# Nitrogen-doped molecular bowls as electron donors in photoinduced electron transfer reactions†

O. A. Stasyuk, <sup>ab</sup> A. J. Stasyuk, <sup>\*ab</sup> M. Solà <sup>\*a</sup> and A. A. Voityuk <sup>\*a</sup>

In recent years, the chemistry of curved  $\pi$ -conjugated molecules has experienced a sharp rise. The inclusion of a heteroatom in the carbon network significantly affects its semiconducting properties. In this work, we computationally study the photoinduced electron transfer in a series of  $C_{60}$  fullerene complexes with experimentally established nitrogen-doped molecular bowls. Our results demonstrate that introducing nitrogen into pentagonal rings of the bowl-shaped  $\pi$ -conjugated molecules and extending the  $\pi$ -conjugation can modulate their electron-transfer properties. Among the studied complexes, the **hub-NCor** $\supset C_{60}$  complex exhibits the most desirable combination of ultrafast charge separation and slow charge recombination, suggesting its potential use in photovoltaics.

## Introduction

Significant advances in the chemistry of curved  $\pi$ -conjugated molecules observed in the last few decades are the result of the progress in their synthesis.<sup>1,2</sup> The bowl-shaped compounds can be considered as structural parts of fullerenes and have attracted great attention<sup>3</sup> since the discovery of fullerenes<sup>4</sup> and nanotubes.<sup>5</sup> Historically, the first synthesized buckybowl with  $C_{5v}$  symmetry is corannulene (**Cor**). In 1966, Barth and Lawton reported on the multistage synthesis of dibenzo[*ghi,mno*]fluoranthene called corannulene.<sup>6</sup> Synthesis of sumanene (**Sum**) – a fullerene segment with  $C_{3v}$  symmetry – was carried out almost 40 years later by Sakurai and Hirao (Fig. 1).<sup>7</sup> In the early 1990s the development of the flash vacuum pyrolysis (FVP) method enabled materials scientists to evaluate these compounds.<sup>8–11</sup> This attention to bowl-shaped molecules arises not only from aesthetic pleasure of curved  $\pi$ -conjugated systems, but also from the fact that they contribute to fundamental research of aromaticity,<sup>12</sup> complexation with molecules and metal ions,<sup>13,14</sup> and strain energy.<sup>1,15,16</sup> It is known that the introduction of heteroatoms into a carbon  $\pi$ -conjugated system can dramatically affect its properties. Doping with nitrogen or boron atoms influences the semiconducting and luminescent properties of carbon materials due to changes in the band structure.<sup>17</sup> Also, the introduction of the heteroatom can create “special areas” due to their electronegative or electropositive characteristics.<sup>18</sup>

Moreover, nitrogen-embedded bowl-shaped molecules are used as model compounds for azafullerenes and nitrogen-doped nanotubes.<sup>19–21</sup>

There are two main types of heteroatom positions within bowl-shaped  $\pi$ -conjugated molecules: the *rim* position, in which a CH unit on the *rim* of a bowl is replaced by a heteroatom; and the *hub* position where a heteroatom is embedded in the central part and connects with three other atoms of the bowl. To date there have only been limited reports on the synthesis of such bowl-shaped compounds.

The first example of azabuckybowl–triazasumanene (**rim-3NSum**) – was reported by Higashibayashi and co-workers in 2012.<sup>20</sup> This is the only synthesized nitrogen-doped sumanene derivative.

The synthesis of azapentabenzocorannulene bearing a nitrogen atom in the core of corannulene (**hub-NCor**) was independently reported in 2015 by Ito and Nozaki, as well as by Hiroto and Shinokubo.<sup>22,23</sup> Azadibenzocorannulene with a nitrogen on the *rim* position (**rim-NCor**) was described by Scott two years later.<sup>24</sup> Very recently, Krzeszewski *et al.* reported a new nitrogen-containing bowl-shaped molecule (**PP-bowl**) consisting of a pyrrolo[3,2-*b*]pyrrole core substituted with six arene rings linked in a circle.<sup>25</sup> In contrast to the “classical” azabuckybowls, the presented bowl features two pentagonal rings located between two heptagons. This molecule could be used as an optoelectronic material due to the electron-rich nature of the pyrrolo[3,2-*b*]pyrrole fragment.<sup>26</sup> Hydrazinobuckybowl, a diaza analog of diindenochrysene (**Hyd-bowl**) with a particularly electron-rich nature, was reported by Higashibayashi and co-workers.<sup>27</sup> More recently, the structure of the nitrogen-embedded  $\pi$ -extended cyclazine (**Cyc-bowl**) was described in 2020 by Deng and Zhang.<sup>28</sup> In general, the introduction of nitrogen or other heteroatoms into bowl-shaped  $\pi$ -conjugated

molecules can be used as an effective strategy for modulating their physicochemical and electronic properties, which greatly expands the diversity and hence the use of such molecules in functional materials.

Here, we study electronic and photoinduced electron transfer (PET) properties of complexes based on C<sub>60</sub> with a number of previously synthesized nitrogen-doped molecular bowls of different topologies. Using the time-dependent density functional theory (TD-DFT), we investigate the efficiency of PET in a particular complex as a function of the structural features of the bowl. The results can be used in the design of N-doped carbon nanomaterials for photovoltaic applications.

## Computational methods

Geometry optimizations were performed by employing the DFT B3LYP<sup>29–31</sup> hybrid exchange–correlation functional with Ahlrichs' def2-SVP basis set.<sup>32,33</sup> The empirical dispersion D3 correction was included using the Becke–Johnson damping scheme.<sup>34,35</sup> Vertical excitation energies were calculated using the TDA formalism<sup>36</sup> with the range-separated CAM-B3LYP<sup>37,38</sup> functional and the def2-SVP basis set,<sup>32,33</sup> as implemented in the Gaussian 16 (rev. A03) program.<sup>39</sup> The same program was used for population analysis in terms of Mulliken,<sup>40</sup> Löwdin,<sup>41</sup> Hirshfeld,<sup>42</sup> iterative Hirshfeld<sup>43</sup> and CM5<sup>44</sup> charges. The formation energy of the complexes and their strain energy were computed with the B3LYP-D3(BJ)/def2-TZVP//B3LYP-D3(BJ)/def2-SVP scheme.<sup>45</sup> A Morokuma-like energy decomposition analysis (EDA)<sup>46–48</sup> was performed using the Amsterdam Density Functional (ADF) program at the B3LYP-D3(BJ)/TZP//B3LYP-D3(BJ)/def2-SVP.<sup>49</sup> The topological analysis of the electron density distribution was conducted using the “Quantum Theory of Atoms in Molecules” (QTAIM).<sup>50</sup> The AIMALL suite of programs<sup>51</sup> was applied to evaluate the bond critical points and associated bond descriptors. Molecular structures and frontier molecular orbitals were visualized using the Chemcraft 1.8 program.<sup>52</sup> Details on the analysis of excited states, calculation of solvent effects, electron transfer

rates, reorganization and interaction energies can be found in the ESI.†

## Results and discussion

### Ground state properties

The complementary concave–convex interaction between C<sub>60</sub> fullerene and pristine corannulene leads to the formation of an 1 : 1 complex. Although the complex was observed in the gas-phase and on a metal surface, its binding constant is not high. Yokoi *et al.* found that enhanced electron donating properties of the molecular bowl cause its closer association with electron-deficient C<sub>60</sub> both in solution and in the solid state. In particular, the binding constant between the *tert*-butyl derivative of **hub-NCor** and C<sub>60</sub> was measured to be  $3.8 \times 10^3$  L mol<sup>−1</sup>,<sup>23</sup> in contrast to the binding constant values of 280–475 L mol<sup>−1</sup> for substituted corannulenes.<sup>53</sup> The pronounced electron-rich character of the nitrogen-containing bowls and the electron-deficient nature of C<sub>60</sub> encouraged us to study the ground state (GS) properties of six van der Waals (vdW) complexes, **rim-NCor**⊃C<sub>60</sub>, **hub-NCor**⊃C<sub>60</sub>, **PP-bowl**⊃C<sub>60</sub>, **Hyd-bowl**⊃C<sub>60</sub>, **Cyc-bowl**⊃C<sub>60</sub>, and **rim-3NSum**⊃C<sub>60</sub> (Fig. 2), and their response to photoexcitation compared with the reference systems **Cor**⊃C<sub>60</sub> and **Sum**⊃C<sub>60</sub>. The selected bowls are synthesized derivatives of corannulene and sumanene with the nitrogen atom located at different positions. **Rim-NCor**⊃C<sub>60</sub> and **rim-3NSum**⊃C<sub>60</sub> contain pyridinic N atoms on the periphery, and **Cyc-bowl**⊃C<sub>60</sub> has a pyramidal amine N atom, while pyrrolic N atoms are contained in the central part of other bowls. Each type of N atom has a different effect on the electronic and photophysical properties of the bowls and their complexes.

First, we consider such effects in the bowls by analyzing the frontier molecular orbitals: the highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO). For the bowls with pyrrolic N in a *hub* position, we found a significant reduction in the HOMO–LUMO (HL) gap compared to the undoped bowls (Fig. 2). This can be explained

Fig. 2 Structures and HOMO/LUMO energies of the studied complexes.

by the formation of an aromatic sextet in pentagonal rings and by increasing  $\pi$ -electron delocalization in the bowls. The electron-donating character of the bowls can be described by the HOMO energy. The donating effects decrease by passing from the **PP-bowl** and **Hyd-bowl** with two N atoms to **hub-NCor** with one pyrrolic N atom. The lowest donating properties are found for **rim-NCor** and **rim-3NSum** bowls having pyridinic N.

It is important to note that the LUMO of complexes is localized on the C<sub>60</sub> fragment in each case, while the localization of the HOMO depends on the complex. Because the HOMO of **Cor** and **rim-3NSum** bowls is lower than that of C<sub>60</sub>, the HOMO of their complexes is localized on the fullerene. In other

complexes, the HOMO is localized on the bowls. The HL gap (Table S1, ESI<sup>†</sup>) also depends on the complex. For example, **hub-NCor**⊃C<sub>60</sub>, **PP-bowl**⊃C<sub>60</sub>, and **Hyd-bowl**⊃C<sub>60</sub> have a relatively small HL gap (3.6 to 3.8 eV), while it is about 1 eV larger (ranging from 4.4 to 4.8 eV) in **rim-NCor**⊃C<sub>60</sub>, **rim-3NSum**⊃C<sub>60</sub>, and **Cyc-bowl**⊃C<sub>60</sub>, as well as in the reference systems **Cor**⊃C<sub>60</sub> and **Sum**⊃C<sub>60</sub>. Thus, the HL gap is modulated by the nitrogen content and topology of the  $\pi$ -conjugated system. A larger number of pyrrolic N atoms and an increase in  $\pi$ -conjugation promote narrowing of the HL gap. The formation of the vdW complexes has a rather small effect on the orbital energies of their fragments. In particular, the LUMO energy of the C<sub>60</sub>

<sup>a</sup> The energy values are in kcal mol<sup>-1</sup>. The percentage contributions to the sum of attraction energies ( $\Delta E_{\text{elstat}} + \Delta E_{\text{oi}} + \Delta E_{\text{disp}}$ ) are given in parentheses. <sup>b</sup> Distances between the centers of C<sub>60</sub> and Bowl fragments are in Å.

fragment changes within only 0.25 eV compared to the isolated  $C_{60}$ , while the variation in the HOMO energy located on bowls does not exceed 0.17 eV. The population analysis does not reveal any significant charge transfer between the host (**Bowl**) and the guest ( $C_{60}$ ) in the GS (Table S2, ESI†). Because of that, only minor changes are found in the HOMO and LUMO energies of the molecules by the formation of their complexes.

The stability of the complexes was evaluated by calculating the interaction energy ( $\Delta E_{\text{int}}$ ) between the bowls and  $C_{60}$  (see Table 1). Using a Morokuma-type energy decomposition method, the interaction energy is divided into four components: Pauli repulsion ( $\Delta E_{\text{Pauli}}$ ), electrostatic ( $\Delta E_{\text{elstat}}$ ), orbital interactions ( $\Delta E_{\text{oi}}$ ), and dispersion correction ( $\Delta E_{\text{disp}}$ ) (see computational details in the ESI†).

As seen in Table 1, the least stable complex is **rim-3NSum**  $\supset C_{60}$  due to the larger bowl-depth and weaker dispersion interactions. More extended and less curved buckybowl (**hub-NCor** and **PP-bowl**) form the most stable complexes with  $C_{60}$ . In these complexes, there are shorter distances between the centers of  $C_{60}$  and **Bowl** fragments, more stabilizing dispersion interactions and more destabilizing Pauli repulsions.  $\Delta E_{\text{Pauli}}$  varies from 30.4 kcal mol<sup>-1</sup> for **rim-3NSum**  $\supset C_{60}$  to 49.1 kcal mol<sup>-1</sup> for **PP-bowl**  $\supset C_{60}$ . Among the intermolecular attractions (electrostatic, orbital, and dispersion interactions), the last term dominates contributing from 52 to 57%. It is followed by the electrostatic (about 30%) and orbital (14 to 16%) interactions. We note that the HL gap increases with  $\Delta E_{\text{oi}}$

(Fig. 2). A similar picture was found earlier in vdW complexes of  $C_{60}$  with phosphangulene oxide derivatives.<sup>54</sup>

The topological analysis based on Bader's atoms in molecules theory (QTAIM) was used to obtain additional information about the host-guest interactions. The electron density, its Laplacian, and other topological parameters at the bond critical points (BCPs) were calculated (see Table S3†). The analysis revealed that there are only  $\pi \cdots \pi$  interactions between the host and guest units in **Cor**  $\supset C_{60}$ , **rim-NCor**  $\supset C_{60}$ , **hub-NCor**  $\supset C_{60}$ , **PP-bowl**  $\supset C_{60}$ , **Hyd-bowl**  $\supset C_{60}$ , and **Cyc-bowl**  $\supset C_{60}$ . Additional interactions of the CH  $\cdots$   $\pi$  type are found in **rim-3NSum**  $\supset C_{60}$  and **Sum**  $\supset C_{60}$ . QTAIM molecular graphs for the complexes are given in Fig. S1, ESI†. The topology of the host-guest interactions in the complexes was also described using the non-covalent interaction index (NCI).<sup>55</sup> The NCI isosurfaces are fairly evenly distributed between the **Bowl** and  $C_{60}$  fragments and have a similar shape in all complexes. The reduced density gradient (RDG) plots and NCI isosurfaces are presented in Fig. S2 and S3, ESI†.

### Singlet excited states

The strong electron-accepting properties of fullerene and the relatively small HL gap in the complexes suggest promising PET properties of the systems. To describe the properties of excited states, all systems were divided into 2 fragments: guest (acceptor)  $C_{60}$  and host (donor) bowls. The electron density distribution was analyzed for the 100 lowest-lying excited states.

**Table 2** Excitation energies ( $E_x$ , eV), main singly excited configuration (HOMO (H)–LUMO (L)) and its weight ( $W$ ), oscillator strength ( $f$ ), extent of charge transfer (CT,  $e$ ) or localization of exciton ( $\chi$ ) computed for studied complexes in the gas-phase (VAC). Key parameters are bold italic type

<sup>a</sup> LE<sub>2</sub> state is partially delocalized over the  $C_{60}$  unit. <sup>b</sup> Mixed state with significant contributions of LE and CT.

Three types of excited states were identified: (1) locally excited (LE) states, in which the excitation is mostly localized either on the guest (LE<sub>1</sub>) or on the host molecule (LE<sub>2</sub>) and charge transfer is less than 0.1e (CT < 0.1e); (2) charge transfer (CT) states showing a significant charge separation (CT > 0.8e); and (3) mixed states, where both LE and CT states contribute substantially (0.1e < CT < 0.8e).<sup>14,56</sup>

In the gas-phase, the 100 lowest vertical singlet excitation energies of the complexes are found in the range from 2.55 to 5.25 eV. The analysis revealed two types of LE states (LE<sub>1</sub> and LE<sub>2</sub>) but only one type of CT state. This CT type corresponds to electron transfer from **Bowl** to C<sub>60</sub>, leading to **Bowl**<sup>+</sup>⊃C<sub>60</sub><sup>-</sup>. CT states with opposite charge separation, **Bowl**<sup>-</sup>⊃C<sub>60</sub><sup>+</sup>, were not found in the studied energy range. We note that in all complexes the lowest LE states localized on C<sub>60</sub> are dark. Thus, they can only be populated due to the fast internal conversion of absorbing states of C<sub>60</sub>.

Depending on the nature of the first excited state, the complexes can be divided into two groups. The first group includes **hub-NCor**⊃C<sub>60</sub>, **PP-bowl**⊃C<sub>60</sub>, and **Hyd-bowl**⊃C<sub>60</sub>, in which the CT state is the lowest-lying excited state with the energy ranging from 2.08 to 2.31 eV (Table 2). The second group includes **Cor**⊃C<sub>60</sub>, **rim-NCor**⊃C<sub>60</sub>, **Cyc-bowl**⊃C<sub>60</sub>, **rim-3NSum**⊃C<sub>60</sub>, and **Sum**⊃C<sub>60</sub>. In this group, the LE<sub>1</sub> state with the excitation on C<sub>60</sub> is the lowest one, and the energy of CT states varies from 3.14 to 3.91 eV. We note that in all complexes the energy of LE<sub>2</sub> states with the exciton localized on **Bowl** is higher than that of LE<sub>1</sub> and CT states. For each system, the excited states with a significant oscillator strength are almost completely localized on the C<sub>60</sub> fragment. The selected LE and CT states were additionally analyzed in terms of natural transition orbitals (NTOs), which are shown in Fig. S4–S11 in the ESI.† The NTOs corresponding to local excitations in the C<sub>60</sub> and **Bowl** fragments are of π type and rather evenly distributed over the entire fragment. The occupied and vacant NTOs associated with CT are localized on the bowls and the fullerene, respectively. The main contributions of the Kohn–Sham orbitals to the NTOs are provided in Table S4, ESI.†

## Effects of the environment

A well-proven COSMO-like model<sup>14,57–59</sup> with dichloromethane (DCM) as a solvent was applied to estimate the effect of the polar environment on electronic excitations. The GS dipole moment of the studied complexes is in the range of 0.2 to 1.9 D. The small dipole moments can be explained by the high symmetry of the units (bowls and fullerene) and their mutual arrangement. The GS solvation energy varies from −0.15 to −0.28 eV. The reference corannulene and sumanene complexes have the lowest solvation energies. The higher solvation energy of the complexes with nitrogen-containing bowls is due to the polar C–N bonds. A change in the dipole moment (Δμ) due to GS → LE excitations is rather small and does not exceed 3.9 D. The solvation energies of the GS, LE<sub>1</sub>, and LE<sub>2</sub> states are found to be similar. Detailed solvation data including the analysis of excited states in DCM are given in Tables S5 and S6, ESI.† As expected, the dipole moment of CT states is significantly larger than that of GS and LE states. Depending on a particular complex, Δμ<sup>CT</sup> varies from 21.4 to 26.4 D. The solvation energy of the **Bowl**<sup>+</sup>⊃C<sub>60</sub><sup>-</sup> CT states is significantly larger. Note that the solvent stabilization of CT states in **Cor**⊃C<sub>60</sub> and **rim-3NSum**⊃C<sub>60</sub> is not strong enough to energetically enable the LE<sub>1</sub> → CT transition. In contrast, the stabilization of the CT state in **rim-NCor**⊃C<sub>60</sub>, **Cyc-bowl**⊃C<sub>60</sub>, and **Sum**⊃C<sub>60</sub> is sufficient to reduce the gap between CT and LE<sub>1</sub> to less than 0.3 eV (Fig. 3).

## Electron transfer rates and the effect of excited state geometry relaxation

CT states in the complexes are characterized by a very weak oscillator strength and can therefore not be directly populated by light absorption. However, they can be generated by the decay of LE states. Our calculations showed that excitations with the highest probability of absorption are localized on the fullerene unit. The rates of charge separation (*k*<sub>CS</sub>) and charge recombination (*k*<sub>CR</sub>) were calculated using the semi-classical method proposed by Ulstrup and Jortner.<sup>60</sup> Within this

Fig. 3 Relative energies (in eV) of GS, LE<sub>1</sub>, and CT states for the complexes of interest computed in a vacuum (VAC) and dichloromethane (DCM).

approach, the intramolecular relaxation associated with ET is described by an effective vibrational mode, and the rate is controlled by four parameters: electronic coupling of the initial and final states  $V_{ij}$ , solvation reorganization energy  $\lambda_s$ , reaction Gibbs energy  $\Delta G^0$ , and the effective Huang–Rhys factor  $S_{\text{eff}}$ . A two-state coupling scheme was employed in all cases. The rates were estimated using the effective frequency of  $1600\text{ cm}^{-1}$ , which corresponds to the stretching of C=C bonds. Previously, we demonstrated that the rate of charge separation for similar systems does not change significantly by varying the effective frequency from  $1400$  to  $1800\text{ cm}^{-1}$ .<sup>54</sup> Our tests for the representative complexes **Cor**⊃**C**<sub>60</sub>, **Sum**⊃**C**<sub>60</sub>, and **hub-NCor**⊃**C**<sub>60</sub> confirm the small effect of the effective frequency on the CS rate (Table S7 and Fig. S12, ESI†). The computed parameters and  $k_{\text{CS}}$  in DCM are listed in Table 3.

As seen in Table 3, the electron transfer reactions in the complexes are characterized by moderate internal reorganization energies, which range from 0.15 to 0.28 eV. The  $\text{LE}_1 \rightarrow \text{CT}$  charge separation process in **Cor**⊃**C**<sub>60</sub> and **rim-3NSum**⊃**C**<sub>60</sub> is unlikely because of its highly positive Gibbs energy. In turn, the modest activation energy barrier is responsible for the rather slow charge separation in **rim-NCor**⊃**C**<sub>60</sub>, **Cyc-bowl**⊃**C**<sub>60</sub>, and **Sum**⊃**C**<sub>60</sub>. Electron transfer in these complexes occurs in the normal Marcus regime ( $|\Delta G^0| < \lambda$ ) on the nanosecond timescale or even slower. The characteristic time ( $\tau$ ) was found to be 151.94, 2.46, and 1.07 ns, respectively. At the same time, PET in **hub-NCor**⊃**C**<sub>60</sub>, **PP-bowl**⊃**C**<sub>60</sub>, and **Hyd-bowl**⊃**C**<sub>60</sub> is almost barrierless. The calculated rate constants unambiguously confirm the ultrafast charge separation between the **C**<sub>60</sub> and **Bowl** fragments. Thus, the complexes with the bowls containing

<sup>a</sup> Gibbs energy difference between LE<sub>1</sub> and CT states. <sup>b</sup> Effective value of the Huang–Rhys factor  $S_{\text{eff}} = \lambda_i/\hbar\omega_{\text{eff}}$ , where  $\hbar\omega_{\text{eff}}$  is set to 1600 cm<sup>-1</sup>.

<sup>c</sup> Activation energy barrier for the CT  $\rightarrow$  LE<sub>1</sub> reaction.

the pyrrolic nitrogen atoms and extended  $\pi$ -conjugation demonstrate better PET properties.

Usually, the generated CT states are deactivated by charge recombination to the ground state. For large conjugated systems, the effect of internal geometry reorganization on  $\Delta G^0$  is rather small and can be safely neglected.<sup>61,62</sup> However, in the studied complexes, the **Bowl** fragment is relatively small, and the relaxation effect can be significant. Thus, we studied the effect of geometry relaxation on the rate of charge recombination in DCM for *rim*-NCor $\supset$ C<sub>60</sub>, *hub*-NCor $\supset$ C<sub>60</sub>, *PP*-bowl $\supset$ C<sub>60</sub>, *Hyd*-bowl $\supset$ C<sub>60</sub>, *Cyc*-bowl $\supset$ C<sub>60</sub>, and *Sum* $\supset$ C<sub>60</sub> (Table 4). The **Cor** and *rim*-3NSum based complexes were not considered because the formation of CT states is unlikely for them.

In contrast to the charge separation, the charge recombination reactions take place in the inverted Marcus region ( $|\Delta G_0| > \lambda$ ). Thus, the relaxation of the CT geometry leads to a decrease in the  $|\Delta G_0|$  and accordingly increases  $k_{\text{CR}}$ . Moreover, the geometry relaxation reduces the activation barrier of the CT  $\rightarrow$  GS reaction.

Since the electron transfer in the *rim*-NCor $\supset$ C<sub>60</sub>, *Cyc*-bowl $\supset$ C<sub>60</sub>, and *Sum* $\supset$ C<sub>60</sub> complexes is characterized by  $\Delta G^0 > 0$  (Table 3), the charge recombination CT  $\rightarrow$  LE<sub>1</sub> state can be considered as an alternative deactivation channel of the CT state. As seen in Table 5, the back electron transfer from the CT to the LE<sub>1</sub> state in the *rim*-NCor $\supset$ C<sub>60</sub>, *Cyc*-bowl $\supset$ C<sub>60</sub>, and *Sum* $\supset$ C<sub>60</sub> complexes is rather fast. Thus, we infer that the CT states in these complexes can hardly be observed.

In summary, for *PP*-bowl $\supset$ C<sub>60</sub>, *Hyd*-bowl $\supset$ C<sub>60</sub>, *Cyc*-bowl $\supset$ C<sub>60</sub>, *rim*-NCor $\supset$ C<sub>60</sub>, *Cyc*-bowl $\supset$ C<sub>60</sub>, and *Sum* $\supset$ C<sub>60</sub> complexes,  $k_{\text{CR}}$  was found to be similar to or even higher than the corresponding charge separation rates. Fast charge recombination is a significant disadvantage as it prevents the efficient extraction of electrons and holes and, consequently, the potential application of these complexes in photovoltaic devices. Only *hub*-NCor $\supset$ C<sub>60</sub> demonstrates ultrafast photoinduced electron transfer on the picosecond timescale ( $\tau = 0.25$  ps) and slow charge recombination ( $k_{\text{CR}}$  is smaller by 3 orders of magnitude than  $k_{\text{CS}}$ ).

## Conclusions

In this work, we studied in detail the ground and excited-state properties of several complexes formed by C<sub>60</sub> fullerene and nitrogen-doped molecular bowls of different topologies using the

DFT/TD-DFT approach. The propensity of a particular complex to photoinduced electron transfer is mainly determined by the electron-donating properties of the bowl. The low HOMO energy of the *rim*-3NSum bowl results in a high activation barrier for electron transfer in *rim*-3NSum $\supset$ C<sub>60</sub>, and thus inhibits this process. PET in the *rim*-NCor $\supset$ C<sub>60</sub> and *Cyc*-bowl $\supset$ C<sub>60</sub> complexes occurs in the normal Marcus regime on the nanosecond timescale. In turn, the *hub*-NCor $\supset$ C<sub>60</sub>, *PP*-bowl $\supset$ C<sub>60</sub>, and *Hyd*-bowl $\supset$ C<sub>60</sub> complexes reveal ultrafast PET occurring on the picosecond timescale. However, the practical application of *PP*-bowl $\supset$ C<sub>60</sub>, *Hyd*-bowl $\supset$ C<sub>60</sub>, and *Cyc*-bowl $\supset$ C<sub>60</sub> may be limited due to fast charge recombination. Only the *hub*-NCor $\supset$ C<sub>60</sub> complex demonstrates the desirable combination of ultrafast charge separation ( $\tau = 0.25$  ps) and relatively slow charge recombination. This makes it a promising candidate for applications in organic photovoltaics.
