## ZnO nanoleaves with superior photodetection properties

Mohammad R. Alenezi,<sup>a</sup> Abdullah M. Almeshal<sup>c</sup> and Abdullah NFNR Alkhaledi<sup>cd</sup>

Controlled multiphase hydrothermal synthesis technique was developed to design and grow hierarchical zinc oxide (ZnO) nanostructures with high surface-to-volume ratio. ZnO nanoleaves (ZNLs) and nanoflakes (ZNFs) assembled from initial monomorphological nanostructures, ZnO nanowires (ZNWs), and ZnO nanodiscs (ZNDs), respectively. These hierarchical nanostructures with 2D nanosheets building blocks were obtained by sequential nucleation and growth following a hydrothermal process. Zinc sulphate was the source of zinc ions in the second growth phase. In comparison to their monomorphological counterparts, the hierarchically designed ZnO nanostructures demonstrated superior ultraviolet detection properties, an improved photosensitivity ( $\sim 10^5$ ), and fast response-time (5 s) and fast recovery-time (1 s). The enhancement in photosensitivity of the ZNLs photodetector was ascribed to the reduced dimensions and increased surface-to-volume ratio. This work is part of the efforts leading the way toward low cost, large scale, and low temperature fabrication of high performance nanostructured ZnO PDs on flexible and transparent substrates.

## Introduction

Zinc oxide (ZnO) nanostructures have been investigated widely owing to their potential applications in many important devices including laser diodes, gas sensors, light-emitting diodes, piezoelectric transducers and generators, and ultraviolet (UV) photodetectors (PDs).<sup>1–21</sup> In particular, UV PDs have a crucial role in different commercial and military applications including pollution monitoring, secure space communications, water purification, flame and missile plume detection, *etc.*<sup>22</sup> Over-exposure to UV is reported to be associated with different health issues such as skin cancer and malignant melanoma. Therefore, it is very important to develop UV PDs with high sensitivity, quick response and recovery, good detectability, and high responsivity.

There are many reports in the literature on the synthesis of hierarchical ZnO nanostructures, including NW arrays,<sup>23</sup> nanohelices,<sup>24</sup> nanopropeller,<sup>25</sup> and tower-like nanocolumns.<sup>26</sup> Usually, these synthesis techniques require high temperature or vacuum conditions, increasing the complexity and cost of the synthesis process. Moreover, the requirements of these high temperature techniques limit the choices of possible substrates

and lead to impurities in the final products. Consequently, the economic feasibility for large scale production is limited highlighting the need to develop low temperature cost-effective solution phase synthesis technique to produce these nanostructures at large scale.<sup>27–29</sup> The hydrothermal synthesis technique is very attractive and has been used intensively and successfully in the production of mono-morphological ZnO nanostructures.<sup>1–7</sup> However, applying the hydrothermal synthesis technique to produce hierarchical ZnO nanostructures with rational control over the morphology and size is still challenging. Hierarchically nanostructured ZnO with one-dimensional (1D) or two-dimensional (2D) building blocks have drawn a great deal of attention recently due to their astonishing physical and chemical properties.<sup>30–35</sup> More specifically, such structures have already been demonstrated to be applicable in the bottom-up production of high-performance devices.<sup>5–8,30–35</sup>

With these systems in mind, we herein report the development of an elegant nucleation and growth strategy to synthesise hierarchical ZnO nanoleaves (ZNLs) and nanoflakes (ZNFs) from initial monomorphological ZnO nanostructures, ZnO nanowires (ZNWs), and ZnO nanodiscs (ZNDs), respectively. This growth strategy allows us to control and optimize the experimental conditions stage by stage and gives a chance to rationally design and synthesize the morphology of nanostructures. The influences of the morphology and structure of the grown hierarchical ZnO nanostructures on their performances as UV photodetectors are also investigated and compared with those of other grown nanostructures.

## Experimental

In this study, every reagent was of analytical grade. Synthesising ZnO nanowires (ZNWs) was performed as detailed in the previous report.<sup>30</sup> Specifically, a seeded silicon (Si) substrate was put into a vial which contained a growth solution (15 mL) comprised of 25–50 mM zinc nitrate, 12.5–25 mM hexamethylene-tetramine (HMTA), 0.35–0.45 M ammonium hydroxide, and 5 mM polyethyleneimine (PEI, end-capped, molecular weight 800 g mol<sup>-1</sup> LS, Aldrich). Next, the vial was covered and put into an oven which had been heated to 90 °C, and heating was continued for 24 hours. Following this, the substrate was rinsed with deionised (DI) water and air-dried at 150 °C for 30 mins. Finally, the prepared ZNWs were suspended uniformly in DI water (20 mL) in an ultrasonic bath.

Preparation of the ZnO nanodiscs (ZNDs) has been previously detailed.<sup>30</sup> In this case, a 15 mL vial of the growth solution which consisted of 100 mM zinc sulphate (ZnSO<sub>4</sub>) and 100 mM HMTA was heated to 75 °C for 3 hours in an oven. Thorough filtering and washing of the grown nanomaterials was then performed using ethanol and distilled water, in sequence.

Subsequently, in the preparation of ZNLs and ZNFs, ZNWs and ZNDs were used as seeds in the second growth stage, respectively. A fresh growth solution of 100 mM zinc sulphate (ZnSO<sub>4</sub>) and 100 mM HMTA was added to a suspension of the initial seeds in a vial, which was then heated to 75 °C in an oven for 3 hours. Lastly, the grown nanostructures are filtered and washed thoroughly with ethanol and DI water.

Analysis of the as-prepared products' crystal structures was performed using powder X-ray diffraction (XRD) using a PANalytical X-pert diffractometer with Cu K $\alpha$  radiation. The morphologies and crystal structures were observed with a scanning electron microscopy (SEM) using a Philips XL-20 scanning electron microscope at 10 kV. Electron diffraction measurements and scanning transmission electron microscopy (STEM) were conducted using a Hitachi-HD2300A microscope, operating at 200 kV. Preparation of the STEM samples was performed by placing a droplet of the diluted nanomaterial suspension in ethanol onto a carbon film-coated copper grid. The surface composition of the ZnO samples were determined using PHI QUANTUM 2000 photoelectron spectrometer (XPS) using a monochromatic magnesium X-ray source. The binding energies were calibrated with respect to the signal for adventitious carbon (binding energy of 284.6 eV).

The fabricated device's electrical aspects were measured using a probe station connected to a Keithley 4200 semiconductor analyser. The source of excitation for the UV detection was a monochromatic UV lamp (UVGL-55 Hand-Lamp from UVP-LLC) with a 50  $\mu$ W cm<sup>-2</sup> intensity at a wavelength of 365 nm. All measurements were carried out at a bias voltage of 2 V.

## Results and discussion

Fig. 1(a and b) show low and high magnification side view SEM images of a ZNWA, respectively. A top view SEM images of the ZNWA are shown in Fig. 1(c). These SEM images clearly show that the produced ZNWA has excellent uniformity and alliance. A single ZNW connecting two electrodes is shown in the SEM

Fig. 1 (a) Low magnification side view SEM image, (b) high magnification side view SEM image, (c) top view SEM image of an array of ZNWs; (d) SEM image of a single ZNW, (e) the corresponding SAED pattern of the ZNWs, and (f) the XRD pattern of the ZNWs.

image presented in Fig. 1(d). The corresponding selected area electron diffraction (SAED) pattern of the ZNWs is shown in Fig. 1(e). ZNWs are single crystal growing along the [0001] direction and their side surfaces are nonpolar {10 $\bar{1}$ 0} planes. Their XRD pattern is presented in Fig. 1(f). This analysis shows that the ZNWs are of high crystallinity representing the hexagonal wurtzite-type ZnO (JCPDS No. 36-1451).

Fig. 2(a–f) present an SEM image, the corresponding SAED pattern, STEM image, XRD pattern, two AFM images of a single ZND, respectively. Most of the exposed facets of the ZND are the polar [0001] surfaces. The XRD pattern and STEM image show that the produced ZNDs are of high crystallinity representing the hexagonal wurtzite-type ZnO (JCPDS No. 36-1451). The AFM analysis shows that the thickness of the grown ZND ranges between 100–150 nm.

As previously reported, hydrothermally grown ZnO nanostructures tend to adopt a 1D form due to the high crystal growth rate in the [0001] direction.<sup>30</sup> In addition, in a former report, we learned that the counter-ions of zinc in the hydrothermal growth environment play a key role in shaping the final morphology of the grown nanostructure.<sup>15</sup> In the current case of the ZNDs, the charge on the top and bottom facets consists of the positive Zn<sup>2+</sup> ions, and so it adsorbs the counter-anions (e.g., SO<sub>4</sub><sup>2-</sup>) preferentially instead of the hydroxyl anions. Subsequently, the [Zn(OH)<sub>4</sub>]<sup>2-</sup> species required for growth are prevented from reaching the top and bottom facets, forcing the nanostructure to grow sideways instead of the expected intrinsic anisotropic growth along the (0001) direction.<sup>30,31</sup>

Thus, in the current system, the two mono-morphological ZnO nanostructures produced in the initial growth phase, namely the ZNWs and the ZNDs, were used as seeds in the second growth phase to produce the desired ZNLs and ZNFs, respectively. SEM images at different magnifications of a single and a group of ZNLs grown from initial ZNWs are shown in Fig. 3(a–d). From the SEM analysis, we can see the impact of using zinc sulphate in the second growth phase, which transformed the initial ZNWs into ZNLs by suppressing the axial growth and forcing the initial ZNW to grow sideways. The growth process in the second phase can be described as a process of stretching the initial ZNW thin.

Fig. 2 (a) SEM image, (b) the corresponding SAED pattern, (c) STEM image, (d) the XRD pattern, (e), and (f) AFM images of the ZNDs.

The ZNLs consists of very thin sheets with a very high surface-to-volume ratio. The majority of the exposed facets in the ZNLs morphology are the polar (0001) facets. Moreover, another hierarchical ZnO nanostructure, ZNFs, was produced using initial ZNDs as seeds in the second growth phase. Fig. 3(e–h) present SEM images at different magnification of ZNFs. From these images one can see that the ZNFs consists of 2D nanosheet building blocks. The surface-to-volume ratio of the hierarchical ZNFs is clearly higher than that of their mono-morphological counterparts. Indicating that they might have a superior performance as UV PDs. SEM analysis clearly shows that the ZNLs and ZNFs have higher surface-to-volume ratios than their mono-morphological nanostructure counterparts, indicating that they could potentially exhibit superior performances as UV PDs.

Following confirmation that ZNLs and ZNFs had been successfully produced, these materials were used to prepare nanostructured ZnO PDs. Similarly, two different ZnO nanostructured PDs were fabricated based on ZNWs and single ZNWs for comparison with the ZNL- and ZNF-based PDs. The photoresponse characteristics of the ZNWA-, single ZNW-, and ZNL-based PDs are presented in Fig. 4(a–c), respectively, where it can be seen that the photosensitivity of the ZNWA-based PD, which is the ratio of the photocurrent  $I_{ph}$  to the dark current  $I_d$ , was  $\sim 30$ . In addition, the response and recovery times were

Fig. 3 SEM image of (a) several ZNLs, (b) and (c) a single ZNL connecting two gold electrodes, (d) at high magnification of a single ZNL, (e–h) SEM images at different magnifications of ZNFs.

42 and 55 s, respectively. During this study, some of the fabricated ZNWA-based PDs showed relatively long the response and recovery times extending to few minutes. It should be noted here that the conduction channel in the ZNWA-based PD is the seed layer under the ZNWs connecting the two gold electrodes (*i.e.*, a polycrystalline film of  $\sim 300$  to  $400$  nm thickness). As indicated in Fig. 4(a), the photo-response of the ZNWA-based PD exhibits a high stability and repeatability, even though its photosensitivity is low, and the response and recovery times are relatively long. Conversely, the single ZNW-based PD exhibited a photosensitivity of  $\sim 1200$ , in addition to response and recovery times of 11 and 15 s, respectively. These significant improvements in the photosensitivity and response and recovery times were attributed to a reduction in the dimensionality of the single ZNWs compared with that of the ZNWAs. Moreover, the photo-response characteristics of the ZNL-based PD showed a further enhanced photosensitivity of  $\sim 10^5$ , which is four and

Fig. 4 The photo-response characteristics of the (a) ZNWA-based, (b) single ZNW-based, and (c) ZNL-based PDs.

three orders of magnitude higher than that of the ZNWA-based PD and the ZNW-based PDs, respectively. The response-time and recovery-time of the ZNLs PD are 5 s and 1 s, respectively. The superiority in photosensitivity of ZNLs PD over the other devices stems from the reduction in its dimensions, high surface-to-volume ratio, and the increased percentage of the exposed polar facets. The PDs fabricated based on the ZNFs were also tested but the results from these tests were unreliable. Some ZNFs PDs showed ultrahigh photosensitivity while others were not that sensitive. This could be a result of the morphology and shape of the ZNFs themselves. Looking at their SEM images in Fig. 3, one can see that the sensing material in the ZNFs is not always exposed to the UV radiation. The ZNFs clearly have ultrahigh surface-to-volume ratio making them suitable for sensing applications, but their morphology is not suitable for UV detection.

The photoresponsivity represents the ratio of the generated photocurrent to the incident light power on the area of the PD and it is presented in eqn (1).<sup>15–19</sup> Using the photocurrent values of 1.2 and 1 nA, and exposed areas of 1 and 12  $\mu\text{m}^2$  for the ZNW and ZNL PDs, respectively; with light power density of 50  $\mu\text{W cm}^{-2}$  at a wavelength of 365 nm, the calculated photoresponsivity values for the ZNW and ZNL PDs were found to be around 2400 and 166.7  $\text{A W}^{-1}$ , respectively.

$$\mathcal{R} = I_{\text{ph}}/P_{\text{opt}}A \quad (1)$$

where  $P_{\text{opt}}$  is the light power density and  $A$  is the ZNW exposed area. As for the ZNB-based PD, the exact exposed area of the UV irradiated field is difficult to calculate due to the hierarchical complex nature of the surface. Subsequently, calculating the exact value of photoresponsivity is difficult as well. However, we hypothesize it is much less than the single-ZNW photoresponsivity because the photocurrent value of the ZNFs is smaller and has a larger exposed area.

The external quantum efficiency  $\eta_{\text{ext}}$  representing how many carriers circulate in the detector per adsorbed photon and per unit time, and it is represented as follow:<sup>15–19</sup>

$$\eta_{\text{ext}} = (\tau/\tau_t) = (hc/e\lambda) \times (I_{\text{ph}}/P_{\text{opt}}A) \quad (2)$$

where  $\tau$  is the hole lifetime and  $\tau_t$  is the time needed for electrons to reach the electrodes, respectively,  $\lambda$  is the excitation wavelength,  $c$  is the velocity of light,  $h$  is Planck's constant, and  $e$  is the electronic charge. For the present ZNW and ZNLs PDs the record external quantum efficiency values are calculated to be 8160 and 566.8, respectively.

These calculated values of the photoresponsivity and external quantum efficiency are compared with those recently reported in the literature for different inorganic metal oxide nanostructure PDs in Table 1.

The generation and transportation processes of carriers in the ZNLs PD are explained in the schematic diagram presented in Fig. 5. It should be noted here that due to the presence of oxygen vacancies ( $V_{\text{O}}$ ) in ZnO, which donate electrons to its conduction band, these materials are considered to be n-type semiconductors.<sup>35</sup> Thus, in dark and under air, the ZNWs adsorb oxygen molecules on their surfaces, which capture electrons from the conduction band to give oxygen ions ( $\text{O}_2^-$ ) and create a low-conductivity depletion layer close to the surface. This in turn leads to the creation of band bending due to the negative charge at the surface, which extends the quantum confinement perpendicular to the ZNW surface owing to the quantum size effects. Hence, a surface potential barrier is generated. As a result, under UV irradiation, electron-hole pairs are created in the ZNWs, wherein the holes are attracted to the negatively-charged surface and become trapped:

Subsequently, oxygen ions neutralise the trapped holes at the surface and increase the conductivity by freeing electrons into the confined core:

**Fig. 5** A schematic diagram depicting the carrier generation and transportation processes in the ZnO UV PDs.

Consequently, the depletion layer becomes narrower under the UV excitation, and the current gradually increases until reaction saturation. Upon ceasing UV irradiation of the ZNWs, electron-hole recombination takes place, causing the oxygen molecules to be re-adsorbed on the ZNW surface. As a result, electrons are recaptured, the depletion layer is widened, and the conductivity of the ZNWs is reduced.<sup>35–37</sup> The conductance of the ZNLs can be expressed as:

$$G = n_0 e \mu \pi (R - 2t_c) / 4l \quad (5)$$

where  $n_0$  is the free charge carrier density,  $\mu$  is the mobility of the charge carriers,  $R$  represents the thickness of the ZNL,  $t_c$  is the thickness of the surface charge region,  $l$  is the length between the two electrodes. The thickness of the depletion region  $t_c$  is given by:

$$t_c = L_D (eV_s / kT)^{1/2} \quad (6)$$

where  $V_s$  is the adsorbate-induced band bending while  $L_D$  is the Debye length. The Debye length in turn is given by:

$$L_D = (\epsilon \epsilon_0 kT / e^2 n_0)^{1/2} \quad (7)$$

where  $\epsilon$  is the relative dielectric permittivity of the nanostructure.<sup>38</sup> The thickness of the ZNLs is comparable to

the Debye length, so the resistance is very high. This justifies the ultrahigh sensitivity of the ZNLs PDs.<sup>39–41</sup>

Basically, the UV detection of ZnO nanostructures is an interfacial reaction process, which impacts its conductivity intensively. Hence, the chemical diffusion and readsorption of oxygen molecules occurring on the ZnO surface is a critical factor in its UV photodetection ability. In addition to the impact of the morphology, size, and surface area of ZnO nanostructures on their UV photodetection properties, the exposed polar facets of the ZnO nanostructures may have an important impact and requires more understanding. Hence, the surface structures of as-grown ZnO nanostructures were analyzed by XPS. Fig. 6(a) presents the Zn 2p XPS peaks of the ZNWs and the ZNLs, which appear to be similar for their position and distribution. On the other hand, their corresponding O 1s XPS peaks are similar. Fig. 6(b and c) present the O 1s XPS peaks of the ZNWs and ZNLs, respectively. The two peaks are asymmetric with a visible shoulder. The two O 1s XPS peaks can be decomposed into three Gaussian components centered at  $\sim 530.1 \pm 0.15$  eV ( $O_L$ ),  $531.5 \pm 0.2$  eV ( $O_V$ ), and  $532.5 \pm 0.15$  eV ( $O_C$ ). Previous studies,<sup>42,43</sup> state that the  $O_L$  component of O 1s spectrum is ascribed to  $O^{2-}$  ions on the wurtzite structure of hexagonal  $Zn^{2+}$  ion array, enclosed by zinc atoms with all of their nearest-neighbour  $O^{2-}$  ions, meaning that the number of oxygen atoms in a fully oxidised stoichiometric scenario can be evaluated by the intensity of this component. The medium binding energy component  $O_V$  is related to  $O^{2-}$  ions in oxygen-deficient regions in the ZnO matrix, whilst the  $O_C$  component is typically the result of dissociated and chemisorbed oxygen species or OH. Therefore, an estimation of the oxygen-chemisorbed abilities of different ZnO crystal exposed surfaces can be made

**Fig. 6** (a) Zn 2p XPS spectra peaks of ZNWs and ZNLs, (b) O 1s XPS spectra of ZNWs, and (c) O 1s XPS spectra of ZNLs.

on the basis of the intensity of O<sub>C</sub> components in the O 1s XPS peak. The relative percentages of the O<sub>C</sub> component in the ZNWs and ZNLs are approximately 3% and 15%, respectively, which indicate that ZNLs may absorb more oxygen species than ZNWs.

## Conclusions

We herein reported the successful development of a facile and cost-effective hydrothermal synthesis technique for the fabrication of high-performance ZnO nanostructured photodetectors (PDs). The ability to rationally control the morphology and structure of the produced nanostructure was demonstrated by tuning the experimental parameters employed during the growth process. Importantly, the ZnO nanoleaf-based ultraviolet PD (ZNL-based UV PD) demonstrated an ultrahigh photosensitivity ( $\sim 10^5$ ), a good response time (5 s), and a fast recovery time (1 s) compared to other devices prepared using different ZnO nanostructures. The ultrahigh photosensitivity of this system was due to the reduction in size, the ultrahigh surface-to-volume ratio, and increase portion of exposed polar facets compared to those of the other tested mono-morphological nanostructures. Our observations therefore indicate that the hydrothermal technique presented herein should be readily extendable to the low-cost and large-scale fabrication of other practical devices using a range of metal oxides.
