs are excellent species to be efficiently used as positive T_1 MR imaging contrast agents. Notably, the longitudinal relaxivity (r_1) of the codoped CDs is greater than that of Magnevist, a commercially available Gd-DTPA contrast agent. Interestingly, the additional incorporation of Yb^{3+} as a doping ion in CDs can enable them to be CT contrast agents because of the high degree of X-ray absorption of Yb.¹⁰⁰ The slope of the linear relationship between CT values and Yb contents (14.4 HU mm^{-1}) is higher than that of clinically used iobitridol (*i.e.*, 5.0 HU mm^{-1}). This work provides a simple approach for preparing CDs with unique contrast properties for multimodal bioimaging and encourages further exploration for their application in nanobiomedicine.

However, safety concerns limit at the application of Gd or Yb complexes in renal-compromised patients. Nontoxic Mn or Fe is induced in CDs as a novel contrast agent for T_1 -weighted MR imaging to overcome this shortcoming. Our group also reported Mn-CDs with a simultaneous bimodal FL/MR imaging characteristic through solvothermal treatment of the precursor

Mn(II) phthalocyanine at $180 \text{ }^\circ\text{C}$.¹⁰¹ The MR signal intensities of Mn-CDs increase with concentration. *In vivo* T_1 -weighted MR imaging results confirm the high retention rate of Mn-CDs in tumors. Quantitatively, at 6 h postinjection of Mn-CDs, the MR signal intensity at the tumor site increases by $\sim 320\%$. By contrast, after the i.v. injection of CDs without doped Mn(II), the MR imaging signal remains nearly unchanged. Jayasree *et al.* prepared zerovalent iron (ZVI) doped-CDs with a size of approximately 10 nm.¹⁰² The obtained ZVI-doped-CDs exhibit a paramagnetic property with r_1 of $4.93 \text{ mM}^{-1} \text{ s}^{-1}$, indicating their capability of being used as a positive MR imaging contrast agent. They further modified ZVI-doped CDs with the liver-targeting polysaccharide pullulan and then investigated their capability of being used as dual MR and optical imaging contrast agents for specifically targeting the liver *in vivo*. Another novel, safe, and efficient T_1 contrast agent based on $Fe^{3+}@F,N$ codoped-CDs was developed by Bi's group.¹⁰³ $Fe^{3+}@F,N$ codoped-CDs exhibit r_1 of $5.79 \text{ mM}^{-1} \text{ s}^{-1}$, which is higher than those of $Fe^{3+}@CD$ ($4.23 \text{ mM}^{-1} \text{ s}^{-1}$) and free Fe^{3+} ($1.59 \text{ mM}^{-1} \text{ s}^{-1}$). Therefore, the codoped CD can be considered new T_1 -weighted MR imaging contrast agents for clinical use because of their biosecurity, high r_1 , strong emission, and cheap synthesis. Novel metal-free CDs, as MR contrast agents, have also been found to act as alternative safe contrast agents for T_1 -weight MR imaging. Zhang and coworkers developed a metal-free boron-doped CQD by using 4-vinylphenylboronic acid and boric acid as precursors (Fig. 7a).¹⁰⁴ As shown in Fig. 7b, the obtained B-CQDs show an extra-high r_1 of $18.277 \text{ mM}^{-1} \text{ s}^{-1}$, which is greater than that of Gd-CDs ($11.35 \text{ mM}^{-1} \text{ s}^{-1}$).¹⁰⁰ After subcutaneous injection, B-CQDs with a small diameter enhance the contrast in T_1 -weighted imaging *in vivo* (Fig. 7c). They are promising materials based on CDs for MR imaging in the biological field.

CD chemical exchange saturation transfer (CEST) MR imaging contrast agents have also been reported. Liu and coworkers prepared novel arginine-modified CDs (AC-dots) with abundant exchangeable protons of hydroxyl, amine, and amide anchored

on the surface for CEST MR imaging without paramagnetic doping (Fig. 8a).¹⁰⁵ They encapsulated AC-dots with liposomes (Lipo-AC-dots) to increase the cellular uptake of AC-dots (Fig. 8b). As reported, the CEST CDs can be applied as a new type of metal-free MR imaging agents to detect human glioma cells *in vitro* (Fig. 8c) and *in vivo* (Fig. 8d) after intracranial implantation. This study can be further extended to design and synthesize CDs with new structures and functions of new CEST MR imaging contrast agents.

3. Carbon dots for photo-induced cancer treatment

In early stages, CDs were only used as fluorescent probes to construct FL-imaging-mediated drug delivery by combining them with anticancer drugs for tumor treatment because of their unique luminescent properties.^{106–108} For example, Chen *et al.* successfully loaded Chlorin e6 (Ce6), a traditional PS, on the surface of CDs and demonstrated that CD-Ce6 is a good candidate with an excellent tumor-homing and PDT ability mediated by NIR FL imaging.¹⁰⁹ Zheng and coworkers developed a Förster resonance energy transfer (FRET)-based CD-DOX delivery system that can utilize changes in FRET signals generated by the separation distance between CDs and DOX to monitor real-time anticancer drug release under acidic conditions.¹¹⁰ To integrate the optical properties of CDs and therapeutic performance of anticancer agents, Sun *et al.* successfully conjugated oxidized oxaliplatin on the surface of CDs.¹¹¹ *In vitro* and *in vivo* results indicate that the fluorescence of CDs can effectively monitor the track or distribution of oxidized oxaliplatin and thus optimize the injection time and dosage of the medicine. Although CDs as drug carriers have achieved good cancer diagnosis and treatment results, some

serious problems, such as complex synthetic routes and drug leakage, remain. In addition to ensuring excellent optical properties of CDs, providing themselves with intrinsic therapeutic properties has been widely explored in the biological field. In this section, we review recent reports on CDs with inherent PDT, PTT, and multi-modal or stimulus-responsive phototherapeutic properties to clarify their important role in cancer therapy.

3.1 Carbon dots with intrinsic photodynamic properties

As a non-invasive treatment triggered by light, PDT has gradually evolved as the fourth-line anticancer method following surgery, chemotherapy, and radiotherapy.^{112–114} In PDT, PSs transfer energy to surrounding oxygen under the excitation of a specific wavelength light to produce ROSSs, including 1O_2 , $O_2^{\bullet-}$, H_2O_2 , and $\bullet OH$, which can strongly kill or cause cancer cell apoptosis.^{115–117} In 2011, Christensen *et al.* demonstrated that CDs with a surface passivated by polyethylene glycol can produce ROS upon irradiation with blue light.¹¹⁸ In 2012, Markovic and coworkers were the first to prove the photodynamic cytotoxicity of CDs toward cancer cells.¹¹⁹ Since then, CDs with intrinsic PDT properties have attracted considerable attention. In 2014, our group developed a new PDT agent based on CDs with NIR emission by using PT2 as a carbon source.³⁹ The 1O_2 yield of CDs is as high as 1.3. The super high 1O_2 yield of CDs is attributed to two pathways (Fig. 9a): one is the energy transfer from the path from the T_1 state to the S_0 state *via* traditional PSs (the 1O_2 yield is always less than 1.0), and the other occurs from the S_1 state to the T_1 intersystem crossing transition. Therefore, the superposition of these two approaches can ensure that the 1O_2 yield of CDs is greater than 1.0. These excellent 1O_2 properties of CDs enable them to achieve an effective PDT of cancer *in vitro* (Fig. 9b) and *in vivo* (Fig. 9c). However, this CD PS has low therapeutic efficacies for deep tumor tissues due to its absorption in the visible

Fig. 9 (a) Schematic of the 1O_2 generation by classical PSs (left) and GQDs (right). (b) *In vitro* PDT effects of HeLa cells treated with GQDs under light irradiation. light region. In addition, the positive charges of CD surface produce undesirable effects *in vivo* via i.v. administration, consequently resulting in mouse death.¹²⁰ To address these limitations, our group prepared an NIR-light-responsive CD nanosphere (CDNS) *via* self-assembly by using individual CDs as building units.¹²¹ In comparison with individual CDs, the assembled CDNSs exhibit a red-shifted absorption of ~ 50 nm, a broader absorption band from 400 nm to 800 nm, and a stronger NIR emission peak at 730 nm. The positively charged surface of CD changes into the negatively charged surface of CDNSs. CDNSs can efficiently generate $^1\text{O}_2$ with a high QY of 45.4% under NIR laser irradiation. Thus, NIR-light-responsive FL-imaging-guided PDT can be simultaneously performed after i.v. administration *in vivo*. To overcome difficulties in synthesizing CDs with an intrinsic PDT activity, Zhu *et al.* imbedded various metals [$M = \text{Zn(II)}$ or Mn(II)] or metal-free tetra-(*meso*-aminophenyl)porphyrin into CDs during carbonization.¹²² They experimentally demonstrated that the as-prepared CDs have excellent characteristics, such as NIR emission, good water solubility, and favorable biocompatibility, which are observed in porphyrins and pristine CDs. *In vitro* results show that these porphyrin-embedded CDs exhibit a remarkable PDT efficacy against tumor cells upon irradiation. Tan's group reported fluorescent CDs with the four basic nucleotides of DNA as precursors.¹²³ They compared four kinds of CDs and found that adenosine triphosphate-CDs show the highest fluorescence QY of 13.9%, adenosine diphosphate-CDs exhibit the best photostability that maintains 97.6% fluorescence intensity after 30 min of UV illumination, and deoxyadenosine monophosphate (dAMP)-CDs have the highest $^1\text{O}_2$ QY of 1.20. dAMP-CDs have a good cell absorption ability indicated by their fluorescence and efficacy of killing cancer cells *in vitro* under white light treatment.

CDs with PDT functions have been rarely reported because of a complex preparation route and difficulties in choosing carbon sources. A simple and straightforward strategy to prepare PDT CDs has been an emerging focus. For example, Xie *et al.* prepared a porphyrin-containing CD (triphenylporphyrin (TPP) CD) and demonstrated its effective photodynamic activity in tumor treatment.¹²⁴ As shown in Fig. 10a, TPP CDs are synthesized from monohydroxyphenyl TPP and chitosan. After hydrothermal treatment at 180 °C for 20 h, the generated TPP CDs retain the aromatic structure of TPP. As a result, TPP CDs gain photodynamic properties. In addition, diketopyrrolopyrrole-derived CDs (DPP CDs) prepared through hydrothermal method (Fig. 10b) maintain the ability of DPP to generate $^1\text{O}_2$.¹²⁵ Moreover, green carbon sources (*e.g.*, natural biomass) are good candidates for the preparation of CDs with intrinsic PDT properties. Our group developed a kind of CDs with the natural biomass of pheophytin as a raw carbon source *via* a microwave method (Fig. 10c).¹²⁶ The obtained hydrophobic CDs exhibit an NIR emission peak at 680 nm and a high $^1\text{O}_2$ yield with a QY of 0.62. After the assembly with DSPE-mPEG2000, CD assemblies are used not only as an efficient FL imaging agent but also as a smart PDT agent *in vitro* and *in vivo*. Mobin and coworkers prepared nitrogen-doped CDs (N@VRCDs) by using ethylenediamine as a nitrogen source and *Vigna radiata* sprouts as a sole carbon

Fig. 10 (a) Synthetic route of TPP CDs. Reproduced with permission from ref. 124. Copyright 2017, Wiley-VCH. (b) Schematic of DPP CDs for the PDT of cancer. Reproduced with permission from ref. 125. precursor.¹²⁷ N@VRCDs also exhibits remarkable light-induced cytotoxicity to cancer cells at an $^1\text{O}_2$ QY of 0.41. Thus, they may be used as a potential theranostic agent.

As a consequence of the common operation of the type II pathway, most existing PDT systems exhibit high O_2 dependence and involve a dramatic consumption of O_2 . Unfortunately, aggressive cancer cell proliferation and insufficient blood supply lead to low O_2 concentrations in the tumor interior, thereby causing a significantly reduced PDT efficacy.¹²⁸ In contrast to type II route, the type I PDT takes place by either electron or hydrogen atom abstraction *via* excited PS from substrates. This process produces respective radical ions or radicals, and type I PDT has been shown to be effective even under low O_2 conditions. Therefore, the preparation of CDs for type I PDT may be a new approach to Wang and coworkers prepared reduced graphene oxide quantum dots (rGOQDs) *via* a simple sonication-assisted thermal exfoliation of graphite powders followed by the reduction of hydrazine hydrate at 90 °C (Fig. 11a).¹²⁹ The obtained rGOQDs under white light can effectively produce a variety of ROS, including $^1\text{O}_2$, H_2O_2 , and $\text{O}_2^{\bullet-}$. Furthermore, the yield of ROS from rGOQDs is about two times that from GOQDs because the reduction of GOQDs with hydrazine hydrate decreases the band gap and valence band of GOQDs and results in the production of more electron hole pairs. Shen *et al.* reported hyaluronic acid-derived CDs (HA-CDs) that can produce $\text{O}_2^{\bullet-}$ instead of $^1\text{O}_2$ for PDT (Fig. 11b).¹³⁰ Given the large amount of HA remaining on the surface, the as-prepared HA-CDs can actively target CD44-receptor-overexpressing cancer cells. They demonstrated the effective generation of $\text{O}_2^{\bullet-}$ from ESR measurements (Fig. 11c). Meanwhile, they mainly attributed

3.2 Carbon dots with intrinsic photothermal properties

As another mode of phototherapy for cancer, PTT induces the death of cancer cells through photothermal agents harvest light energy and then convert to heat for increasing the environment temperature.^{131–134} In 2015, our group developed a CD PTT agent by using PPA as a precursor (Fig. 12a).⁸⁹ CDs exhibit an excellent photothermal effect with a high conversion efficiency of 38.5% (Fig. 12b); thus, they can be simultaneously used for FL/PA-imaging (as described in Section 2.2)-guided PTT of

Fig. 12 (a) Synthetic route of PPA-derived CDs. (b) Temperature increase in CDs with varying concentrations as a function of irradiation time (671 nm laser, 2 W cm⁻²). (c) Relative viability of HeLa cells incubated with CDs before and after irradiation by 671 nm laser. (d) *In vivo* thermal imaging of tumor sites irradiated by 671 nm laser (2 W cm⁻²) at 6 h after i.v. injection of CDs. (e) Temperature change curves of tumor sites as a function of irradiation time. (f) Relative growth curves of tumor after different treatments. Reproduced with permission from ref. 89. Copyright 2015, Wiley-VCH.

cancer in living mice. As shown in Fig. 12c, under 671 nm laser irradiation (2.0 W cm⁻²), the viabilities of HeLa cells decrease significantly as the concentration of CDs increases, and approximately 100% mortality rate is achieved at 200 µg mL⁻¹ CDs. When treated with CDs following with NIR laser illumination, the temperature of tumor is higher than 60 °C (Fig. 12d and e). By comparison, the maximum temperature of tumor in the laser-only group is approximately 39.5 °C, indicating the key role of CDs in heat generation. Therefore, CDs significantly suppress tumor growth under NIR laser irradiation as shown in Fig. 12f. Since then, the use of CDs as PTT agents for cancer treatment has provided a basis for further developing these materials. For example, Lin *et al.* reported a red emissive CD (R-CD) PTT agent with citric acid as a carbon source and formamide as a solvent, respectively.⁴⁴ They pointed out that formamide plays an important role in the preparation of R-CDs because it or its decomposed products participate in R-CD formation. R-CDs exhibit a high photothermal conversion efficiency of 43.9% under the irradiation of 671 nm laser, ensuring their excellent photothermal effects against cancer cells *in vitro*. Qu and coworkers prepared N- and S-codoped NIR-emitting CDs with citric acid as a carbon source, urea as a nitrogen-doping source, and dimethylsulfoxide as a solvent and sulfur-doping source.¹³⁵ The as-prepared CDs show a broad absorption band with maximum absorption at 600 nm, a strong NIR emission peak at 720 nm, and a high photothermal conversion efficiency (59.19%, 655 nm laser). This work demonstrates that the developed CDs are highly efficient in the PTT of cancer in mouse models and can be simultaneously visualized *via* bimodal FL/PA imaging. They also used previously reported humidity-induced CD assemblies (supra-CDs) as contrast agents for PA imaging and photothermal agents for PTT.⁹² After i.v. injection, supra-CDs can accumulate in tumor tissues as revealed by *in vivo* PA imaging and effectively inhibit tumor growth under 655 nm laser irradiation.

The abovementioned CDs are mostly activated by different red lights, but their shallow tissue penetration leads to poor PTT effects. Studies have also explored NIR CDs that can absorb NIR light to produce heat for the treatment of deep tumors (Table 2). In Section 2.2, N-CDs synthesized by Kim *et al.* using citric acid and nitric acid can be applied not only as a PA imaging contrast agent to assess their renal clearance after hypodermic injection but also as an NIR PTT agent to the photothermal ablation of tumors with N-CDs injected near a tumor region followed by irradiation with 808 nm laser.⁹⁰ The mentioned NIR-II CDs with watermelon as a precursor also exhibit a high photothermal efficiency of 30.6% under 808 nm laser irradiation and show strong potential for the thermal ablation of cancer.⁶⁹ In addition, Pan and coworkers reported a nitrogen and oxygen codoped CD (N-O-CD) from 1,3,6-trinitropyrene and polyethylenimine as shown in Fig. 13a.¹³⁶ Black N-O-CDs exhibit a strong optical absorbance in the NIR region, ensuring their high photothermal conversion efficiency of 38.3% under the irradiation of 808 nm laser. *In vivo* PTT experiments demonstrate that an intensive penetration depth of 808 nm laser and high-efficiency

Table 2 NIR light-induced CDs prepared from different carbon sources and their photothermal properties

Carbon source	Method	Doping	Excitation wavelength (nm)	Photothermal conversion efficiency (%)	Ref.
Citric acid, nitric acid	Solvothermal	N	808	—	90
Watermelon juice	Hydrothermal	N	808	30.6	69
1,3,6-Trinitropyrene, polyethylenimine	Hydrothermal	N, O	808	38.3	136
Cyanine dye, poly(ethylene glycol)	Solvothermal	O	808	38.7	137
F127, phenol, formaldehyde	Solid-state transformation	N, O	808	42.3	138
Nigrosin, manganese acetate	Hydrothermal	Mn, N	808	7.6	139
Polythiophene, diphenyl diselenide	Hydrothermal	S, Se	880	—	79

heat generation achieve an excellent therapeutic efficacy with 100% tumor destruction. Xie *et al.* prepared an NIR CD PTT agent (CyCD) from a hydrophobic cyanine dye CyOH and poly(ethylene glycol) (Fig. 13b).¹³⁷ The as-prepared CyCDs possess NIR emission from 600 nm to 900 nm and show a high photothermal conversion efficiency of 38.7%; thus, the as-prepared CyCDs act as ideal nanotheranostic agents for NIR FL imaging and PTT *in vitro* and *in vivo*. Huang's group also synthesized highly crystalline CDs (HCCDs) with tunable full-color emissions, a strong PA imaging effect, and a high photothermal ability.¹³⁸ As shown in Fig. 13c, HCCDs are prepared *via in situ* solid-state transformation with freeze-dried mesoporous phenolic resin generated from F127, phenol, and formaldehyde at 350 °C with NaCl/LiCl/KNO₃ as catalyst. High temperature prompts the high crystallization of carbon cores, which are responsible for strong photothermal/photoacoustic effects. Therefore, HCCDs have been successfully used for the sensitive FL imaging and deep space-resolved PA

imaging-guided PTT of glioma. In addition to nonmetallic elements, some metal elements (*e.g.*, Zn and Gd) are doped in CDs to improve their photophysical and photochemical properties. Mn is one of the essential trace elements and important to human health. It has a multivalent state, which is conducive to conducting a valence state process and improving the optical properties. Cai *et al.* doped Mn into nigrosin-originated CDs (Mn-CDs).¹³⁹ In comparison with nigrosin-originated CDs, the as-prepared Mn-CDs possess wide absorbance, strong fluorescence emission, and excellent photothermal effects under NIR light. After the *in vivo* injection of Mn-CDs, *in vivo* FL/PA imaging results reveal that Mn-CDs can passively target tumor tissues *via* the enhanced permeation and retention (EPR) effect. When specimens are exposed to 808 nm laser light, the temperature of tumor tissues with Mn-CD accumulation can increase rapidly to achieve the goal of PTT. In addition to fluorescence emission, the TPE mechanism is applicable to PTT to overcome the shallow tissue penetration of exciting light. Lan *et al.*

prepared a S- and Se-codoped CD with intrinsic TPE-induced fluorescence and photothermal properties by using a polythiophene derivative and diphenyl diselenide.⁷⁹ As shown in Fig. 13d, S-Se-CD can be simultaneously used for the two-photon-excited FL-imaging-guided NIR PTT of cancer. Thus, they can be used as a basis for promoting the biomedical application of CDs as phototheranostic agents.

3.3 Smart carbon dots for multimodal cancer therapy

Although PDT and PTT have some anticancer treatment advantages, such as low toxic side effects, noninvasive or minimally invasive treatment, and no drug resistance, each treatment suffers from inherent limitations. For example, PDT is generally oxygen dependent. However, a tumor microenvironment (TME) is usually hypoxic,¹⁴⁰ which can severely hinder the therapeutic efficacy of PDT.^{141–143} In addition, PTT usually requires high laser power, and the generated hyperthermia inevitably damages normal tissues around tumors. Considerable effort has been devoted to developing multimodal treatment that integrates the advantages of each technique to meet high therapeutic requirements and overcome the inherent limitations of each phototherapeutic technique.^{144–146} Some well-designed nanoplatform-based CDs with intrinsic theranostic properties are available for multimodal cancer treatment. In 2016, our group designed a multifunctional nanoplatform of gold nanorod@silica-CDs (GNR@SiO₂-CDs) as phototheranostic agents (Fig. 14a).¹⁴⁷ In GNR@SiO₂-CDs, GNRs act as PA imaging and PTT agents with 808 nm laser, and CDs serve as FL imaging and PDT agents with 635 nm laser. The high sensitivity and good spatial resolution of the bimodal FL/PA

images of tumor demonstrate that GNR@SiO₂-CDs can gradually accumulate in tumors through the EPR effect after i.v. administration. Thus, this technique provides valuable information for the follow-up light-induced treatment of tumors. Furthermore, the damage induced by the synergy of PDT and PTT to cancer cells is more severe than that caused by either PDT or PTT alone. However, synergistic PTT/PDT utilizes two light sources to separately induce PDT and PTT, and problems on high laser power for PTT remain unsolved. Lin and coworkers loaded PS Ce6 onto amino-rich red emissive CDs (Ce6-RCDs) for synergistic PTT/PDT against cancer triggered by a single 671 nm laser (Fig. 14b).¹⁴⁸ Ce6-RCDs provide remarkably higher anticancer effect upon a low power density of laser (0.50 W cm⁻²) than the equivalent Ce6 or RCDs under the same irradiation conditions. Ce6-RCDs also show FL/PA bimodal imaging properties, which can be employed for guidance during phototherapy. Mauro *et al.* decorated an NIR CD PTT agent (CDs-PEG-BT@IT) with the targeting molecule biotin and the anticancer drug irinotecan to actively recognize cancer cells (Fig. 14c).¹⁴⁹ CD-PEG-BT@IT can be used as nanoheaters that can trigger local hyperthermia and massive chemotherapeutic drug release inside tumors. Thus, these substances can efficiently provoke tumor death.

In comparison with the abovementioned multimodal therapeutic nanoplatforms prepared using CDs with intrinsic single phototherapeutic properties as carriers, CDs with intrinsic multimodal therapeutic properties have the advantages of optimizing preparation steps, requiring low cost, and preventing drug leakage. In 2016, our group prepared NIR CDs with red-light emission from 640 nm to 680 nm by using polythiophene

Fig. 14 Mechanism of different CD-based nanoplatforms, including GNR@SiO₂-CDs, for multimodal anticancer therapy (a). Reproduced with permission from ref. 147. benzoic acid.¹⁵⁰ The CDs show dual PDT and PTT effects with an $^1\text{O}_2$ QY of 27% and a photothermal conversion efficiency of 36.2%. These excellent characters of CDs enable themselves to be used not only as red FL imaging probes but also as efficient PDT/PTT therapeutic agents. This study is the first to prove the utilization of CDs for the imaging-guided synergistic PDT/PTT *in vivo* by using a single laser. The HBCDs we prepared can also be used for synergistic PDT/PTT (Fig. 15a).⁹¹ HBCDs can effectively produce $^1\text{O}_2$ (0.38) and heat (27.6%) under 635 nm laser irradiation. As shown in Fig. 15b and c, when tumor tissues are illuminated with 635 nm laser (0.8 W cm^{-2}) after the *i.v.* injection of HBCDs, the temperature of tumor tissues rapidly increases to $56.4 \text{ }^\circ\text{C}$, which can sufficiently induce severe photothermal damage to cancer cells. Although the growth of the tumors of mice treated with single PDT (635 nm, 0.1 W cm^{-2}) is efficiently inhibited, it cannot be completely eliminated. By contrast, the growth of the tumors of mice treated with synergistic PDT/PTT is entirely inhibited without recurrence after 14 days of treatment (Fig. 15d and e). These results indicate that the treatment efficacy of the synergistic PDT/PTT modality is better than that of the single PDT. Furthermore, Jiang and coworkers used Cu(II) to engineer the structural characteristics of CDs and obtain NIR absorption for heat and ROS production.¹⁵¹ The as-prepared Cu-CDs can inhibit cancer growth *via* synergistic PTT/PDT. In addition, Cu-CDs can act as FL imaging and IR thermal imaging agents to visualize *in vitro* and *in vivo* treatments, respectively.

3.4 Tumor microenvironment stimulus-responsive CDs-based nanotheranostic

A TME is a complex integrated system composed of tumor cells, immune and inflammatory cells, tumor-related fibroblasts,

adjacent interstitial tissues, microvessels, and various cytokines and chemokines.^{152,153} In comparison with normal tissues, the TME has unique properties, such as overexpressed biomarkers, hypoxia, mild acidity, high glutathione (GSH) and H_2O_2 , can reduce the anti-cancer effectiveness of phototherapy.^{154–156} However, the TME has positive and negative effects. TME features can provide opportunities for preparing stimulus-responsive phototheranostic nanoplatforms to achieve efficient and less toxic tumor treatment.¹⁵⁷

In comparison with normal cells, several receptors, ligands, or extracellular protein motifs, such as integrin $\alpha_v\beta_3$, transferrin, transmembrane cell surface protein (CD44), and folic acid, are expressed in tumor cells or overexpressed in tumor cells. These substances can serve as specific targets for drug delivery into tumor cells. Fan *et al.* modified folate on the surface of CDs with NH_2 through amide bonds.¹⁵⁸ CDs exhibit a high specific targeting capacity for various cancer cells, including OCM-1, MUM2B, and OM431, and this capacity is attributed to the surface folic acid modification of CDs. After CDs are combined with autophagy inhibitors, they are released in the cytoplasm, and a good therapeutic efficiency is achieved in 26 types of tumor cells. *In vivo* experiments demonstrate that CDs can achieve good therapeutic effect and real-time imaging tumor therapy. The pre-described HA-CDs in Section 3.1 with HA as a carbon source not only act as novel PSs with an $\text{O}_2^{\bullet-}$ generation ability under appropriate light irradiation but also actively target various CD44 overexpressed tumor cell lines because of the specific targeting capability of HA to CD44.¹³⁰ Therefore, HA-CDs can selectively kill cancer cells with a high CD44 expression.

Intratumoral acidosis is another remarkable character of TME. The lactic acid accumulation caused by the Warburg effect and the slow waste product washout caused by a blocked lymphatic drainage are the main causes of the onset of intratumoral acidosis.^{159,160} Many pH-responsive charge-convertible CD-based drug delivery systems are developed on the basis of intratumoral acidosis. For example, Zhou's group designed low toxicity hybrid PEG-chitosan@CD nanogels, which combine the functional building blocks of fluorescent CDs, thermoresponsive nonlinear PEG, pH-responsive chitosan, and the chemotherapy agent DOX.¹⁶¹ Embedded CDs provide hybrid nanogels with a high photothermal ability and a TPF cellular imaging ability to light tumor cells under UV and NIR laser excitation. The protonation of NH_2 on chitosan in mild acid and the integrated nonlinear PEG endow hybrid nanogels with pH and thermal dual-responsive ability to enable the regulated release of the loaded anticancer drug DOX. With hybrid nanogels, the combined synergistic chemo-PTT treatment achieves a high therapeutic efficacy. They also reported another DOX-loaded chitosan-CD hybrid nanogel (CCHN).¹⁶² As shown in Fig. 16a, CCHNs exhibit efficient NIR photothermal conversion and intelligent drug release in response to NIR light and acidic pH. Zhao *et al.* prepared CD-Pt(IV)@PEG-(PAH/DMMA) nanoparticles.¹⁶³ The surface modified dimethylmaleic acid (DMMA) of CD-Pt(IV)@PEG-(PAH/DMMA) hydrolyzes under a mildly acidic condition ($\text{pH} < 6.8$) in a TME to release amino groups, thereby converting the negative surface charge to a positive charge; as such, drug nanocarriers easily

Fig. 16 Schematic of pH-responsive CD-based drug delivery systems, including (a) CCHNs. Reproduced with permission from ref. 162. Copyright 2017, American Chemical Society. (b) CD-Pt(IV)@PEG-(PAH/DMMA). Reproduced with permission from ref. 163. Copyright 2016, American Chemical Society. (c) CD-RGD-Pt(IV)-PEG. Reproduced with permission from ref. 164. Copyright 2016, American Chemical Society.

enter a cancer cell *via* electrostatic absorption with a negatively charged cell membrane (Fig. 16b). *In vitro* and *in vivo* studies demonstrate that drug nanocarriers with a charge conversion property under the stimulation of a TME show an enhanced antitumor efficiency. Zhao's group designed a pH/redox dual-responsive CD-RGD-Pt(IV)-PEG nanosystem with fluorescent CDs as imaging-guided drug carriers, cisplatin (Pt, IV) as a prodrug, and RGD peptide as an active targeting ligand.¹⁶⁴ Given the hydrolysis of benzoic-imine bond at extracellular tumor pH (6.5–6.8), the inner targeting RGD peptide of CD-RGD-Pt(IV)-PEG can be exposed to the effective uptake by cancer cells through the RGD integrin $\alpha\gamma\beta3$ interaction (Fig. 16c). *In vitro* results indicate that nanosystems exhibit an enhanced tumor extracellular microenvironment that triggers targeting and anticancer drug delivery. Additionally, Na and coworkers also prepared pH-sensitive CDs (pSCDs) from citric acid and 1-(3-aminopropyl)imidazole.¹⁶⁵ Given that imidazole on the surface of CDs can be protonated in an acidic TME (pH 6.5), the surface charge reversion of pSCDs can trigger the effective release of DOX.

Many stimulus-responsive CD-based nanoparticles responsive to highly expressed GSH in a TME have been constructed to facilitate drug release. Xue's group developed a dual-responsive nanoplatfrom by using a PEGylated shell and a fluorescent CD core with pre-modified DMMA containing disulfide-bond-bearing hyper-branched ploy(amido amine; HPAP) as shown in Fig. 17a.¹⁶⁶ DMMA hydrolysis in a TME causes the surface charge reversal of nanoplatforms to facilitate their accumulation in tumor tissues. Then, GSH can degrade the S–S bond on

the surface of CDs, causing the nanoplatform to shrink and promoting the loaded gene drug release in the tumor site. Wang *et al.* developed a tumor-targeted and multistimulus-responsive CD-based drug delivery system.¹⁶⁷ As shown in Fig. 17b, the oxidized mesoporous carbon nanoparticles (MCN-COOH) with an excellent photothermal property are utilized to encapsulate DOX through the S–S bond, and then their outer surfaces are capped with CDs (CDHA) with a tumor targeting ability. The CDHA can prevent premature drug release and enable the visualization of tumor sites and the anticancer drug to actively deliver to tumor cells. The drug release of MC-CDHA/DOX systems can be triggered by pH and GSH in a TME for a highly efficient chemophotothermal synergistic therapy under NIR light irradiation.

Hypoxia caused by the rapid proliferation of cancer cells strongly restricts the efficiency of type II PDT for tumors. CD-based photodynamic nanoplatforms with an O₂ generation ability have been developed to solve this problem. The H₂O₂ concentration at tumor sites is usually higher than that of normal tissues and can be catalyzed by MnO₂ to O₂ under acidosis in a TME for enhanced PDT.^{168,169} Recently, our group developed a CD/MnO₂-PEG nanohybrid with previous PT2-CD PS as a reducing agent and potassium permanganate as an oxidation agent.¹⁷⁰ The as-prepared nanohybrids exhibit an “off” state in a normal physiological environment. However, given the high sensitivity of MnO₂ to a TME, CD/MnO₂-PEG nanohybrids change from an “off” state to an “on” state with synchronously enhanced fluorescence, ¹O₂ generation, and MR imaging signal. The MnO₂–H₂O₂ redox reaction at a reduced

pH *in situ* generates massive O₂ in tumor sites, significantly promoting the PDT efficacy of CD/MnO₂-PEG nanohybrids. Subsequently, we developed versatile MnO-doped CDs as acidic H₂O₂-driven oxygenators to regulate tumor hypoxia for enhanced PDT (Fig. 18).¹⁰¹ Mn can catalyze overexpressed H₂O₂ in a tumor region to O₂ under a mildly acidic TME. Thus, tumor hypoxia is prevented, and PDT efficacy is synergistically enhanced. After the assembly with DSPE-PEG, Mn-CD assembly exhibits an excellent capability for NIR FL (745 nm) and T₁-weighted MR imaging to guide cancer treatment.

In contrast to oxygen-dependent of PDT II, the type I PDT pathway can occur in a hypoxic environment. This pathway involves electron transfer and radical (e.g. O₂^{•-} and •OH) formation from direct ionization events. In this case, unlike ¹O₂, which is derived from O₂, •OH is generated from H₂O, thereby minimizing oxygen dependence. In addition, PTT, which converts the energy of electrons to heat, is an important oxygen-independent phototherapy. Therefore, to enhance the therapeutic efficiency in hypoxic TMEs, Zhao's group designed a hybrid nanomedicine (CD-IR820-Aptamer) against hypoxic tumors.¹⁷¹ CD-IR820-Aptamer constructed with CDs, IR820 dye, and antivascular endothelial growth factor simultaneously exhibits type I PDT, type II PDT, and PTT under single 808 nm laser irradiation. Through these three phototherapeutic pathways, the proposed CD-IR820-Aptamer can achieve a high efficiency for the treatment of solid tumors. Additionally, based on natural photosynthesis, a new O₂ generation strategy *via* light-driven water splitting was introduced by Zhang *et al.* to relieve hypoxia in tumors.¹⁷² CDs doped with C₃N₄ are prepared with a strong absorption in the red region, and this property is beneficial to light-driven water splitting to produce O₂. After a C₃N₄-based nanocomposite (PCCN) is assembled with an amphipathic polymer, consisting of PS protoporphyrin IX and the tumor-targeting sequence RGD with PEG as a linker, PCCN can accumulate in tumor tissues through the active RGD targeting effect and split water to produce O₂ and ¹O₂ through the energy transmission of PSS under 630 nm laser irradiation. This strategy can effectively overcome the restriction of tumor hypoxia in PDT and inhibit solid tumor growth.

4. Concluding remarks and perspectives

Although in-depth studies on CD-based cancer nanotheranostics have gained rapid growth, exploiting smart CDs for cancer theranostics remains in infancy. Current nanotheranostics based on CDs are far from being applied to clinical uses. Therefore, remarkable efforts should be devoted to implementing such promising, low toxic, and good biocompatible carbon nanomaterials for basic biomedical studies and potential clinical uses in the future.

(1) Nanotheranostics should be exploited to develop simple and low-cost approaches for the mass production of CDs. Moreover, some issues, such as size control, batch-to-batch reproducibility, and purification, associated with realizing large-scale synthesis should be addressed.

(2) The new progress toward the development of CDs as multifunctional theranostics and the expansion of CD-related studies in biomedical fields are expected to be further achieved. To this end, the design of new precursors as carbon sources is urgently needed to prepare CDs with novel properties, such as strong emission in NIR-I (700–900 nm) or NIR-II (1100–1600 nm) with a high QY, multimodal bioimaging functions combining at least three of the imaging modalities of FL, PA, MRI, and CT; the new therapeutic modalities (sonodynamic, electrodynamic, and chemodynamic therapies or immunotherapy); and the capability of a TME (pH, hypoxia, H₂O₂, GSH, and enzyme) response to precisely target and enhance therapeutic effects. In addition to cancer therapy, research on the biomedical use of CDs in other diseases, such as cardiovascular, cerebrovascular, and respiratory system diseases, and wound-healing should be given considerable attention.

(3) Previous reports revealed that CD assemblies can enhance or regulate the properties of an individual CD. For instance, surface properties can be regulated from hydrophobicity to hydrophilicity, and light response in the NIR region can be improved. However, CD assemblies in nanotheranostics have yet to be fully investigated. For example, bioinspired and biomimetic carriers self-assembled by using nanoparticles, peptides, or copolymers as building blocks with features similar to those of biological systems, such as cells, pathogens, and organelles, have been considered more advantageous than conventional nanocarriers. This phenomenon is attributed to their specificity to carry a theranostic moiety to a targeted site, with a high potential to resolve any obstacles encountered in drug delivery.¹⁷³ Constructing bioinspired and biomimetic systems based on CDs *via* self-assembly is highly expected to resolve the obstacles of current CD nanotheranostic agents, such as short circulation time in blood, instability in a complex biological environment, and relatively low tumor-homing ability, and selectivity through the EPR effect.

(4) Yan and coworkers first reported that Fe₃O₄ NPs possess an intrinsic peroxidase-mimicking activity.¹⁷⁴ Since then, various nanomaterials, such as noble metal, oxides and carbonaceous nanostructures have been found to mimic the catalytic activity of different natural enzymes, including peroxidase, oxidase, and

catalase, and these nanomaterials are called nanozymes.^{175–178} Nanozymes have emerged as novel materials in nanobiomedicine. Studies have also suggested that nanozyme activities can be regulated by pH, H₂O₂, and GSH concentrations associated with TMEs and by external stimuli such as light, ultrasound, and heat. These collective properties of nanozymes enable them to maximize their diagnostic and therapeutic efficacies against tumors. CDs have been extensively studied as a peroxidase mimic for glucose detection.¹⁷⁹ However, multistimulus-responsive CDs with enzyme-like activities under physiological conditions for cancer theranostics have yet to be fully explored. Therefore, by combining the catalytic property of nanozyme systems with inherent nature, stimulus-responsive CD nanozymes may show potential for application in tumor nanotheranostics.

(5) Nanotheranostic development focuses on enhancing the efficacy, accuracy, and safety of the diagnosis and treatment of diseases. Therefore, the systematic and long-term studies are still needed to comprehensively explore their biological effects. Moreover, the biodistribution, circulation, translocation, metabolism, biodegradation, and long-term toxicology and secretion of CDs should be investigated in detail. These issues are the most important and challenging ones to translate current CD nanotheranostics from the bench to the bedside.

With the rapid development of CDs, we expect to see more practical uses in various fields not only in nanobiomedicine but also in environment, energy, agriculture, and national security. We believe that these aforementioned unsolved issues will continue to be hopeful and challenging field for further studies on CDs in terms of their basic studies and practical applications.
