# *In situ* regeneration of copper catalysts for long-term electrochemical CO<sub>2</sub> reduction to multiple carbon products†

Cornelius A. Obasanjo,<sup>a</sup> Ali Shayesteh Zeraati,<sup>b</sup> Hadi Shaker Shiran,<sup>b</sup> Tu N. Nguyen,<sup>ac</sup> Sharif Md. Sadaf,<sup>d</sup> Md Golam Kibria<sup>b</sup> and Cao-Thang Dinh<sup>\*,a</sup>

The valorization of carbon dioxide (CO<sub>2</sub>) via electrochemical CO<sub>2</sub> reduction (ECR) has attracted great interest as a pragmatic approach to tackle greenhouse gas emissions. Multiple carbon (C<sub>2+</sub>) products, such as ethylene (C<sub>2</sub>H<sub>4</sub>), ethanol (C<sub>2</sub>H<sub>5</sub>OH), and propanol (C<sub>3</sub>H<sub>7</sub>OH), are highly valuable chemicals and of great demand. Copper (Cu)-based catalysts are so far the only electrocatalytic materials that allow CO<sub>2</sub> reduction to C<sub>2+</sub> products at industrially relevant current densities ( $\geq 100$  mA cm<sup>-2</sup>). However, most Cu-based catalysts are unstable in long-term reactions (>100 hours), with the main reasons being the potential-induced surface reconstruction, deposition of impurities, and catalyst aggregation and leaching, among others. Herein, we report an *in situ* catalyst regeneration strategy that can extend the operation time of Cu-based catalysts. By periodically adding segments of anodic currents to electrolysis, a Cu catalyst is partially oxidized to CuO<sub>x</sub> in each cycle, as confirmed by *in situ* Raman studies, leading to the restoration of the catalytically active sites for C<sub>2+</sub> products. We found that the oxidation current density and time significantly affect the selectivity and stability of Cu catalysts. Applying this strategy to a Cu catalyst – which is stable for ~5 h towards C<sub>2+</sub> products during a continuous electroreduction under neutral-pH conditions, we were able to extend the operating time to ~120 h in a flow cell system. The catalyst maintained a high faradaic efficiency (FE) for C<sub>2</sub>H<sub>4</sub> of  $\geq 50\%$  at a fixed cathodic current density of 150 mA cm<sup>-2</sup> for over 60 h and continued to operate with a C<sub>2</sub>H<sub>4</sub> FE  $\geq 40\%$  for the entire length of the reaction time. This work opens up an avenue to enhance the stability of Cu electrocatalysts, via controlling the operating procedure during electrolysis.

Dr. Cao Thang Dinh is an assistant professor of Chemical Engineering at Queen's University. He received his master's and PhD degrees in Chemical Engineering from Laval University in 2010 and 2014, respectively. From 2014 to 2019, Dr Dinh was a postdoctoral fellow in the Department of Electrical and Computer Engineering at the University of Toronto. His research focuses on developing electrochemical processes for renewable fuel and chemical production from carbon dioxide, water and renewable electricity.

## Introduction

The imminent threat of rising global temperatures has resulted in shifting weather patterns and disruption of nature's normal balance. Reducing carbon dioxide (CO<sub>2</sub>) emissions is critical and urgent; otherwise, humanity will be impacted by more and more severe weather events, together with food insecurity and global health issues. Carbon capture, utilization, and sequestration play an essential role in mitigating CO<sub>2</sub> emissions.<sup>1,2</sup> The development of CO<sub>2</sub> utilization technologies such as electrochemical CO<sub>2</sub> reduction (ECR) offers a pragmatic strategy to tackle emissions,<sup>2</sup> as CO<sub>2</sub> is converted into numerous valuable products without concerns of its immediate re-emission to the atmosphere.<sup>3</sup>

A wide range of electrocatalytic materials for ECR have been investigated and reported in the literature. Electrocatalysts with high selectivity (FE > 80%) and long-term stability (>100 h) when performing at industrially relevant current densities (>100 mA cm<sup>-2</sup>) have been reported for single carbon (C<sub>1</sub>) products such as carbon monoxide<sup>4–7</sup> and formic acid/formate.<sup>8–10</sup> Cu and Cu-based catalysts have drawn great interest for ECR studies, not only because of their natural abundance and low cost, but also due to their unique feature as the only catalysts capable of converting CO<sub>2</sub> into valuable C<sub>2+</sub> products at high current density.<sup>11–17</sup> Recent improvements in Cu-based catalysts and cell design have promoted ECR at elevated current densities even beyond 1 A cm<sup>-2</sup>.<sup>14</sup> In some cases, high selectivity under alkaline and neutral-pH conditions was achieved, with FE values in the range of 40–72% and 41–52% for C<sub>2</sub>H<sub>4</sub><sup>13,14</sup> and C<sub>2</sub>H<sub>5</sub>OH,<sup>12,15</sup> respectively. Interestingly some high-performing ECR Cu-based electrocatalysts with C<sub>2</sub>H<sub>4</sub> ≥ 75%<sup>18,19</sup> have also been demonstrated with stability ≤ 100 h and current density < 100 mA cm<sup>-2</sup>. Nevertheless, the reported stability of ECR has been limited to a few operating hours<sup>13,20,21</sup> for these C<sub>2+</sub> products. In most cases, the Cu-based catalysts are rapidly deactivated, particularly when ECR reactions are conducted in neutral-pH or acidic media, as the competing hydrogen evolution reaction (HER) prevails after a short period.<sup>22</sup> Notably, performing ECR under alkaline conditions has previously been shown to extend the catalyst operating time while displaying good selectivity for C<sub>2+</sub> products. However, under these conditions, CO<sub>2</sub> directly reacts with KOH and forms bi/carbonate salts, necessitating additional energy expenses for electrolyte and CO<sub>2</sub> regeneration.<sup>13</sup> Thus, there is a need to design suitable electrocatalysts and/or devise electrolysis procedures that can stably produce C<sub>2+</sub> products in neutral or acidic environments to make the ECR technology more economically competitive.

Improving the stability of Cu electrocatalysts in low pH media still remains a great challenge.<sup>20,23–26</sup> A wide array of reasons for Cu catalyst electrode failure have been reported, including poisoning by reaction products,<sup>27</sup> deposition of metal impurities from the electrolyte,<sup>28</sup> potential-induced surface reconstruction exposing inactive facets,<sup>29–37</sup> and dissolution and redistribution of the catalyst outer surface.<sup>38,39</sup> For gas diffusion electrodes (GDEs), which allow ECR to operate at industrially relevant current densities, catalyst deactivation is also due to the flooding of the

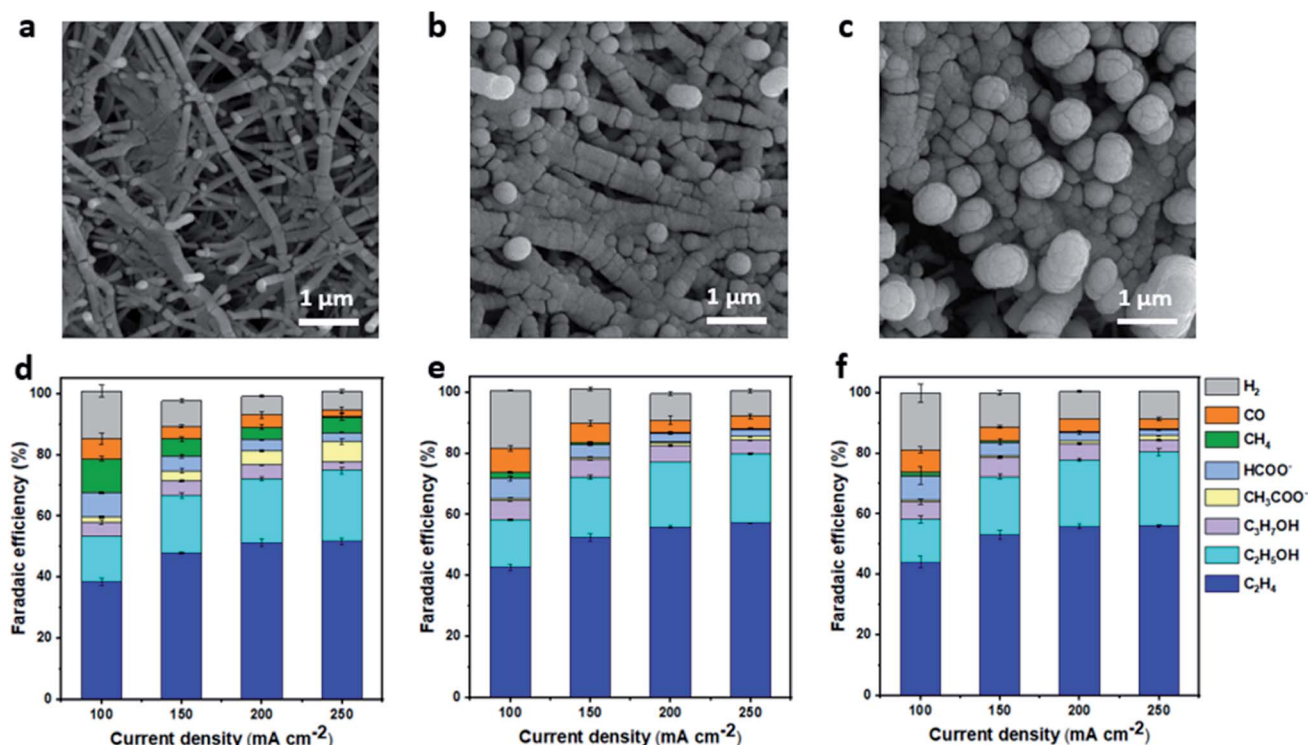

porous gas diffusion layer and the precipitation of bi/carbonate salts that block the transport of CO<sub>2</sub> gas to catalytic sites. To address the instability of Cu-based catalysts, strategies such as pulse electrolysis<sup>25,26,40–42</sup> or employing electrolytically-cleaned electrolytes have been reported.<sup>43</sup> It is also worth knowing that pulsed ECR has also been extensively studied towards enhancing C<sub>2+</sub> product selectivity.<sup>44–47</sup> Pulsed potential electrolysis has been exploited towards enhancing the stability of Cu-based electrocatalysts. Jännsch Y. *et al.*<sup>26</sup> used 25 s at –1.38 V and 5 s at –1.0 V (*vs.* Ag/AgCl) to increase the stability of C<sub>2</sub>H<sub>4</sub> production from less than 8 h to at least 16 h. Engelbrecht A. *et al.*<sup>25</sup> extended a 16 h potentiostatic electrolysis to about 85 h and 95 h *via* variation of cathodic pulse potential (*t*<sub>c</sub> = 25 s, *t*<sub>a</sub> = 5 s, *U*<sub>c</sub> = –1.6 V, *U*<sub>a</sub> = –0.18 V, *vs.* Ag/AgCl) in combination with two different modes of electrolyte management, respectively. They both achieved C<sub>2</sub>H<sub>4</sub> FEs below 40% which were demonstrated at current densities below 100 mA cm<sup>-2</sup>. However, to the best of our knowledge, none of these approaches have been able to demonstrate long-term stability towards C<sub>2+</sub> products with high FE and at a high reaction rate in a flow cell configuration.

Herein, we report an *in situ* surface regeneration strategy to extend the operating time of a Cu electrocatalyst in neutral-pH media. The strategy is based on previous observation that oxide-derived Cu (OD-Cu) catalysts are effective for selective CO<sub>2</sub> reduction to C<sub>2+</sub> products.<sup>48,49</sup> We exploited the copper oxide formed during the regeneration step of a thoroughly optimized oxidation and reduction cycle to target an extended ECR to C<sub>2+</sub> products. With this *in situ* regeneration strategy, we achieved an order of magnitude improvement in operating time, with the Cu electrode operating at a cathodic current density of 150 mA cm<sup>-2</sup> for ~120 h. It maintained FE values for C<sub>2</sub>H<sub>4</sub> ≥ 50% for over 60 h and remained operating with C<sub>2</sub>H<sub>4</sub> FE ≥ 40% for the entire reaction time.

## Results and discussion

### Performance of Cu/PTFE catalysts at high current densities in a neutral-pH electrolyte

To fabricate Cu gas diffusion electrodes, we deposited metallic Cu on a porous polytetrafluoroethylene (PTFE) membrane with an average pore size of 0.45 microns, using the sputtering technique. The PTFE membrane was chosen because it has been demonstrated to be a durable gas diffusion layer, significantly suppressing flooding, allowing stable ECR to C<sub>2+</sub> products in flow-cell configurations under highly alkaline conditions.<sup>13</sup> The nominal thickness of the Cu layer was controlled, varying from 200 to 1000 nm. The morphologies of Cu/PTFE samples were characterized by scanning electron microscopy (SEM) (Fig. 1a–c). Cu particles were conformally deposited on PTFE fibers, forming a continuous Cu layer shell on the PTFE fiber core. The size of the Cu/PTFE fiber increases with increasing the Cu nominal thickness, leading to smaller pore size in the PTFE membrane (Fig. 1a–c and S1†). High magnification images show a similar Cu surface texture of small Cu particles with multiple grain boundaries for all Cu thicknesses (Fig. 1a–c and S1†).

**Fig. 1** Characterization and ECR selectivity of Cu/PTFE. Scanning electron microscopy (SEM) images of Cu/PTFE with nominal Cu thicknesses of 200 nm (a), 700 nm (b) and 1000 nm (c). CO<sub>2</sub> reduction product distribution at different cathodic current densities in 1 M KHCO<sub>3</sub> electrolyte using Cu/PTFE with nominal thicknesses of 200 nm (d), 700 nm (e) and 1000 nm (f). The FE error bar was calculated based on data collected from different experimental trials ( $n = 3$ ). Potential data for the determination of ECR selectivity of Cu/PTFE for all samples are provided in the ESI (Fig. S3).†

ECR performance of Cu/PTFE GDEs was evaluated with a flow-cell reactor using 1 M KHCO<sub>3</sub> catholyte. A bipolar membrane was used to separate the anode and cathode compartments. Nickel (Ni) foam and 1 M KOH solution were used as the anode and anolyte, respectively. The ECR of Cu/PTFE catalysts was studied in the cathodic current density range of 100–250 mA cm<sup>−2</sup> using chronopotentiometry. Gaseous products were analyzed with in-line gas chromatography while liquid products were collected and analyzed using nuclear magnetic resonance (NMR) (Fig. S2†). All Cu/PTFE samples showed FE values for C<sub>2</sub>H<sub>4</sub> between 38 and 55% in the studied current range, with a total C<sub>2+</sub> (C<sub>2</sub>H<sub>4</sub>, C<sub>2</sub>H<sub>5</sub>OH, C<sub>3</sub>H<sub>7</sub>OH, and C<sub>2</sub>H<sub>3</sub>O<sub>2</sub><sup>−</sup>) FE of >70% achieved at current densities of 150–250 mA cm<sup>−2</sup> (Fig. 1d–f). This performance is consistent with previous reports on Cu/PTFE catalysts using similar testing conditions.<sup>21,50</sup> We observed that Cu thickness showed little impact on the overall product selectivity within the explored current density range. While the total C<sub>2+</sub> was lower at 100 mA cm<sup>−2</sup> for all Cu/PTFE samples, the value increased about 15–20% at current densities between 150 and 250 mA cm<sup>−2</sup>. At these higher current densities, the Cu/PTFE GDEs maintained a good C<sub>2+</sub> FE of >70%. However, at current densities beyond 300 mA cm<sup>−2</sup> we observed a decrease in the total C<sub>2+</sub> FE with a corresponding increase in H<sub>2</sub> and CH<sub>4</sub>. The FE value of CH<sub>4</sub> was found to be the highest on the 200 nm Cu/PTFE sample and was approximately 10 times higher at all current

densities explored. These results suggest that the thickness of Cu/PTFE can be optimized to either achieve a high FE for C<sub>2+</sub> products (thick Cu/PTFE) or a high FE for CH<sub>4</sub> (thin Cu/PTFE).

To study the stability of the GDEs, we performed the ECR reaction at a fixed current density of 150 mA cm<sup>−2</sup> and analyzed the gaseous products over time. The thickness of the Cu layer had a significant effect on the stability of Cu/PTFE. For the 200 nm Cu/PTFE, the C<sub>2</sub>H<sub>4</sub> FE was stable at around 50% for about 1 h before it started decreasing rapidly, reaching 15% after 1.5 h of continuous reaction (Fig. 2a). After 1 h of reaction, the FE values of both CH<sub>4</sub> and H<sub>2</sub> started increasing, with H<sub>2</sub> being the dominant product after 1.5 h (Fig. 2a–c). The stability of Cu/PTFE catalysts was significantly improved with an increase in Cu nominal thickness. The 1000 nm Cu/PTFE maintained a C<sub>2</sub>H<sub>4</sub> FE of 50% for 5 hours (Fig. 2a). For all Cu/PTFE samples, CH<sub>4</sub> and H<sub>2</sub> were the two main products when the C<sub>2</sub>H<sub>4</sub> FE started decreasing (Fig. 2b and c), while CO selectivity slowly decreased over time (Fig. S4†).

Previous studies on the stability of Cu catalysts for ECR in aqueous electrolytes have identified three main deactivation mechanisms among others. First, the Cu surface undergoes a reconstruction process, exposing the Cu sites (*e.g.* (111) facet) that are more selective towards CH<sub>4</sub> formation and H<sub>2</sub> production.<sup>51</sup> This surface reconstruction usually occurs on the sub-10 nm scale. Second, metal impurities such as Fe and/or Ni present in the electrolyte, which can be deposited on the surface

Chronopotentiometric plots for the three samples are provided in the ESI (Fig. S5–S7).†

of Cu catalysts during electrolysis, form highly active sites for  $\text{H}_2$  production.<sup>52</sup> The last mechanism involves the reduction of oxidized Cu species ( $\text{Cu}^+$ ,  $\text{Cu}^{2+}$ ) in Cu-based catalysts during the ECR process. Because oxidized Cu species and/or sub-surface oxygen are critical for  $\text{CO}_2$  reduction to  $\text{C}_{2+}$  products, the disappearance of these species makes the catalyst less selective toward  $\text{C}_{2+}$  products over time.<sup>53–55</sup> Furthermore, for gas-phase ECR in flow systems using gas diffusion electrodes, the flooding of the gas diffusion layer and the precipitation of bi/carbonate salts can block the diffusion of the  $\text{CO}_2$  reactant, leading to the suppression of  $\text{CO}_2$  reduction.<sup>3</sup>

To identify the deactivation mechanism in our system, we first checked if flooding and salt precipitation were the main reasons. ECR at  $150 \text{ mA cm}^{-2}$  was performed continuously until the  $\text{C}_2\text{H}_4$  FE decreased to around 25%. The current density was then reduced to 125, 100, 75 and  $50 \text{ mA cm}^{-2}$  and the gaseous products were analyzed accordingly. The FEs for  $\text{H}_2$  and  $\text{CH}_4$  remained high with lowering the current density, implying that  $\text{CO}_2$  diffusion limitation was not the reason for the drop in  $\text{C}_2\text{H}_4$  FE (Fig. S8†). To further confirm that flooding was not the major mechanism for the deactivation of our Cu/PTFE sample, we investigated electrode flooding in our flow cell system using a capacitance change measurement.<sup>56</sup> We quantified the electrochemical double-layer capacitance in an attempt to track the

ingress of the electrolyte into the GDE during electrolysis. This capacitance measurement obtained through the cyclic voltammetry technique, in the non-faradaic region with variable scan rates, can offer insights into the changes that occurred at the electrode–electrolyte interface. The cyclic voltammetry was carried out between  $-0.05 \text{ V}$  and  $-0.20 \text{ V vs. Ag/AgCl}$  with scan rates of 10, 50, 100, 150 and  $200 \text{ mV s}^{-1}$ . We observed no significant change in the electrochemical double-layer capacitance (Fig. S9–S11†). The capacitance was found to be around  $0.5756 \text{ mF cm}^{-2}$  at the open circuit potential before the start of continuous electrolysis,  $0.5309 \text{ mF cm}^{-2}$  after 3 h of electrolysis and  $0.5143 \text{ mF cm}^{-2}$  after approximately 6–7 h of continuous operation (Fig. S11†). The FE of  $\text{C}_2\text{H}_4$  was about 56% after 3 h and decreased to about 42% at the end of the continuous operation.

To check for a change in the catalyst surface morphology, we compared the SEM images of the Cu/PTFE sample before and after continuous ECR tests (Fig. 2d and e). The surface texture of Cu/PTFE appeared to change after the reaction as the particle size became smaller. While this could be due to the surface construction, it may also have originated from the oxidation of the Cu surface when the sample was exposed to air after the reaction. High resolution Cu 2p X-ray photoelectron spectroscopy (XPS) of the sample ( $1000 \text{ nm}$ ) shows the presence of CuO

and  $\text{Cu}(\text{OH})_2$  after the reaction (Fig. 2f). The survey XPS spectra show no peaks for Fe and Ni in all samples while small peaks of C, F and Cl were detected (Fig. S12†). These data suggest that impurity could not be the main cause of lower  $\text{C}_2\text{H}_4$  selectivity. We therefore reason that surface reconstruction and changing of the Cu oxidation state and sub-surface oxygen could be the main contributors to the deactivation of Cu/PTFE catalysts.

### Regeneration of Cu catalysts by *in situ* oxidation

The development of highly selective OD-Cu catalysts for  $\text{CO}_2$  reduction to  $\text{C}_{2+}$  products<sup>48,49,57–60</sup> motivated us to pursue an *in situ* regeneration of the deactivated Cu catalyst, using an electrochemical oxidation process to transform Cu back to Cu oxide. We reason that this oxidation step may address the main deactivation mechanisms of Cu-based catalysts since it can reproduce the selective OD-Cu catalysts. In addition, it might also enable the dissolution of metal impurities such as Fe on the Cu surface back to the electrolyte.

To investigate the recovery of Cu catalyst selectivity toward  $\text{C}_2\text{H}_4$  via *in situ* electrochemical oxidation, we first performed continuous ECR tests at a current density of  $150 \text{ mA cm}^{-2}$  until

the  $\text{C}_2\text{H}_4$  FE decreased to around 10–15% (Fig. 3a). Next, we performed repeated oxidation–reduction cycles until a stable  $\text{C}_2\text{H}_4$  FE was achieved (Fig. 3a). The oxidation current density was varied between  $0.4$  and  $1 \text{ mA cm}^{-2}$  while the reduction current density and time were fixed at  $150 \text{ mA cm}^{-2}$  and  $5 \text{ min}$ , respectively. The FE of  $\text{C}_2\text{H}_4$  was analyzed at the end of each reduction cycle. The oxidation time was studied to maximize  $\text{C}_2\text{H}_4$  FE. In all cases, the oxidation charges ( $Q = I \times t$ ) explored were either 36, 24, or 12 mC. As shown in Fig. 3b–e, the  $\text{C}_2\text{H}_4$  FE increases after each oxidation–reduction cycle while the FEs for  $\text{H}_2$  and  $\text{CH}_4$  slowly decrease (Fig. S13–S16†). The FE for CO remains relatively constant with the oxidation–reduction cycle (Fig. S13–S16†).  $\text{C}_2\text{H}_4$  FE values >50% were achieved at all oxidation current densities, with higher applied charges allowing the catalysts to operate with higher  $\text{C}_2\text{H}_4$  FE for each oxidation current density. This suggests that a higher oxidation current density only needs a shorter time to recover the high FE for  $\text{C}_2\text{H}_4$ .

The maximal FE for  $\text{C}_2\text{H}_4$  was found to be a function of the oxidation charge regardless of the oxidation current density applied in our studied range (Fig. 3f) with a FE of 53–56% being

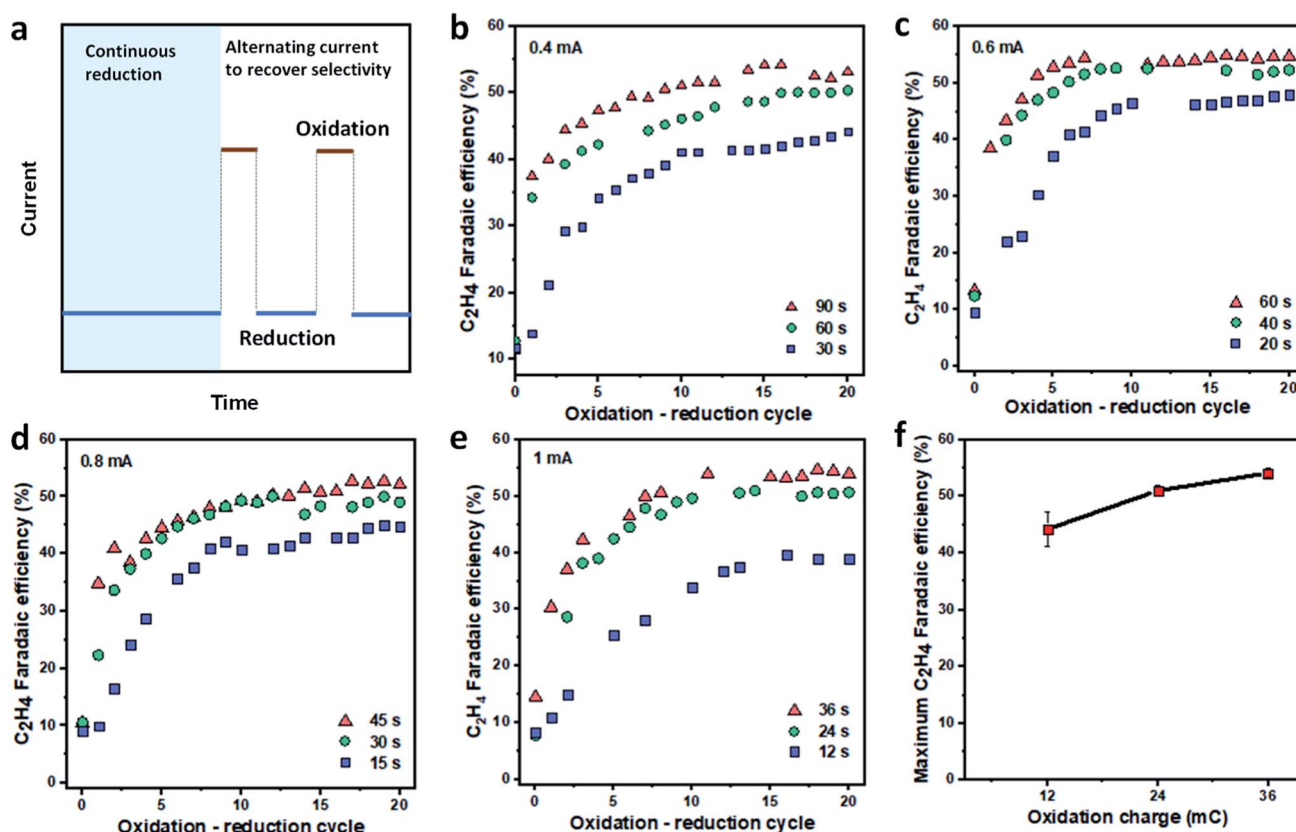

Fig. 3 Regeneration of Cu catalysts by *in situ* oxidation. (a) Oxidation–reduction program for the recovery of  $\text{C}_2\text{H}_4$  FE. All samples were operated continuously at a fixed reduction current density of  $150 \text{ mA cm}^{-2}$  until the  $\text{C}_2\text{H}_4$  FE decreased to around 10–15%. The catalysts were then subjected to 20 repeated oxidation–reduction cycles. Each oxidation–reduction cycle involves an oxidation step at a designated current and time, followed by ECR at  $150 \text{ mA cm}^{-2}$  for 5 minutes. The gas products were analyzed at the end of each reduction cycle. The recovery of FE for  $\text{C}_2\text{H}_4$  is shown with oxidation current densities of  $0.4 \text{ mA cm}^{-2}$  (b),  $0.6 \text{ mA cm}^{-2}$  (c),  $0.8 \text{ mA cm}^{-2}$  (d) and  $1 \text{ mA cm}^{-2}$  (e) at different oxidation periods. The dependence of maximum  $\text{C}_2\text{H}_4$  FE on oxidation charge (f). The deviation was calculated based on data at different oxidation current densities but with similar oxidation charges ( $n = 4$ ). The FE values for CO,  $\text{H}_2$  and  $\text{CH}_4$  during the oxidation–reduction cycle are provided in the ESI (Fig. S13–S16†). The morphology of Cu/PTFE after *in situ* electrochemical oxidation is presented in the ESI (Fig. S17†).

recovered when the oxidation charge was  $\geq 24$  mC. In addition, at each given oxidation current density and time condition, we found that the  $\text{C}_2\text{H}_4$  FE quickly recovered in the first 10 cycles before reaching a plateau. The presence of such a plateau suggests that (i) the 5 min ECR reaction after each oxidation step is not long enough to cause catalyst deactivation and (ii) the ratio between the catalytic sites for  $\text{C}_2\text{H}_4$  and other products is dependent on the applied charge of the oxidation current density, which governs the final  $\text{C}_2\text{H}_4$  FE.

### *In situ* Raman studies on oxidized Cu species

To shed light on how the oxidation current density and time affect product selectivity, we performed *operando* Raman analysis. This technique allowed us to investigate the catalyst structure and surface adsorbates during reduction and oxidation. We first studied the surface of Cu/PTFE catalysts during a continuous ECR process. The CO intermediate is usually observed by surface enhanced Raman scattering (SERS) at three Raman shift regions:  $280\text{--}290\text{ cm}^{-1}$  for the restricted rotation of adsorbed CO,  $360\text{--}370\text{ cm}^{-1}$  for Cu-CO stretching, and  $1800\text{--}2100\text{ cm}^{-1}$  for  $\text{C}\equiv\text{O}$  stretching.<sup>61,62</sup> All *in situ* Raman measurements in this study were performed using a 785 nm laser which exhibits suitable SERS activity. Signal enhancements were performed and control experiments with two different laser wavelengths were carried out to study the effect of laser excitement wavelength (Fig. S18†). The Raman shift in the range of  $520\text{--}530\text{ cm}^{-1}$  can be assigned to the Cu-OH band. It has been shown that higher intensity of the Cu-CO stretching band can be assigned to a higher coverage of the CO intermediate and higher  $\text{C}_{2+}$  selectivity.<sup>63</sup> A significant decrease in the intensity of restricted rotation of adsorbed CO and Cu-CO stretching compared to the Cu-OH can be seen by increasing the reduction time (Fig. 4a). This is a sign of the deactivation of copper by less CO coverage resulting in a reduced amount of  $\text{C}_2\text{H}_4$ . These observations are in agreement with the drop in  $\text{C}_2\text{H}_4$  FE over the reaction time.

Given the observed removal of adsorbed CO species and a significant drop in  $\text{C}_2\text{H}_4$  formation, we performed *in situ*

Raman studies using the oxidation–reduction strategy as a remedy against this deactivation. As the oxidation current density was applied, the Cu-CO and Cu-OH species disappeared, and the  $\text{CuO}_x$  bands emerged in the range of  $450\text{--}700\text{ cm}^{-1}$ . These oxide species were visible after 20 s of oxidation current (Fig. 4b). The  $\text{CuO}_x$  bands disappeared entirely while the Cu-CO and Cu-OH species reappeared after the reduction cycle. It has been shown that these  $\text{CuO}_x$  crystals reduced into small Cu grains developing OD catalysts which facilitated the C–C coupling and accounted for enhanced  $\text{C}_2\text{H}_4$  selectivity.<sup>63–65</sup> Interestingly, by applying cathodic current the restricted rotation of adsorbed CO and Cu-CO stretching is recovered, confirming the re-coverage of CO. By repeating the oxidation–reduction cycles, more intense Cu-CO bonds were formed, which indicates enhanced CO coverage. Roldán Cuenya *et al.*<sup>63</sup> showed that the intensity of ratio of the Cu-CO stretching band to the CO rotation band can be correlated to the CO coverage and a higher ratio leads to more C–C coupling and  $\text{C}_{2+}$  formation. Our SERS analysis illustrates an increasing trend of this ratio with increasing the number of oxidation–reduction cycles. This confirms a better CO coverage on the surface of the catalyst leading to the sustained  $\text{C}_2\text{H}_4$  FE (Fig. S19†).

### Extending catalyst lifetime with the alternating current strategy

Having identified the oxidation conditions for recovering  $\text{C}_2\text{H}_4$  FE, we set out to prolong the catalyst lifetime by performing an alternating oxidation–reduction current procedure (Fig. 5a). The reduction current density was fixed at  $150\text{ mA cm}^{-2}$  while the oxidation current density and time, as well as the reduction time, were varied to optimize the operation conditions. We first fixed the oxidation charge of 36 mC and varied the oxidation current density (from  $0.4$  to  $1\text{ mA cm}^{-2}$ ) and oxidation time (36 to 90 s). The reduction current density and time were  $150\text{ mA cm}^{-2}$  and 5 min, respectively. We found that all operational procedures showed similar stability, maintaining  $\text{C}_2\text{H}_4$  FE  $\geq 50\%$  for at least 10 hours (Fig. 5b), doubling the time of the continuous reduction procedure. The FE for CO slowly

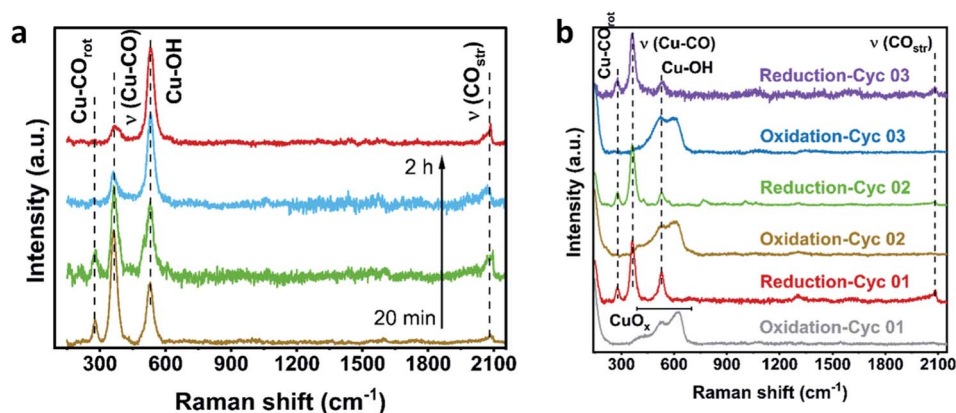

Fig. 4 *In situ* Raman studies on oxidized Cu species of Cu/PTFE. (a) *In situ* SERS of Cu/PTFE conducted at different times of reaction in  $\text{KHCO}_3$  electrolyte at a current density of  $30\text{ mA cm}^{-2}$ . (b) The structure and surface adsorbates during reduction and oxidation cycles at  $0.6\text{ mA cm}^{-2}$  oxidation current density for 20 s.

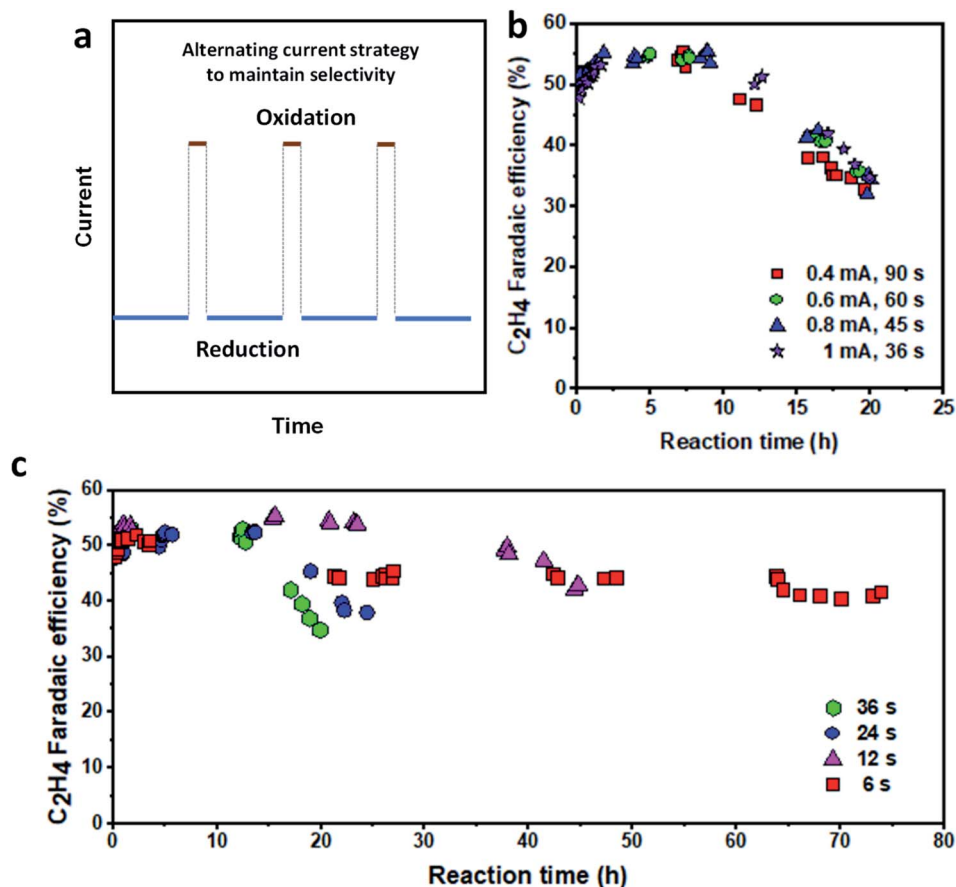

Fig. 5 Stability of the Cu/PTFE catalysts with the alternating current strategy. (a) Schematic illustration of the alternating current strategy. (b) Oxidation charge optimization at a fixed reduction current density of  $150 \text{ mA cm}^{-2}$  for 5 min reduction time. The cathodic potential *versus* time plot is provided in Fig. S21.† (c) Oxidation time optimization at a fixed current density of  $150 \text{ mA cm}^{-2}$  for 5 min reduction time and an oxidation current density of  $1 \text{ mA cm}^{-2}$  (the oxidation time was varied between 6 s and 36 s). The cathodic potential *versus* time plot is provided in Fig. S23.†

decreased while H<sub>2</sub> and CH<sub>4</sub> FEs increased over time (Fig. S20†). Therefore, varying the oxidation current density and time plays a negligible role if the oxidation charge is fixed.

To further explore the effect of the oxidation charge, we then fixed the oxidation current density at  $1 \text{ mA cm}^{-2}$  and varied the oxidation time from 6 to 36 s. The reduction current density and time are  $150 \text{ mA cm}^{-2}$  and 5 min, respectively. While larger oxidation charge leads to higher C<sub>2</sub>H<sub>4</sub> FE, the catalyst becomes less stable when the oxidation time (oxidation charge) is increased (Fig. 5c). With a 36 s oxidation time, the catalyst showed the highest C<sub>2</sub>H<sub>4</sub> FE of 54% but was stable at above 50% for 14–16 h before dropping quickly to about 30% in 20 h of operation. In contrast, when the oxidation time was reduced to 6 s, the catalyst operated stably for up to 75 h, although with a lower C<sub>2</sub>H<sub>4</sub> FE of 40% and above (Fig. 5c). Under all operating conditions, the FE of CO slowly decreased while those of H<sub>2</sub> and CH<sub>4</sub> increased steadily with the reaction time (Fig. S22†). These results suggest that the oxidation time could not be tuned to achieve both high C<sub>2</sub>H<sub>4</sub> FE and long stability simultaneously. While the catalyst can operate with an initial C<sub>2</sub>H<sub>4</sub> FE of about 50% at all oxidation times, each operating condition tends to temporarily arrive at a constant FE as mentioned earlier, beyond

which the cumulative effect of the total oxidation time over the catalyst operating lifetime begins to significantly impact the catalyst performance. Therefore, it can be hypothesized that the total amount of charge (the product of a given oxidation charge and the number of times it was cycled) throughout the lifetime of the operating catalyst determines the overall stability of the Cu/PTFE catalyst electrode.

To extend the lifetime of the catalyst, we turned our attention to the reduction time. We reason that if the stability of the catalyst depends only on the oxidation charge, the overall operating time can be extended by increasing the reduction time. We fixed the reduction current density ( $150 \text{ mA cm}^{-2}$ ), oxidation current density ( $1 \text{ mA cm}^{-2}$ ) and time (24 s) and varied the reduction time. As shown in Fig. 6a, increasing the reduction time extended the overall catalyst lifetime (time to maintain a C<sub>2</sub>H<sub>4</sub> FE  $\geq 40\%$ ). Based upon our optimized operating conditions, the longest catalyst lifetime of  $\sim 120 \text{ h}$  was achieved at a reduction time of 45 min. At this condition, the C<sub>2</sub>H<sub>4</sub> FE was maintained at over 50% for more than 60 h, which is around ten times longer than the continuous operation (5 h). The CO FE decreased rapidly in the first 20 h and is then relatively stable (Fig. S24†). The CH<sub>4</sub> FE slowly increased over time

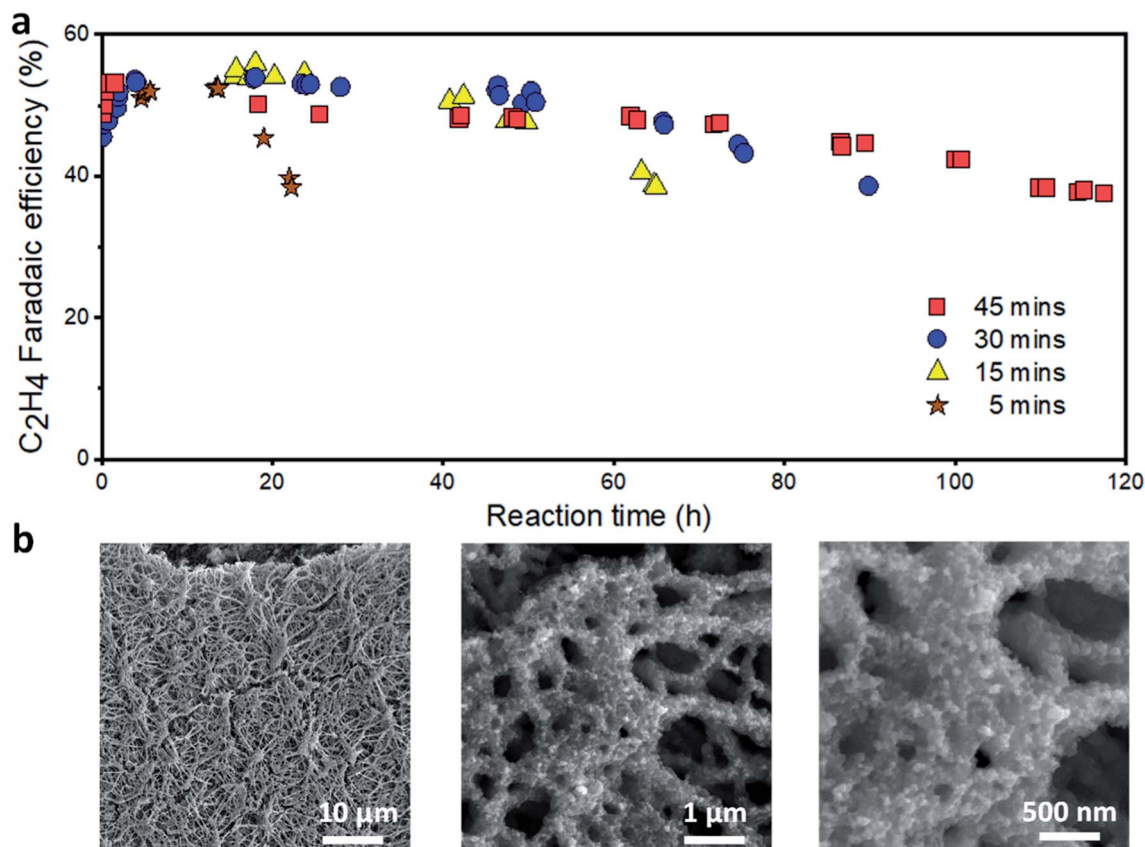

Fig. 6 Stability of the Cu/PTFE catalysts with the optimized alternating current strategy in 1 M KHCO<sub>3</sub>. (a) Reduction time optimization (varying from 5 to 45 min) at 150 mA cm<sup>-2</sup> and a fixed oxidation current density and time of 1 mA cm<sup>-2</sup> and 24 s, respectively. (b) SEM of Cu/PTFE after the oxidation–reduction strategy using 45 min reduction at a current density of 150 mA cm<sup>-2</sup> and a fixed oxidation current density and time of 1 mA cm<sup>-2</sup> and 24 s, respectively. The cathodic potential versus time plot is provided in Fig. S27.†

while the H<sub>2</sub> FE varied in the range of 10–15% (Fig. S25 and S26†). Furthermore, under these operating conditions, we found that a further increase of the reduction time and/or oxidation charge does not improve the catalyst lifetime, at least for when we aim to maintain a C<sub>2</sub>H<sub>4</sub> FE ≥ 40%. An operation of the catalyst under the same conditions, but with a higher oxidation charge (60 mC), was carried out for ~58 h (Fig. S28†).

A limited Cu catalyst lifetime with the optimized oxidation and reduction conditions implies a major deactivation mechanism different from the potential induced surface reconstruction and surface impurities discussed above. To identify the major cause of the gradual decrease in C<sub>2</sub>H<sub>4</sub> FE over the operating time, we characterized the Cu catalyst after the reaction using SEM. The catalyst layer (Fig. 6b) was found to be much thinner than that for the catalysts before (Fig. 2d) or after continuous ECR tests (Fig. 2e). We reason that the Cu at the Cu/PTFE interface and at the top of the catalyst layer can migrate during the oxidation cycle *i.e.*, when Cu is oxidized to Cu oxide. This gradual migration of Cu species over the reaction time could lead to the redistribution of Cu on the PTFE substrate, forming Cu/PTFE locations with different Cu thicknesses. In a flow cell configuration, phenomena such as catalyst fragmentation<sup>66</sup> and agglomeration,<sup>37,67</sup> Ostwald ripening,<sup>36,68</sup>

particle dissolution and (electro-) redeposition<sup>39</sup> of dissolved copper species in the form of new smaller Cu fragments, as we observed in Fig. 6b, cannot be neglected. Over time, these effects could result in the formation of some areas with very thick Cu while the Cu layer may disappear in other areas, leading to the degradation of the Cu/PTFE catalyst layer when using the alternating current approach. In addition, the impact of other associated failure mechanisms resulting from the type of electrolyzer system architecture being used can lead to a systemic failure of the overall cell system. For a flow cell architecture, as we employed in this study, the additional impact of flooding and salt formation within the PTFE pores cannot be ignored for an extended testing time. These failure mechanisms, through the interdependent nature of the cell system architecture, directly impact and combine with the major failure resulting from our strategy to suppress the stability performance of the electrolyzer system and thereby limit its overall operating time.

## Conclusions

In this work, we have introduced an *in situ* regeneration of Cu catalysts for stable CO<sub>2</sub> reduction to multiple carbon products. Our strategy involves an alternating current operating

procedure in which the catalysts are periodically regenerated by the oxidizing Cu surface. By optimizing the oxidation and reduction current density and time, a ten-fold increase in Cu catalyst lifetime has been achieved. Our optimal oxidation–reduction strategy enables the Cu catalyst to operate for an extended time ( $\sim 120$  h) and maintain a significant FE of  $\geq 50\%$  at a fixed current density of  $150 \text{ mA cm}^{-2}$  for the first 62 h, while the reaction continued with a selectivity of  $\geq 40\%$  for the entire length of the operation. *In situ* Raman characterization confirmed the presence of copper oxide species during the oxidation cycle. This approach could potentially open up an opportunity for the long-term use of Cu and Cu-based catalysts for effective ECR to  $\text{C}_{2+}$  products and the realization of the electrochemical  $\text{CO}_2$  conversion technology.

## Experimental

### Electrode preparation

The copper cathode gas diffusion electrodes were prepared by magnetron sputtering using a Kurt J. Lesker PVD 75 vacuum deposition system. Pure Cu sputtering (99.99%) metal targets (3" diameter) were used with a DC source in pure argon plasma in a sputter-down configuration. The samples were affixed to a 150 mm diameter rotating platen with Kapton tape, with a target-to-platen distance of  $\sim 165$  mm. Cu was sputtered onto a porous hydrophobic polytetrafluoroethylene (PTFE) gas diffusion layer with a 450 nm mean pore size using 120 W DC power and 4 mTorr pressure to achieve a deposition rate in the range of 0.76–1.06 angstroms per second. Approximately 200 nm, 700 nm, and 1000 nm nominally thick Cu films were sputtered onto the PTFE substrate.

### Electrochemical $\text{CO}_2$ reduction

Electrochemical  $\text{CO}_2$  reduction experiments were performed in a customized gas-fed flow cell configuration. The flow cell is made up of three compartments which are for  $\text{CO}_2$  gas, catholyte, and anolyte. Aqueous solutions of 1 M  $\text{KHCO}_3$  (Sigma-Aldrich) and 1 M KOH (Sigma-Aldrich) were used as the catholyte and anolyte, respectively. A bipolar membrane (Fumasep) was used for the experiment. The sputtered Cu/PTFE gas diffusion electrode (GDE), which is the working electrode, was carefully positioned between the catholyte chamber and a continuous flow of  $\text{CO}_2$  gas stream through the back of the cathode compartment. The catalyst side of the cathode compartment of the GDE was made to face the electrolyte. The cathode chamber was equipped with a leak-free Ag/AgCl in 3 M KCl reference electrode. The orientation of the bipolar membrane used was reverse biased with respect to the electrodes, where the cation-exchange layer (CEL) was made to face the cathode and the anion-exchange layer (AEL) was made to face the anode, thus maintaining separate pH in both sides of the electrolyzer compartment. Nickel foam (MTI Corp.) was used as the counter electrode in the anode compartment. Gaseous  $\text{CO}_2$  was allowed to flow past the back of the GDL at a constant flow of 30 sccm by means of a mass flow controller. Since only a fraction of the  $\text{CO}_2$  gas is used in the reaction

process towards  $\text{CO}_2\text{RR}$  products, the electrolyzer outlet flow rate from the  $\text{CO}_2$  gas chamber was measured using a digital volumetric flow meter and was used in the calculation of the faradaic efficiency of the reaction products. The electrolytes were circulated in both compartments using peristaltic pumps. The electrochemical measurement experiments were performed using a potentiostat (Metrohm). The electrochemical potentials were compared against Ag/AgCl (3 M KCl) reference.

The gaseous products were quantified using online gas chromatography (GC, PerkinElmer Clarus 590). The GC was equipped with a thermal conductivity detector (TCD) and a flame ionization detector (FID). The chromatography instrument was directly connected to the outlet of the  $\text{CO}_2$  gas chamber of the customized gas-fed flow cell for continuous online analysis. The liquid products were analyzed using nuclear magnetic resonance spectroscopy (NMR). The  $^1\text{H}$  NMR spectra of freshly collected liquid products were acquired on an Auto-400 ultrashield Bruker instrument operating at a denoted spectrometer frequency given in megahertz (MHz) at  $25^\circ\text{C}$  in  $\text{D}_2\text{O}$  using water suppression mode, with dimethyl sulfoxide (DMSO) as a reference.

All potential data were presented *versus* Ag/AgCl. However, iR-compensation was performed, and the details are presented in the supplementary section (Fig. S29 and S30†).

### Capacitance change measurement

The double layer capacitance was evaluated by regressing the measured working electrode charging current as a function of potential scan rate. The scan rates of 10, 50, 100, 150 and  $200 \text{ mV s}^{-1}$  were applied. The potential range of  $-0.20 \text{ V}$  to  $-0.05 \text{ V}$  *vs.* Ag/AgCl was chosen only within limits where the HER and OER would be avoided and where capacitive current could be adequately evaluated. Charging current was determined as an average of the absolute values of the anodic and cathodic currents. The capacitance was determined as the value of the slope of the charging current *versus* the potential scan rate.

### Sample characterization

The surface morphology and composition of the catalysts were investigated using scanning electron microscopy (TESCAN-SEM system) operated at 5–10 kV acceleration voltage. X-ray photoelectron spectroscopy (XPS) measurements were carried out with a VG Escalab 220i-XL spectrometer using polychromatic Al  $K\alpha$  radiation (1486.6 eV).

### *In situ* Raman

Raman spectroscopy was executed with a Renishaw Raman spectrometer equipped with a  $\lambda = 785 \text{ nm}$  laser as the excitation source and a  $63\times$  immersion objective lens. All *in situ* experiments were carried out with a laser power of 0.1 mW over 10 acquisitions with an exposure time of 10 seconds. The custom-designed flow cell had an electrolyte reservoir and a gas channel separated by a gas diffusion electrode. The immersion objective was dipped in the electrolyte reservoir to collect the spectra. A Pt wire as the anode, sputtered copper on PTFE as the cathode,

and Ag/AgCl as the reference electrode were dipped in the electrolyte reservoir filled with 1.0 M  $\text{KHCO}_3$  electrolyte. The area of the cathode in this configuration was  $1 \text{ cm}^2$ . During the experiments, a continuous 30 sccm  $\text{CO}_2$  gas flow was delivered to the cathode through the gas channel. The sputtered copper samples were reduced at  $30 \text{ mA cm}^{-2}$  for at least 2 h before the oxidation/reduction cycles.
